where E_{beam} is the beam energy in GeV, and a, b and c are the stochastic, constant and noise contributions, respectively. The noise term is fixed to $c = 0.18$ GeV, corresponding to the measured

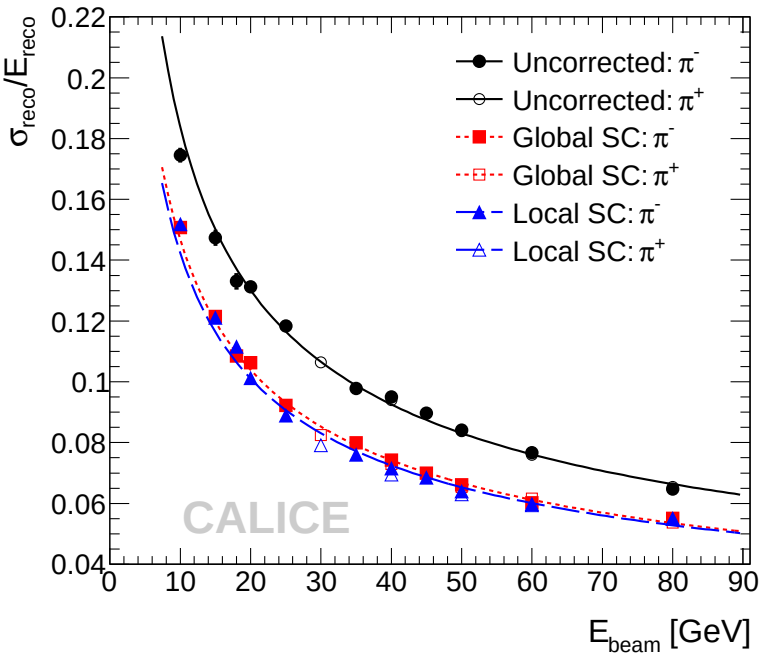

Figure 4. Energy resolution versus beam energy without compensation and after local and global software compensation. The curves show fits using Equation 2.2, with the black solid line showing the fit to the uncorrected resolution, the red dotted line to the global software compensation and the blue dashed line to the local software compensation. The stochastic term is $(57.6 \pm 0.4)\%$, $(45.8 \pm 0.3)\%$ and $(44.3 \pm 0.3)\%$, with constant terms of $(1.6 \pm 0.3)\%$, $(1.6 \pm 0.2)\%$ and $(1.8 \pm 0.3)\%$ for the uncorrected resolution, global software compensation and local software compensation, respectively.

noise contribution in the full CALICE setup taking into account contributions from the ECAL (0.004 GeV), the AHCAL (0.06 GeV) and the TCMT (0.17 GeV). These values are obtained from the standard deviation of the noise levels measured in dedicated runs without beam particles as well as in random trigger events constantly recorded during data taking. From the fit, the stochastic term of the uncorrected hadron energy resolution of the AHCAL is determined to be $(57.6 \pm 0.4)\%/\sqrt{E/\mathrm{GeV}}$ and the constant term to be $(1.6 \pm 0.3)\%$.

3. Software compensation: motivation and techniques

In ideal sampling calorimeters the energy measured for electromagnetic showers is directly proportional to the incoming particle energy. In the absence of instrumental effects such as non-linearities or saturation of the readout, the energy of a particle can thus be obtained by multiplying the visible signal by a single energy-independent factor accounting for the non-measured energy depositions in the passive absorber material.

The calorimeter response to hadron-induced showers is more complicated [14], since these showers have contributions from two different components: an electromagnetic component, originating primarily from the production of π^0s and ηs and their subsequent decay into photon pairs; and a purely hadronic component. The latter includes "invisible" components from the energy

loss due to the break-up of absorber nuclei, from low-energy particles absorbed in passive material and from undetected neutrons, depending on the active material. This typically leads to a reduced response of the calorimeter to energy in the hadronic component, and thus overall to a smaller calorimeter response to hadrons compared to electromagnetic particles of the same energy. Since the production of π^0s and ηs are statistical processes, the relative size of the two shower components fluctuates from shower to shower, which, combined with the differences in visible signal for electromagnetic and purely hadronic energy deposits, leads to a deterioration of the energy resolution. In addition, the average fraction of energy in the electromagnetic component depends on the number of subsequent inelastic hadronic interactions and thus on the initial particle energy. The electromagnetic fraction of hadronic showers increases with increasing particle energy [15], often resulting in a non-linear response for non-compensating calorimeters.

There are two fundamentally different approaches to improve the energy resolution of a hadronic sampling calorimeter. One approach is to eliminate the issue of different response to electromagnetic and hadronic components by design, through the construction of so-called compensating calorimeters. This can be achieved by specific choices of absorber and active material which enhance the sensitivity to neutrons, and thus to the hadronic component of the shower, and by appropriately chosen sampling fractions. However, these conditions impose very strict requirements on the materials used and on the overall geometry of the whole detector system. One prominent example of a compensating calorimeter is the uranium-scintillator calorimeter of the ZEUS experiment [16, 17], which reached a stochastic resolution term of $34.5\%/\sqrt{E/\mathrm{GeV}}$ for single pions [18].

On the other hand, for intrinsically non-compensating calorimeters, compensation can be achieved by so-called "off-line weighting" or "software compensation" techniques. These techniques assign different weights to electromagnetic and hadronic energy deposits on an event-by-event basis. The differing spatial structure of the electromagnetic and hadronic components of particle showers can be used to characterise the origin of energy deposits. Since the radiation length is much shorter than the nuclear interaction length in heavy absorbers used in hadronic calorimeters, electromagnetic sub-showers are more compact than purely hadronic sub-showers, generally resulting in a higher energy density of the electromagnetic component. The application of software compensation techniques relies on longitudinal and lateral segmentation of the calorimeters, to provide the necessary information for a measurement of the energy density of particle showers. One of the first applications of such techniques was in the WA1/CDHS scintillator steel calorimeter, where an improvement of the hadronic resolution between 10% and 30% was achieved in the energy range of 10 GeV to 140 GeV [19]. These techniques were further refined and applied in various experiments, such as the H1 liquid argon calorimeter [20] and the ATLAS calorimeter system [21].

With its unprecedented high granularity, the CALICE AHCAL is well suited for such techniques. In the present paper, two techniques based on an event-by-event analysis of the hit energy distributions are discussed. The local software compensation (LC) procedure is based on a re-weighting of each individual hit depending on the local energy density. The global software compensation (GC) procedure uses the distribution of hit energies to derive one global factor for the correction of the reconstructed energy of the complete hadronic shower. The parameters used for both techniques are determined from test beam data, as discussed in detail below. The available data set is split into two samples of equal event count, a training data set and the data set used to

study the energy reconstruction. This ensures a statistical independence of the data used to determine the parameters for the software compensation algorithms and the data used to evaluate the performance of the techniques.

3.1 Local software compensation

The local software compensation technique improves the energy reconstruction for hadrons by applying weights to the energy recorded in every cell of the AHCAL within a hadronic shower. The weights are chosen based on the local energy density, which is taken as a measure of the likelihood that a given cell belongs to an electromagnetic or a hadronic sub-shower. In the present study, the energy content of a cell, divided by its volume, is taken as the relevant local energy density. Electromagnetic sub-showers typically have a higher energy density than purely hadronic ones, and, due to the non-compensating nature of the AHCAL, result in a larger detector signal per unit of deposited energy. Thus, cells with a higher energy content are assigned a lower weight in the total energy sum than cells with a low energy content to correct for this difference. The reconstructed energy of each event corrected with local software compensation, E_{LC}, is thus given by introducing weights for each AHCAL hit in Equation 2.1, resulting in

$$E_{\mathrm{LC}} = E_{\mathrm{ECAL}}^{\mathrm{track}} + \frac{e}{\pi} \cdot \left(\sum_i (E_{\mathrm{HCAL},i} \cdot \omega_i) + E_{\mathrm{TCMT}} \right) \tag{3.1}$$

where ω_i is the energy density dependent weight applied to the cell energy $E_{\mathrm{HCAL},i}$.

To make the technique robust against fluctuations entering due to the relatively low number of hits in a given event, the single cell energy density distribution is subdivided into bins in energy density, as illustrated in Figure 5 (a). The binning is also needed for the minimisation technique chosen here for the determination of the weights as discussed below. For each bin, a separate weight is determined which is applied to all hits that fall into that particular bin. The number of sub-divisions in energy density is chosen as a compromise between the requirements for fine subdivisions to maximise the sensitivity of the algorithm to differences in shower structure on one hand, and the stability of the determination of the weights and of the algorithm on the other hand. While a fine binning improves the sensitivity to the shower structure, a robust determination of the weights requires sufficient statistics in each bin, and changes of the weights from bin to bin. The performance of the local software compensation does not depend on the precise choice of bin number and bin borders.

Since the overall energy density of hadronic showers changes with energy, the weights ω depend both on the cell energy density ρ and on the particle energy. The weights, as a function of energy density and particle energy, are determined from the training data set extending over the full energy range studied here. The optimal weights are found by minimising a simplified χ^2 given by the function $\chi^2 = \sum_i (E_{\mathrm{LC},i} - E_{\mathrm{beam}})^2$, where $E_{\mathrm{LC},i}$ is the reconstructed energy of a given event using software compensation, and the sum runs over all events used for the weight determination. In this minimisation, the bin by bin weights are used as free parameters. Figure 5 (b) shows the optimal weights determined with this procedure for four different energies. The weights at a given beam energy can be parametrized by

$$\omega = p_0 + p_1 \cdot \exp(p_2 \cdot \rho), \tag{3.2}$$

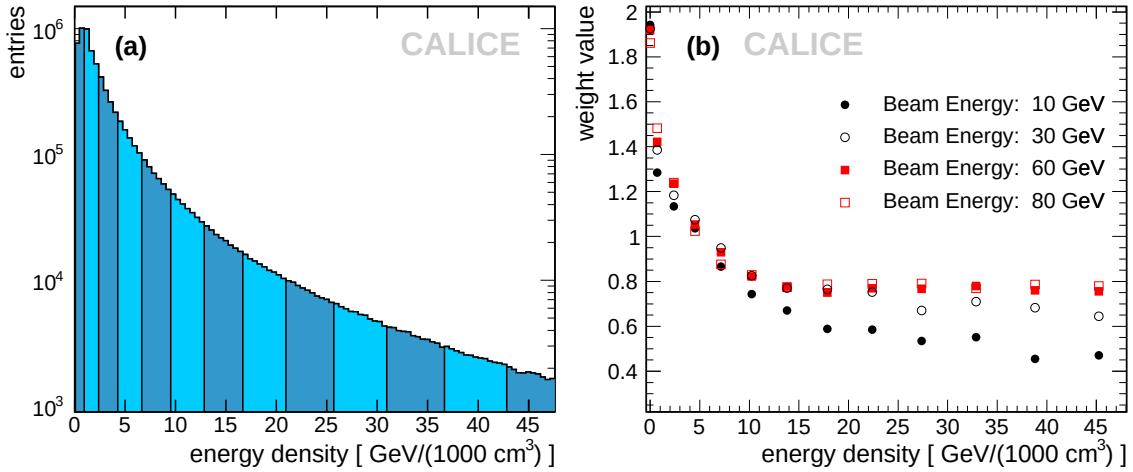

Figure 5. (a) Distribution of the cell energy density in the AHCAL for 40 GeV pion showers. The energy density is given by the uncorrected reconstructed energy in that cell, divided by the corresponding absorber volume. The different energy density bins used in the analysis are indicated by colour shades. (b) Optimal weights as a function of energy density for different beam energies, determined without constraints of a specific functional form in the first iteration of the minimisation.

where ρ is the energy density corresponding to the centre of the energy density bins introduced above, and p_0, p_1 and p_2 are parameters of the weight function. These parameters depend on the beam energy, with their energy dependence following exponential functions in particle energy for p_0 and p_1, and a logarithmic function in particle energy for p_2. A robust determination of the weights is achieved by an iterative minimisation procedure, where the free parameters p_0, p_1 and p_2 are consecutively fixed to the function determined in the previous minimisation stage.

For the application of this technique to data, no *a priori* knowledge of the particle energy is required, as the uncorrected reconstructed particle energy is used instead of E_{beam} to select the correct weight parametrisation. Since the energy dependence of the weight parameters is not very steep, this does not introduce a noticeable bias for the reconstructed energy. A second iteration does not lead to significant further improvement and is thus not performed in the reconstruction.

3.2 Global software compensation

The global software compensation technique improves the energy resolution for hadrons by applying a single weight to the reconstructed shower energy. This weight is derived from the distribution of hit energies in the hadronic shower, providing sensitivity to the overall energy density, and thus to the fraction of hits in electromagnetic sub-showers. Since electromagnetic sub-showers are characterised by a high local energy density, a hadronic shower with a large electromagnetic content will have a larger fraction of high-energy hits than a shower with predominantly hadronic contributions.

The determination of the event weight is based on a phenomenological approach using the fraction of calorimeter hits below a certain energy threshold. This fraction is computed for each event, and provides a measure of the importance in each shower of low-density energy deposits, which are expected to be predominantly of hadronic origin. Based on this, with an additional consideration of the overall hit energy distribution given by the number of hits below the mean energy

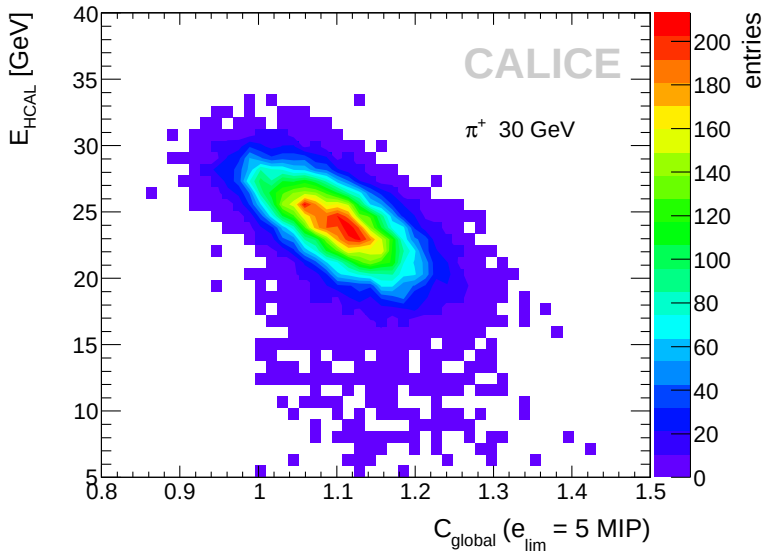

Figure 6. Correlation of the factor C_{global} and the reconstructed energy in the AHCAL, E_{HCAL}, for showers induced by π^+ at 30 GeV.

value of the hit energy, the factor C_{global} is constructed, which is used to correct the reconstructed energy. This factor, calculated for each event, is given by the ratio of the number of shower hits with a measured visible signal below a given threshold e_{lim} and the number of shower hits with a measured visible signal below the mean value of the hit energy spectrum for that particular event. Figure 6 illustrates the sensitivity of the factor C_{global} to the reconstructed energy, for a value of e_{lim} = 5 MIP applied to π^+ events at 30 GeV. The clear anti-correlation between the reconstructed energy and C_{global} provides the basis for an improved energy reconstruction using this factor. The anti-correlation is due to the fact that events with a high electromagnetic content tend to have a larger number of high-energy hits above e_{lim} and thus a lower C_{global}, while those events have a higher reconstructed energy.

The value of e_{lim} was optimised to provide good performance of the algorithm over the full energy range, with the linearity of the detector response taken as a key factor. While higher values for e_{lim} provide stricter separation of electromagnetic and non-electromagnetic events, if the value is set too high this results in asymmetric distributions of C_{global} at lower energy, leading to reduced performance. These asymmetries originate from the reduced number of high-energy hits at low particle energies. For example, a large fraction of 10 GeV pion showers have essentially no hits above 7 MIP. Too low values, on the other hand, result in a non-linear response due to the reduced sensitivity to the electromagnetic component at higher particle energies. Best performance was obtained for a value of e_{lim} = 5 MIP. For the highly granular core of the calorimeter, this corresponds to an energy density of 7.4 GeV/1000 cm^3 in Figure 5 (a). For the energy range studied, the mean hit energy is between 2.7 to 4.7 MIP. Figure 7 shows the distributions of C_{global} for different energies, demonstrating its energy dependence, originating from the change of the overall hit energy spectrum with changing particle energy. When applying C_{global} in the energy reconstruction, this dependence has to be corrected for, as discussed below.

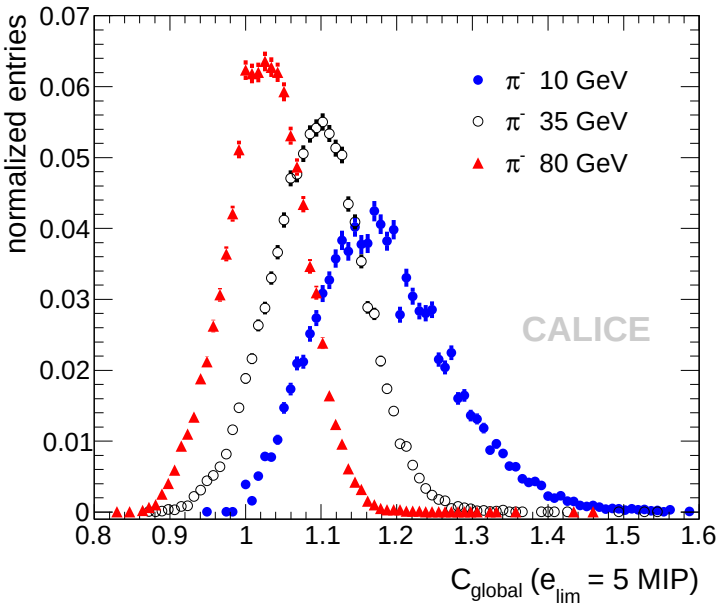

Figure 7. Distributions of the factor C_{global} for hadronic showers induced by π^- with an energy of 10 GeV (blue squares), 35 GeV (black circles) and 80 GeV (red triangles), respectively. Statistical errors are shown.

The reconstructed energy with global software compensation is obtained in two steps. First, a corrected shower energy is calculated by multiplying the reconstructed energy in the AHCAL and in the TCMT by the factor C_{global}, giving $E_{\text{shower}} = C_{\text{global}} \cdot (E_{\text{HCAL}} + E_{\text{TCMT}})$. From this corrected shower energy, the final reconstructed energy with global software compensation for a given event, E_{GC}, is then obtained from

$$E_{\text{GC}} = E_{\text{ECAL}}^{\text{track}} + E_{\text{shower}} \cdot P_{\text{global}}(E_{\text{shower}}), \tag{3.3}$$

where $P_{\text{global}}(E_{\text{shower}})$ is a function which accounts for the energy dependence of the compensation parameters, visible in Figure 7 as the shift of the mean of C_{global} with energy. This function depends on the corrected shower energy E_{shower} and is given by a second-order polynomial, $P_{\text{global}}(E_{\text{shower}}) = a_0 + a_1 \cdot E_{\text{shower}} + a_2 \cdot E_{\text{shower}}^2$. The parameters for this function are obtained from a fit of the dependence of the corrected shower energy E_{shower} on the true deposited energy given by the beam energy corrected for the energy deposited in the ECAL, and are extracted from a training data set extending over the full energy range considered here. They are found to be $a_0 = 0.982 \pm 0.007$, $a_1 = 0.0041 \pm 0.0003$ GeV^{-1} and $a_2 = (-2.2 \pm 0.3) \cdot 10^{-5}$ GeV^{-2}.

The application of the global software compensation technique does not require knowledge of the beam energy, since the energy reconstructed in the HCAL and TCMT is used also in the determination of the correction of the energy dependence of the compensation parameters.

4. Results

To evaluate their performance, both software compensation techniques are applied to test beam

data and to simulated data. The parameters for the algorithms are determined using test beam data following the training procedures outlined above.

4.1 Application of software compensation to test beam data

When applying the software compensation techniques to test beam data, the energy dependent compensation factors are determined event-by-event using the uncorrected reconstructed energy. Figure 2 shows the distribution of reconstructed energies for the uncorrected reconstruction compared with both software compensation techniques studied. The results are shown for pions with energies of 10 GeV and 80 GeV. In both cases, the software compensation algorithms improve the energy resolution, evidenced by a narrowing of the distributions, while preserving or even improving the Gaussian form of the distributions. The algorithms also bring the mean value of the reconstructed energy closer to the beam energy, resulting in small shifts of the maxima visible in Figure 2. The mean reconstructed energy with local and global compensation techniques, compared to the uncorrected response without compensation, is shown in Figure 3 for all energies studied. For both techniques, all points fall within $\pm 1.5\%$ of linearity.

The energy resolution before and after compensation is shown in Figure 4. Good agreement between the π^- and π^+ samples is observed. The energy dependence of the energy resolution is well described by Equation 2.2 with a fixed noise term $c = 0.18$ GeV as discussed in Section 2.3. The fit results are summarised in Table 2. The application of software compensation results in a decrease of the stochastic term while the constant term remains unchanged. Both compensation techniques show very similar performance, with the local software compensation providing a slightly smaller stochastic term, and slightly better performance at intermediate energies.

Table 2. Stochastic, constant and noise term contributions to the resolution of the CALICE AHCAL determined with a fit of Equation 2.2 to data.

	a [%]	b [%]	c [GeV]
uncorrected	57.6±0.4	1.6±0.3	0.18
local compensation	44.3±0.3	1.8±0.2	0.18
global compensation	45.8±0.3	1.6±0.2	0.18

Figure 8 shows the relative improvement of the energy resolution achieved with the software compensation techniques, defined as the ratio of the resolution after software compensation σ_{SC} (local or global) to the uncorrected resolution σ_{unc}. The improvement ranges from $\sim$12% to $\sim$25% in the energy range studied, for both techniques, with approximately 3% better relative improvement observed for the local technique in the energy range from 25 GeV to 60 GeV. The reduced performance at high energy is partially due to increased leakage into the TCMT. Energy deposits in the TCMT are not weighted in the local software compensation since their energy density is not well defined. In the global software compensation, the weight is applied also to TCMT energy deposits, but those are not considered in the determination of the weighting factor due to the different readout geometry which leads to increased uncertainties in the weight determination.

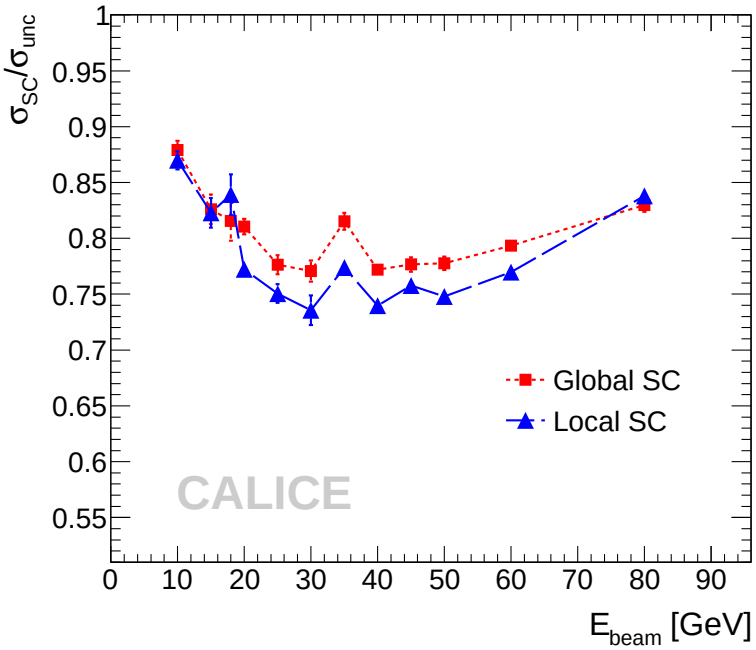

Figure 8. Energy dependence of the relative improvement of the resolution with local and global software compensation observed for data. Where available, results for π^- and π^+ are averaged for clarity.

4.2 Comparison to Monte Carlo simulations

The stability of both software compensation techniques, as well as the realism of simulation models, is tested using Monte Carlo simulations. For this purpose, the software compensation algorithms with coefficients derived from data are applied to Monte Carlo samples generated with a detailed detector model in GEANT4.9.4 [22] using two physics lists: QGSP_BERT and FTF_BIC [23]. The QGSP_BERT physics list was chosen because it is the most widely used model in high energy physics experiments at present. The FTF_BIC physics list, in turn, has provided good results in a previous CALICE analysis [6] and is completely independent from QGSP_BERT.

Details on the simulation procedure for the AHCAL can be found in [13]. For the chosen physics lists, samples of π^+ and π^- events were simulated at the same energies as the data points using beam profiles, detector temperatures and voltage settings from the data runs. The calibration of the simulation was performed at the MIP level by converting the simulated energy deposits in the scintillator into MIPs using the most probable energy loss of muons determined in simulations. The simulated data sets were passed through the same event selection and reconstruction procedures as real data, using the conversion factors from the MIP scale to reconstructed energy determined for data as discussed in Section 2.3. This also includes the requirement for an identified primary inelastic interaction in the first five layers of the AHCAL.

The uncorrected reconstructed energy as a function of beam energy is shown for data and both physics lists in Figure 9 (a). The relative deviation from the beam energy, shown in Figure 9 (b), indicates that simulations with both physics lists behave differently than the data. Both models overestimate the reconstructed energy at high particle energies. In addition, QGSP_BERT exhibits

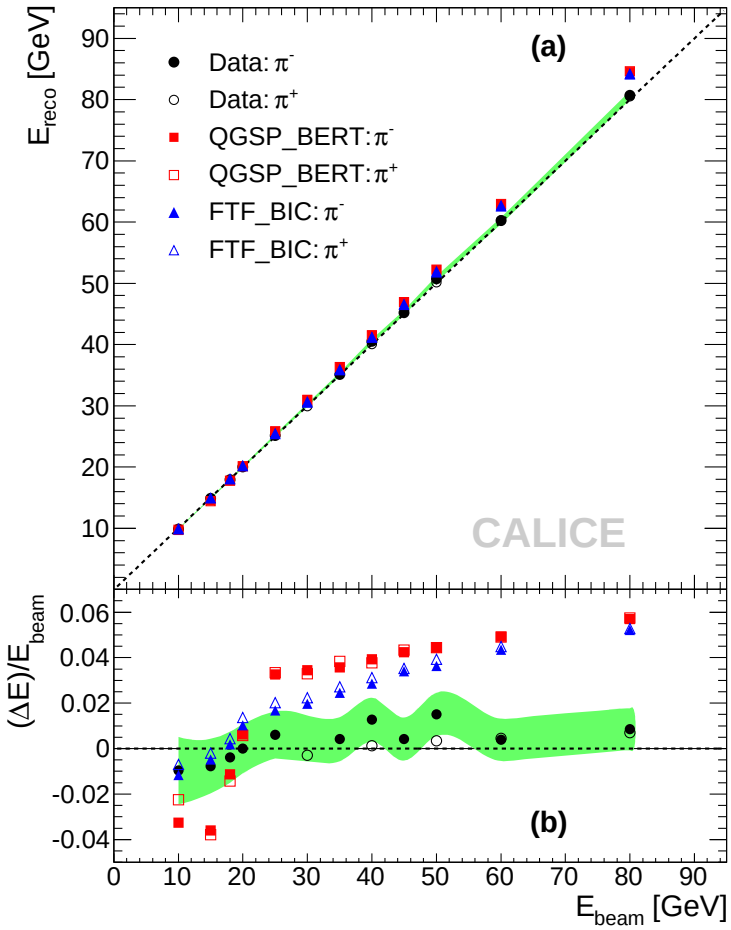

Figure 9. (a) Uncorrected response to pions and (b) relative residuals to beam energy versus beam energy for data (black circles), QGSP_BERT (red squares) and FTF_BIC (blue triangles). Filled and open markers indicate π^- and π^+, respectively. Dotted lines correspond to $E_{\text{reco}} = E_{\text{beam}}$, while the green band shows systematic uncertainties for the uncorrected π^- data sample.

fluctuations in the transition region between different models in the region between 10 GeV and 20 GeV. In general, the reconstructed energy for simulations is less linear than for data.

Figure 10 shows the energy resolution without software compensation, comparing data and simulations. Again, the behaviour of the simulations is different from that of the data, with both models underestimating the resolution at low energy, and with FTF_BIC overestimating the resolution above 30 GeV. This difference leads to a reduced stochastic resolution term with a significantly increased constant term. The results of the fits to the data points using Equation 2.2 are summarised in Table 3.

The shape of the distribution of the hit energy density is quite well reproduced by both physics lists, providing the basis for an application of the software compensation algorithms to simulations using the parameters determined from data. Figure 11 shows the distributions for two representative energies. The distributions are normalized to the number of entries to show the overall shape while

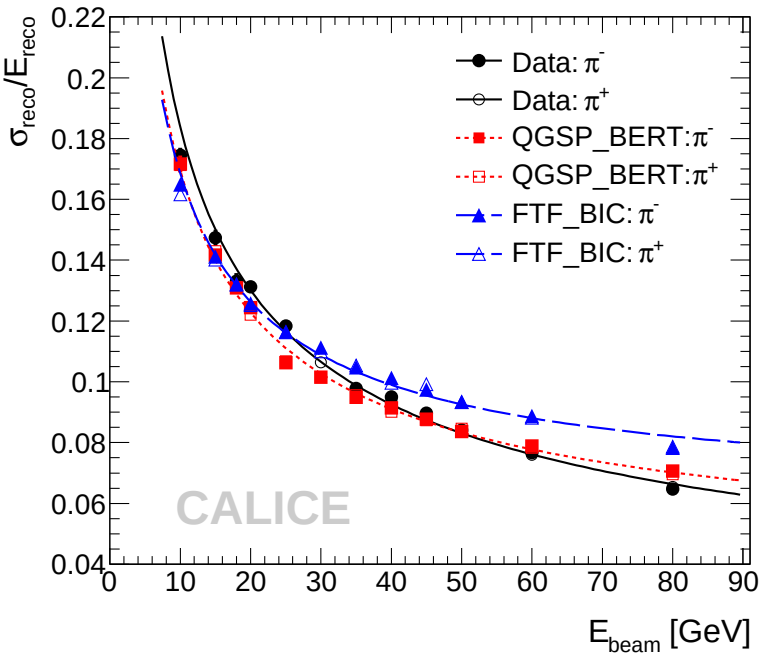

Figure 10. Uncorrected energy resolution versus beam energy for data as well as simulations using the physics lists QGSP_BERT and FTF_BIC. The curves show fits using Equation 2.2. The stochastic terms are $(57.6 \pm 0.4)\%$, $(51.8 \pm 0.3)\%$ and $(49.4 \pm 0.3)\%$, with constant terms of $(1.6 \pm 0.3)\%$, $(4.0 \pm 0.1)\%$ and $(6.1 \pm 0.1)\%$ for data, QGSP_BERT and FTF_BIC, respectively.

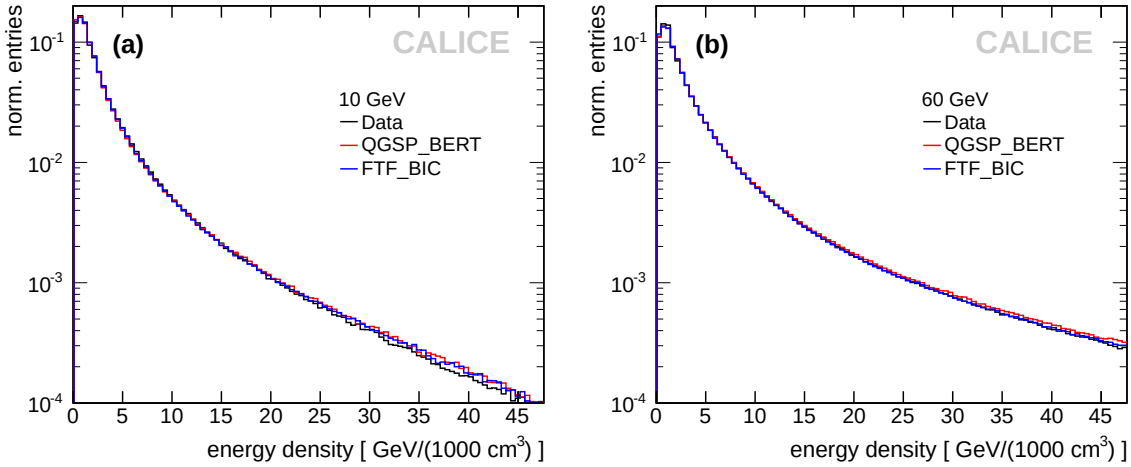

Figure 11. Energy density distribution for data and the two physics lists QGSP_BERT and FTF_BIC for (a) 10 GeV and (b) 60 GeV. The energy density is given by the uncorrected reconstructed energy in that cell, divided by the corresponding absorber volume. The distributions are normalized to the number of entries (number of hits).

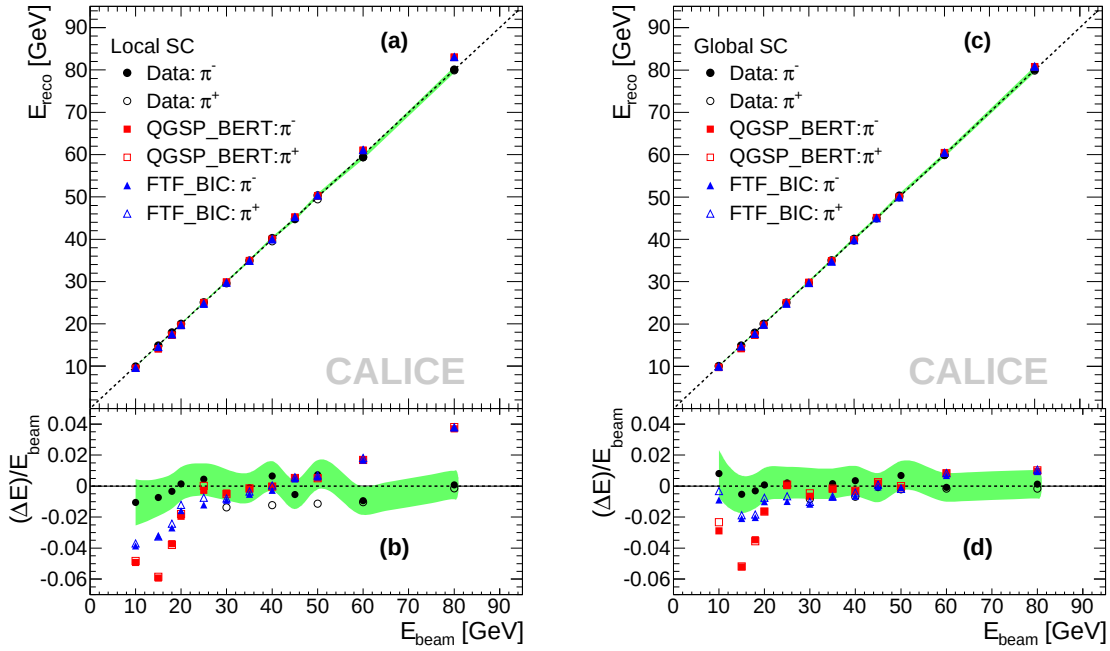

Figure 12. Detector response to pions with software compensation comparing data and simulations. For both data and simulations compensation parameters derived from data are used. (a) Response with local software compensation and (b) corresponding relative residuals to beam energy. (c) Response with global software compensation and (d) corresponding relative residuals to beam energy.

ignoring differences in the normalisation originating from different energy sums. The distributions show a slight overestimation of the fraction of high-density hits by the simulations. In addition, uncertainties in the treatment of saturation effects of the photon sensor lead to an excess of cells with very high energy content well beyond the range shown in the figure.

The effect of the application of the software compensation algorithms, with parameters extracted from data, on the reconstructed energy in simulations is shown in Figure 12. For both compensation techniques, the underestimation of the detector response at low energy, in particular by the QGSP_BERT physics list, remains present. At intermediate energies from 20 GeV up to 50 GeV, the application of software compensation results in an improved response linearity and in a better agreement between data and simulations for both physics lists considered. At higher energy, a significant overestimation of the reconstructed energy by simulations is seen with local software compensation, while the global software compensation technique successfully corrects the non-linearity of the simulations in that energy regime. This difference in behaviour is partially due to uncertainties in the treatment of saturation effects in simulations, and potentially also receives a contribution from imperfect descriptions of the shower structure by the shower models themselves. In the simulations, the number of cells with very high energy content is overestimated and exhibits a longer tail than in data, as discussed above. This affects the correction factor of the global software compensation by construction, resulting in a lower shower weight for simulations compared to data at the same energy on average, bringing data and simulations into better agree-

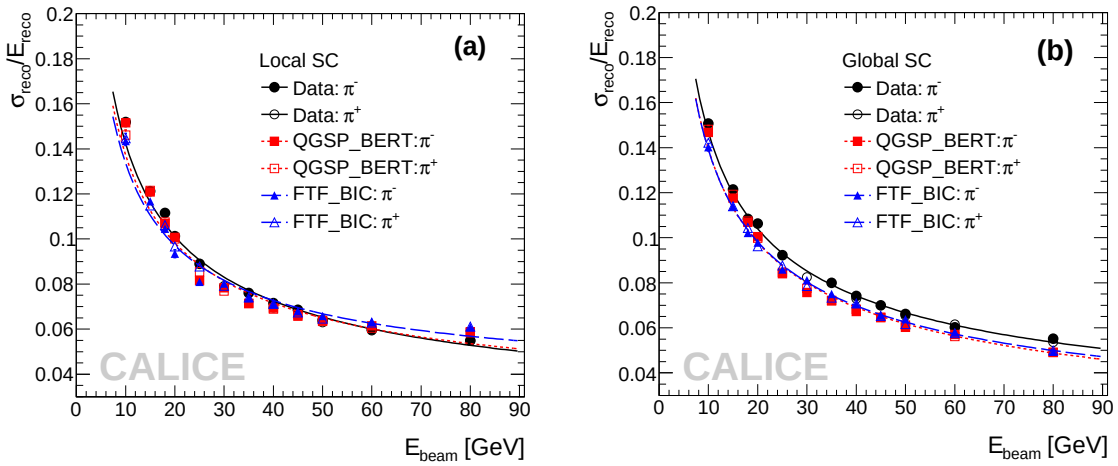

Figure 13. Energy resolution for pions with local (a) and global (b) software compensation comparing data and simulations. For both data and simulations compensation parameters derived from data are used. The curves show fits using Equation 2.2. The fit results for the local software compensation are $(44.3 \pm 0.3)\%$, $(42.3 \pm 0.2)\%$ and $(40.4 \pm 0.3)\%$ for the stochastic term, with constant terms of $(1.8 \pm 0.2)\%$, $(2.5 \pm 0.1)\%$ and $(3.4 \pm 0.1)\%$ for data, QGSP_BERT and FTF_BIC, respectively. For the global software compensation, the results are $(45.8 \pm 0.3)\%$, $(43.6 \pm 0.2)\%$ and $(43.4 \pm 0.3)\%$ for the stochastic term, with constant terms of $(1.6 \pm 0.2)\%$, $(0.0 \pm 0.2)\%$ and $(1.1 \pm 0.2)\%$ for data, QGSP_BERT and FTF_BIC, respectively.

Table 3. Fit results using the function given in Equation (2.2) for simulations with and without software compensation, compared to the corresponding values for data.

	a [%]	b [%]	c [GeV]
uncorrected data	57.6±0.4	1.6±0.3	0.18
uncorrected QGSP_BERT	51.8±0.3	4.0±0.1	0.18
uncorrected FTF_BIC	49.4±0.3	6.1±0.1	0.18
local compensation data	44.3±0.3	1.8±0.2	0.18
local compensation QGSP_BERT	42.3±0.2	2.5±0.1	0.18
local compensation FTF_BIC	40.4±0.3	3.4±0.1	0.18
global compensation data	45.8±0.3	1.6±0.2	0.18

ment. The local software compensation technique applies constant weights for very high-energy hits, as can be seen in Figure 5 (b). It is thus less sensitive to these differences between data and simulations and preserves the discrepancy in visible energy for high beam energies.

Figure 13 shows the energy resolution for simulations compared to that for data for both software compensation techniques. The local software compensation largely preserves the differences between data and simulations for the physics list QGSP_BERT, but results in a better agreement of FTF_BIC with data, in agreement with the behaviour observed for the reconstructed energy. The

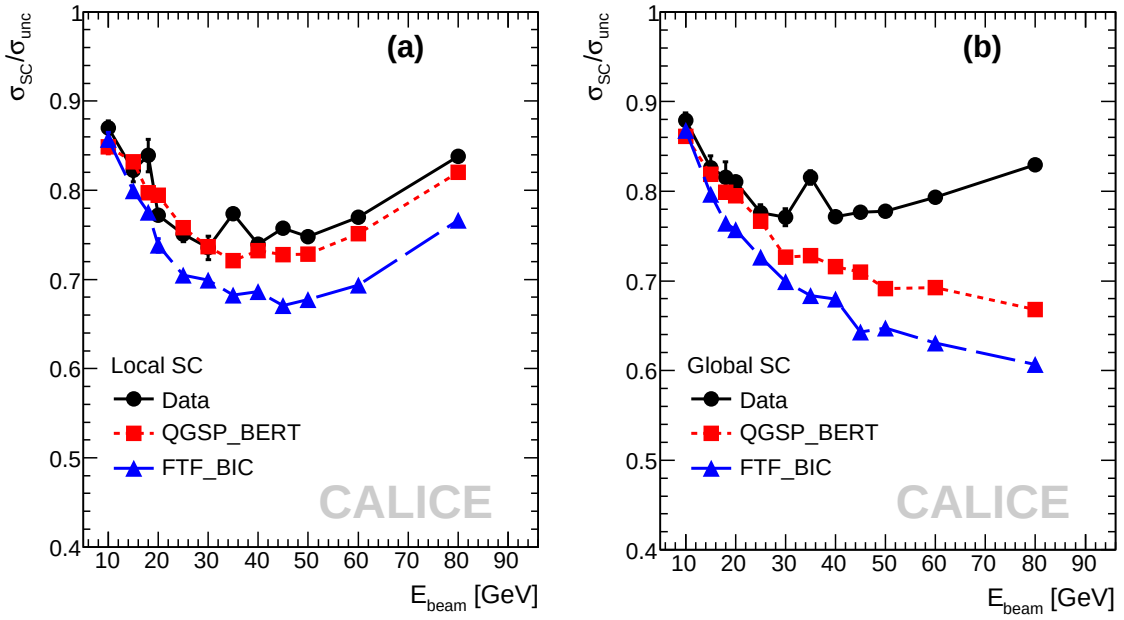

Figure 14. Energy dependence of the relative improvement of the resolution for data and simulations using the physics lists QGSP_BERT and FTF_BIC, (a) with local software compensation and (b) with global software compensation. Where available, results for π^- and π^+ are averaged for clarity.

global software compensation brings the overall trend of the resolution with energy for data and simulations into good agreement, with better resolution seen for simulations with both physics lists than for data. The results of the fits to the data points using Equation 2.2 are summarised in Table 3, together with the results obtained without software compensation.

The relative improvement in resolution compared to the uncorrected energy resolution is shown in Figure 14 for data and simulations. For the local software compensation, the improvement with respect to energy observed in data is well reproduced by the QGSP_BERT physics list. For FTF_BIC, a considerably bigger improvement is seen for the simulations at high energy than is seen in data. This higher improvement at high energies results in the better agreement of the energy resolution in data and in simulations discussed above. For the global compensation approach, the behaviour up to 30 GeV is well modelled by QGSP_BERT, while an up to 20% higher improvement, compared to that for data, is seen in simulations at the highest energies considered. The reason for this different behaviour of local and global software compensation is the same as for the different high-energy behaviour for the reconstructed energy as discussed above.

5. Conclusion

The hadronic energy resolution of the CALICE analogue hadron calorimeter is studied using test beam data collected in 2007 at the CERN SPS. The calorimeter, with an instrumented volume of approximately 1 m^3 and a depth of 5.3 λ_I, is highly segmented in both longitudinal and lateral direction, with a total of 7608 electronic channels. The intrinsic energy resolution of the CALICE AHCAL for hadrons is measured to be $58\%/\sqrt{E/\mathrm{GeV}}$, with a constant term of 1.6%.

The unprecedented granularity of the CALICE AHCAL provides excellent possibilities for the application of software compensation algorithms to improve the energy resolution of the calorimeter based on event-by-event information on the energy density structure of the showers. Two techniques have been presented here, together with results from test beam and from simulated data samples. The local software compensation technique uses local energy density information for a cell-by-cell re-weighting of energy deposits, while the global software compensation technique uses the distribution of cell energies to derive one overall weighting factor for each shower. Both techniques show similar performance, with a relative improvement of the energy resolution ranging from 12% to 25% over the studied energy range from 10 GeV to 80 GeV, resulting in a reduction of the stochastic term to $45\%/\sqrt{E/\mathrm{GeV}}$. In GEANT4 simulations with the QGSP_BERT and the FTF_BIC physics lists, the detector response is considerably more non-linear than in data. The physics list QGSP_BERT provides a satisfactory description of the energy resolution. The application of software compensation using parameters determined from data brings the resolution into better agreement with data. Here, the improvement of the energy resolution using the local software compensation technique observed for the QGSP_BERT physics lists is comparable to that observed for data, while larger differences are observed for FTF_BIC and for the global software compensation technique.

Neither of the described techniques requires an *a priori* knowledge of the particle energy. The energy dependent compensation factors are selected based on the uncorrected reconstructed energy. Although this energy dependence places some restrictions on the implementation of both techniques in a collider environment with a high particle density in hadronic jets, their application in the context of particle flow algorithms should be possible based on identified calorimeter clusters. The jet energy resolution can profit from the improved hadronic energy resolution directly through a better measurement of the neutral hadronic component, but also indirectly from an improved matching of reconstructed tracks and calorimeter energy during the clustering phase.

Acknowledgments

We gratefully acknowledge the DESY, CERN and Fermilab managements for their support and hospitality, and their accelerator staff for the reliable and efficient beam operation. We would like to thank the HEP group of the University of Tsukuba for the loan of drift chambers for the DESY test beam. The authors would like to thank the RIMST (Zelenograd) group for their help and sensors manufacturing. 交付決定額

計画研究 B01 班に配分された交付額を表 1 に示す。

表 1. 交付決定額（配分額）　（金額単位：円）

年度	直接経費	間接経費	合計
平成 23 年度	7,400,000	2,220,000	9,620,000
平成 24 年度	10,800,000	3,240,000	14,040,000
平成 25 年度	10,900,000	3,270,000	14,170,000
平成 26 年度	10,300,000	3,090,000	13,390,000
平成 27 年度	10,300,000	3,090,000	13,390,000
総計	49,700,000	14,910,000	64,610,000

研究成果

1. 研究開始当初の背景

宇宙進化、特に初期宇宙の出来事に関しては未知の点が多く残されている。特に、宇宙暗黒物質の正体、宇宙のバリオン・反バリオン非対称性の期限、インフレーションの機構など、宇宙の成り立ちを理解する上でも重要となる問題については、まだ全くと言って良いほど何もわかっていない。これら重要な問題の解決には、素粒子標準理論を超える物理の理解が必要不可欠である。そして、高エネルギー実験・宇宙観測の結果が多数得られると期待される今後数年間こそ、それらをもとに、初期宇宙に関する理空きを飛躍的に進歩させる時期となる。

2. 研究の目的

本研究の目的は、このような重要な時期に、本領域を構成する多方面の実験物理学者や様々な分野の素粒子理論研究者との密接な協力のもと、初期宇宙に関する研究を行い、初期宇宙像を確立させることにある。特に重要な以下のテーマについては、初期段階から研究を進め、結論を得たい：(1)素粒子模型の確立と宇宙論の構築、(2)暗黒物質の起源と生成過程の解明、(3)テラスケールの物理の宇宙進化への影響、(4)インフレーションの理解。そしてその結果をもとに、宇宙進化のシナリオを理解し、初期宇宙像を確立させる。

3. 研究の方法

実験研究者との密接な連携のもと、素粒子理論および宇宙理論的な考察と数値計算に基づき研究を進める。

4. 研究成果

LHC 実験において、125GeV の質量を持つヒッグス粒子が発見されたことは、素粒子標準模型の確立のみならず、標準模型を超える物理の方向性、さらにそれに基づく宇宙論に大きな影響を与えている。本研究計画ではヒッグス粒子の発見を踏まえつつ多岐にわたる研究を行ってきた。以下に主な研究成果をあげる。

ヒッグス粒子発見が超対称標準模型に与える示唆についての研究

LHC 実験で発見された 125GeV のヒッグス粒子の質量を超対称理論で説明するには、超対称粒子が重いか、最少超対称標準模型を拡張する必要がある。

1）ゲージ一重項を加えた超対称標準模型の拡張について詳細に研究した。特に、Peccei-Quinn 対称性を持つ模型を構成するとともに、ヒッグスセクターとその超対称対からの量子補正によってヒッグス粒子の質量を 125GeV まで大きくすることができることを示した。また、一重項スカラー粒子が軽い場合には、ゲージ二重項のヒッグス粒子との混合により後者の質量が 125GeV まで増大できることを示した。これらの模型における暗黒物質の性質など宇宙論的影響を考察した。

2）超対称粒子の質量スケールは 10TeV 程度にあるという可能性（高スケール超対称模型）の重要性を指摘し、将来そのような模型の実験的検証が可能であるかを議論した。そのような模型においては、特に Wino が暗黒物質となる可能性があるが、暗黒物質直接探査実験によってその可能性がどの程度検証できるかの定量的解析を行った。さらに、Wino 粒子の LHC 実験における発見可能性を議論するとともに、フレーバーの破れ実験等を用いて高スケール超対称模型を検証する可能性についても研究を行った。

超対称 Peccei-Quinn 模型に基づく宇宙論の研究

超対称化された Peccei-Quinn 模型に基づく宇宙進化について、宇宙初期の熱的プラズマがアクシオンやその超対称パートナーであるアクシーノの運動に与える影響を特に考慮しつつ、研究を行った。そして、宇宙初期のプラズマとの相互作用によるスカラー場の振動の減衰は通常無視されているが、特にアクシーノ場に関しては、プラズマとの相互作用がその運動に大きな影響を与え得ることを明らかにした。

ヒッグスインフレーション

LHC 実験によって発見されたヒッグス粒子がインフレーションを引き起こす可能性について検証した。具体的には，運動項のヒッグス場自身への依存性を用いることでインフレーションを実現する running kinetic inflation を提唱し，特に BICEP2 実験の結果と整合する事を示した．またヒッグス粒子の質量から示唆されるプランクスケールにおける縮退した真空との間のドメインウォールがインフレーションを起こす可能性を指摘した．

ヒッグス粒子と暗黒輻射

ヒッグスセクターをポータルとして隠れたゲージ対称性と結合しているシナリオにおいて，隠れたゲージ粒子が暗黒輻射として現在のエネルギーに寄与する可能性を提唱した．特に，暗黒輻射の存在量とヒッグスの invisible decay とが相関しており，宇宙的な観測と LHC 実験が相補的な制限を与えることを示した．特にこの暗黒輻射は自己相互作用を持っており，将来の CMB 観測からその粘性パラメターへの制限，発見が期待できる．

領域との関係

素粒子論的宇宙論の研究を進め、新たな宇宙像を確立していくには、LHC におけるヒッグス粒子の発見と性質の研究及び新現象の探索に関する情報が不可欠である。本研究班は、本領域における LHC 実験に関わるグループ、とりわけヒッグス粒子に関する実験的研究（A01)、標準模型を超える物理の探索（A02)、テラスケール物理の現象論的研究（A06）との密接な連携により新たな方向性を見出していこうとしている。さらに、関連する素粒子物理学の理論的研究、特に B02 班で進めている標準模型を超える物理へのアプローチや、B03 班の弦理論からのアプローチ、B04 班によるフレーバーの物理からの知見を活かしながら研究を進めることができた。これらの連携にあたっては、領域全体で行ってきたシンポジウムや研究集会が非常に有効であった。

Abstract: We study a Peccei-Quinn invariant extension of the next-to-minimal supersymmetric Standard Model (NMSSM), which turns out to be free from the tadpole and domain wall problems. Having a non-renormalizable coupling to the axion superfield, the SM singlet added to the Higgs sector can naturally generate an effective Higgs μ term around the weak scale. In the model, the lightest neutralino is dominated by the singlino, which gets a mass only through mixing with the neutral Higgsinos. We explore the phenomenological consequences resulting from the existence of such a relatively light neutralino. The coupling of the SM singlet to the Higgs doublets is constrained by the experimental bound on the invisible Z-boson decay width. Under this constraint, we examine the properties of the SM-like Higgs boson paying attention to its mass and decays. We also demonstrate a UV completion of the model in SU(5) grand unified theory with a missing-partner mechanism.

1 Introduction

The next-to-minimal supersymmetric Standard Model (NMSSM) introduces a SM singlet S to explain the origin of a supersymmetric Higgs μ term of the MSSM [1, 2]. However, if S is a true singlet under all symmetries, it becomes difficult to embed the NMSSM into a more fundamental theory such as a grand unified theory (GUT). This is because the GUT partners of the MSSM Higgs doublets also couple to S and radiatively generate a large tadpole for S, destabilizing the gauge hierarchy [3–6]. Non-renormalizable interactions are another source of large tadpoles [7–9]. A symmetry under which S transforms non-trivially can solve the tadpole problem, but generally introduces another problem. If one considers a discrete symmetry, dangerous domain walls would be formed in the early universe [10, 11]. On the other hand, a global symmetry spontaneously broken by S and the Higgs doublets would give rise to an unacceptable visible axion. Additional structure is thus needed to generate μ dynamically from the coupling of S to the Higgs doublets while providing a viable framework for the grand unification.

In this paper, we point out that the difficulties arising due to the singlet S can be avoided in a Peccei-Quinn invariant extension of the NMSSM (PQ-NMSSM) where the PQ symmetry is spontaneously broken at a scale much higher than the weak scale by the axion superfield. The PQ symmetry forbids the generation of large tadpoles for S while solving

the strong CP problem [12, 13]. Furthermore, the domain wall problem can be resolved in the presence of PQ messengers that couple to the axion superfield. It also turns out that a non-renormalizable coupling of S to the axion superfield naturally leads S to get a vacuum expectation value around the weak scale.

The Higgs and neutralino sectors are considerably modified by the addition of S. In the PQ-NMSSM, the lightest neutralino consists mostly of the singlino because it acquires a small mass through mixing with the neutral Higgsinos after the electroweak symmetry breaking. The presence of such a relatively light neutralino leads to phenomenological consequences different from other NMSSM models. In particular, the LEP bound on the invisible Z-boson decay width places a stringent constrain on the coupling of S to the Higgs doublets if the decay mode is kinematically allowed. This constraint becomes important at large $\tan\beta$. We also note that loops involving the Yukawa coupling of the singlino give an additional positive contribution to the SM-like Higgs mass. This contribution is insensitive to $\tan\beta$, and arises when the Higgsinos are lighter than other MSSM sparticles. Another interesting feature is that the decay of the SM-like Higgs boson into a pair of the lightest neutralino can be dominant at low $\tan\beta$.

Since interactions of S are controlled by the PQ symmetry, it is possible to embed the PQ-NMSSM into GUT models without the tadpole problem. The associated UV completion is then related to the doublet-triplet splitting problem. We find that incorporating the PQ symmetry in a missing-partner model for supersymmetric SU(5) GUT [14, 15] can lead to the PQ-NMSSM at low energy scales. In addition, it naturally achieves a phenomenologically acceptable value of the axion decay constant as $F_a \sim \sqrt{M_{\rm SUSY} M_{\rm Pl}}$ with $M_{\rm SUSY}$ being the SUSY breaking scale. The PQ symmetry is also important for suppressing harmful dimension 5 operators for proton decays.

This paper is organized as follows. In the next section, we present the model and discuss its general properties and various constraints on the singlet couplings. Then, in section 3, we construct a low energy effective theory below the SUSY breaking scale to examine the phenomenological aspects resulting from the existence of a singlino-like light neutralino. Section 4 is for the discussion on how to UV complete the model. The PQ-NMSSM can arise as a low energy theory of a missing-partner GUT model. Section 5 is the conclusion.

2 PQ-invariant extension of the NMSSM

In this section, we extend the NMSSM[1] to incorporate the PQ symmetry and study the properties of the model. The PQ-invariant extension turns out not only to provide a solution to the strong CP problem [28–30] but also to solve both the tadpole and domain wall problems. We also examine constraints on the coupling of S to the Higgs doublets.

[1] Extensions of the MSSM with a SM singlet have been received revived attention [16–27] after the first results on the Higgs search at the LHC had been announced.

JHEP04(2012)022

2.1 Model

In the PQ-NMSSM, an effective Higgs μ term is generated by the vacuum expectation value of S which couples to the Higgs doublets and to the axion superfield X through the PQ-invariant interactions

$$\mathcal{L} = \int d^2\theta \lambda S H_u H_d + \int d^4\theta \, \kappa \frac{X^{*2}}{M_{\rm Pl}} S + \text{h.c.}\,, \tag{2.1}$$

for (X, S, H_u, H_d) carrying the PQ charges as $(1, 2, -1, -1)$. All other terms involving S are forbidden by the PQ symmetry in the renormalizable superpotential. A superpotential term $X^2 H_u H_d / M_{\rm Pl}$, which is allowed by $\mathrm{U}(1)_{\rm PQ}$, can be removed by a holomorphic redefinition of S without loss of generality. Here we have taken such a field basis.

In the following, we assume that a mechanism to stabilize X is operative with its vacuum expectation value fixed at $10^{10\text{–}12}\,\text{GeV}$ as required by cosmological and astrophysical observations. As suppressed by $M_{\rm Pl}$, the interactions between X and other scalar fields rarely affect the saxion potential at $|S| \ll |X| \ll M_{\rm Pl}$. The Higgs potential can thus be examined by replacing X with its vacuum expectation value. Then, the involved mass parameters are determined by the SUSY breaking scale $M_{\rm SUSY}$ and the axion decay constant $F_a \sim |X|$. We note that, when treating X as a spurion field, the present model can be regarded as the nMSSM,[2] where the superpotential contains an effective tadpole for S:

$$W_{\rm eff} = \lambda S H_u H_d + m_0^2 (1 + \theta^2 B_\kappa) S\,, \tag{2.2}$$

with $B_\kappa \sim M_{\rm SUSY}$ and

$$m_0^2 \sim \kappa M_{\rm SUSY} \frac{F_a^2}{M_{\rm Pl}}\,. \tag{2.3}$$

The appearance of m_0^2 and B_κ terms can be understood by promoting κ to a function depending on SUSY breaking fields in a hidden sector. It is obvious that the model does not suffer from the tadpole problem because a tadpole for S requires a higher dimensional coupling of S to X as dictated by $\mathrm{U}(1)_{\rm PQ}$. For $F_a = 10^{10\text{–}12}\,\text{GeV}$, $M_{\rm SUSY} \sim 1\,\text{TeV}$ and κ less than order unity, the value of m_0 can naturally be around the weak scale. Hence, it is natural to expect that electroweak symmetry breaking would occur at the correct scale. In fact, the same spirit is shared with the Kim-Nilles mechanism [38] that explains the smallness of μ in extensions of the MSSM with $\mathrm{U}(1)_{\rm PQ}$. Since S and $H_{u,d}$ carry $\mathrm{U}(1)_{\rm PQ}$ charges and develop vacuum expectation values, the Higgs and neutralino sectors have small mixing with X suppressed by F_a.

Let us now examine the vacuum structure of the low energy effective theory given by (2.2). Including soft SUSY breaking terms, the scalar potential of the extended Higgs

[2] The nMSSM [31, 32] assumes specific discrete R symmetries to ensure the absence of large tadpoles for S. A general discussion on the phenomenological aspects of the nMSSM for small $\tan\beta$ can be found in [32–36]. Some cosmological issues have also been discussed in [34–36]. Neglecting small mixing with the axion superfield, the Higgs and neutralino sectors of the PQ-NMSSM have the same phenomenological properties as the nMSSM. However, the cosmological properties can be different depending on the cosmological evolution of the saxion. A continuous symmetry to restrict couplings of S in the NMSSM has been introduced in [37], where it is explicitly broken only by a linear superpotential of S.

JHEP04(2012)022

sector reads

$$V = \frac{1}{8}(g^2+g'^2)(|H_u|^2-|H_d|^2)^2 + \frac{1}{2}g^2|H_u^\dagger H_d|^2 + |\lambda H_u H_d + m_0^2|^2 + |\lambda|^2|S|^2(|H_u|^2+|H_d|^2) + m_{H_u}^2|H_u|^2 + m_{H_d}^2|H_d|^2 + m_S^2|S|^2 + (A_\lambda \lambda S H_u H_d - B_\kappa m_0^2 S + \text{h.c.}), \quad (2.4)$$

where m_i^2 is a soft scalar mass squared, and A_λ is a soft A-parameter. The potential contains four complex parameters, λ, A_λ, m_0^2 and B_κ. Among them, λ and m_0^2 can be made real and positive by a field redefinition of $H_{u,d}$ and X. Furthermore, if $\arg(A_\lambda) = \arg(B_\kappa)$, one can rotate away the phases of A_λ and B_κ by redefining S. We will assume this is the case, for which CP invariance is preserved in the Higgs sector and there is no mixing between scalar and pseudo-scalar fields. From the above scalar potential, it is straightforward to get the conditions for electroweak symmetry breaking. Similarly as in the MSSM, two of them can be written

$$\frac{1}{2}M_Z^2 = \frac{m_{H_d}^2 - m_{H_u}^2\tan^2\beta}{\tan^2\beta - 1} - \mu_{\text{eff}}^2, \qquad \sin 2\beta = \frac{2b_{\text{eff}}}{m_{H_d}^2 + m_{H_u}^2 + 2\mu_{\text{eff}}^2 + \lambda^2 v^2}, \quad (2.5)$$

for μ_{eff} and b_{eff} defined by

$$\mu_{\text{eff}} = \lambda v_S, \qquad b_{\text{eff}} = \lambda(A_\lambda v_S + m_0^2), \quad (2.6)$$

where $\langle|H_u^0|\rangle = v\sin\beta$ and $\langle|H_d^0|\rangle = v\cos\beta$ with $v = 174\,\text{GeV}$. The value of $|S|$ at the vacuum is fixed as

$$v_S = \frac{A_\lambda \lambda v^2 \sin 2\beta + 2B_\kappa m_0^2}{2(m_S^2 + \lambda^2 v^2)}. \quad (2.7)$$

The tree-level mass matrices for the scalar fields are presented in the appendix A.

To explore the global structure of the potential, one can substitute S by the solution of $\partial_S V = 0$. Then, the Higgs potential (2.4) is written

$$V = V|_{S=0} - \frac{|A_\lambda \lambda H_u H_d - B_\kappa m_0^2|^2}{m_S^2 + |\lambda|^2(|H_u|^2+|H_d|^2)}, \quad (2.8)$$

which increases monotonically along the D-flat direction $|H_u^0| = |H_d^0|$ when

$$R_1 \geq 1 \quad \text{and} \quad 3R_1 \geq 2 + R_2, \quad \text{or} \quad 1 \geq R_1^3 \geq R_2, \quad (2.9)$$

where $R_{1,2}$ are defined by $R_1 m_S^2 = |(2\mu_{\text{eff}} - A_\lambda)m_S^2 + (2\mu_{\text{eff}} - A_\lambda \sin 2\beta)\lambda^2 v^2|^{2/3}$ and $R_2 m_S^2 = (2\mu_{\text{eff}} - A_\lambda)^2 - 2(m_{H_u}^2 + m_{H_d}^2 + 2\mu_{\text{eff}}^2 - 2b_{\text{eff}})$. If the above condition is not satisfied, the potential may develop another minimum away from the weak scale.[3] The involved soft

[3] Actually a minimum of the potential does not lie in the D-flat direction unless $m_{H_u}^2 = m_{H_d}^2$. However, as will be shown in the appendix B, a minimum other than the electroweak vacuum, if exists, is located near the D-flat direction for much of the parameter space. This justifies our approach of examining the D-flat direction to see when there can be another minimum. See also [39], where the stability of the electroweak vacuum has been examined within the framework of the effective Lagrangian beyond the MSSM.

JHEP04(2012)022

parameters are then constrained by the requirement that the electroweak vacuum should be a global minimum. For $m_S^2 \sim M_{\rm SUSY}^2 \gg \mu_{\rm eff}^2$, which is the case we shall focus on, the stability condition (2.9) requires $A_\lambda^2 \lesssim m_S^2$ or $m_S^2 \lesssim A_\lambda^2 \lesssim m_A^2$ with m_A being the mass of the CP-odd neutral Higgs boson. Keeping this in mind, we will consider also the case with $A_\lambda \sim M_{\rm SUSY}$, which is favored to avoid large mixing of the SM-like Higgs scalar with the singlet scalar when $\mu_{\rm eff}$ and $\tan\beta$ are large.

An important consequence of $\mathrm{U}(1)_{\rm PQ}$ is the appearance of a relatively light neutralino with a large singlino component. This is because the PQ symmetry prevents the singlino $\tilde{S}$ from having a supersymmetric mass. The lightest neutralino is mostly singlino if the masses of the bino $\tilde{B}$ and wino $\tilde{W}$ are larger than λv, as is the case for $\lambda \lesssim 1$. The neutralino mass matrix for $(\tilde{B}, \tilde{W}^0, \tilde{H}_d^0, \tilde{H}_u^0, \tilde{S})$ is given by

$$\begin{pmatrix} M_{\tilde{B}} & 0 & -M_Z \sin\theta_W \cos\beta & M_Z \sin\theta_W \sin\beta & 0 \\ 0 & M_{\tilde{W}} & M_Z \cos\theta_W \cos\beta & -M_Z \cos\theta_W \sin\beta & 0 \\ -M_Z \sin\theta_W \cos\beta & M_Z \cos\theta_W \cos\beta & 0 & -\mu_{\rm eff} & -\lambda v \sin\beta \\ M_Z \sin\theta_W \sin\beta & -M_Z \cos\theta_W \sin\beta & -\mu_{\rm eff} & 0 & -\lambda v \cos\beta \\ 0 & 0 & -\lambda v \sin\beta & -\lambda v \cos\beta & 0 \end{pmatrix}, \quad (2.10)$$

where θ_W is the weak mixing angle. If we write the lightest neutralino as a linear combination of $(\tilde{B}, \tilde{W}^0, \tilde{H}_d^0, \tilde{H}_u^0, \tilde{S})$:

$$\tilde{\chi}_1^0 = N_1^{\tilde{B}} \tilde{B} + N_1^{\tilde{W}} \tilde{W}^0 + N_1^{\tilde{H}_d^0} \tilde{H}_d^0 + N_1^{\tilde{H}_u^0} \tilde{H}_u^0 + N_1^{\tilde{S}} \tilde{S}\,, \quad (2.11)$$

then we find

$$\begin{aligned} N_1^{\tilde{S}} &= 1 - \frac{1}{2}(1 + \cdots)\epsilon_{\tilde{H}}^2\,, \\ N_1^{\tilde{H}_u^0} &= -\epsilon_{\tilde{H}}(\sin\beta + \cdots)\,, & N_1^{\tilde{H}_d^0} &= -\epsilon_{\tilde{H}}(\cos\beta + \cdots)\,, \\ N_1^{\tilde{B}} &= -\epsilon_{\tilde{B}}\epsilon_{\tilde{H}}(1 + \cdots)\,, & N_1^{\tilde{W}} &= \epsilon_{\tilde{W}}\epsilon_{\tilde{H}}(1 + \cdots)\,, \end{aligned} \quad (2.12)$$

for $\epsilon_{\tilde{H}}^2 \ll 1$ and $|\epsilon_{\tilde{B},\tilde{W}}| \ll 1$. Here the epsilon parameters are defined by

$$\epsilon_{\tilde{H}} \equiv \frac{\lambda v}{\mu_{\rm eff}}\,, \qquad \epsilon_{\tilde{B}} \equiv \frac{g' v \cos 2\beta}{\sqrt{2} M_{\tilde{B}}}\,, \qquad \epsilon_{\tilde{W}} \equiv \frac{g v \cos 2\beta}{\sqrt{2} M_{\tilde{W}}}\,, \quad (2.13)$$

and the ellipsis indicates terms of higher orders in $\epsilon_{\tilde{H}}^2$ or $\epsilon_{\tilde{B},\tilde{W}}$. One can see that $\epsilon_{\tilde{H}} \neq 0$ is needed to make $\tilde{\chi}_1^0$ massive through mixing. In the following discussion, we will neglect small gaugino components of $\tilde{\chi}_1^0$ since it does not change our results substantially. Then, one can find

$$\begin{aligned} m_{\tilde{\chi}_1^0} &\simeq 2\Big(\mu_{\rm eff} N_1^{\tilde{H}_u^0} N_1^{\tilde{H}_d^0} + \lambda v N_1^{\tilde{H}_u^0} N_1^{\tilde{S}} \cos\beta + \lambda v N_1^{\tilde{H}_d^0} N_1^{\tilde{S}} \sin\beta\Big) \\ &= \frac{\lambda^2 v^2 \sin 2\beta}{\mu_{\rm eff}}\left(1 - \frac{\lambda^2 v^2}{\mu_{\rm eff}^2} + \mathcal{O}\left(\frac{\lambda^4 v^4}{\mu_{\rm eff}^4}\right)\right). \end{aligned} \quad (2.14)$$

As we will discuss later, the singlino-like neutralino with a small mass can considerably change the phenomenological properties of the model.

JHEP04(2012)022

Meanwhile, there can exist PQ messengers $\Psi + \bar{\Psi}$ which are vector-like under the SM gauge group and obtain heavy masses from the coupling $X\Psi\bar{\Psi}$ in the superpotential. Such interaction can play an important role in the saxion stabilization because it induces a radiative potential for the saxion after SUSY breaking. The presence of PQ messengers also helps to avoid the domain wall problem. Let us consider N_Ψ pairs of $\Psi + \bar{\Psi}$ forming $\mathbf{5} + \bar{\mathbf{5}}$ representation under SU(5), for which the gauge coupling unification is preserved. Then, the domain wall number is given by

$$N_{\rm DW} = |N_\Psi - 6| \,. \tag{2.15}$$

This implies that the domain wall problem can be resolved for $N_\Psi = 5, 7$. For other cases with $N_{\rm DW} \neq 1$, the formation of dangerous domain walls can still be avoided if the saxion is displaced far from the origin after the inflation ends so that the PQ symmetry is not restored at high temperatures [40].

2.2 Constraints on the model parameters

Since S modifies the Higgs and neutralino sectors, it is of importance to explore constraints on the singlet couplings λ, A_λ, B_κ and m_S^2. Here we focus on the case with $0.1 \lesssim \lambda \lesssim 1$ at the weak scale as would be natural because an effective μ term is generated as $\mu_{\rm eff} = \lambda S$ with S fixed around $M_{\rm SUSY}$. Let us first examine the mixing of the singlet scalar with the Higgs doublets. After taking the rotation of (H_u^0, H_d^0) by an angle β, the mass matrix for the CP-even scalar fields has

$$\begin{aligned}
(M_H^2)_{11} &= M_Z^2 \cos^2 2\beta + \lambda^2 v^2 \sin^2 2\beta \,, \\
(M_H^2)_{13} &= \lambda v (2\mu_{\rm eff} - A_\lambda \sin 2\beta) \,, \\
(M_H^2)_{33} &= m_S^2 + \lambda^2 v^2,
\end{aligned} \tag{2.16}$$

where $(M_H^2)_{11}$ constitutes an upper bound on the mass of the lightest CP-even Higgs boson at the tree-level. In the following, we would like to consider the situation that the SM-like Higgs boson has negligible contamination from the singlet scalar. For $0.1 \lesssim \lambda \lesssim 1$, this is achieved when

$$\frac{\mu_{\rm eff}^2}{m_S^2} \left| 1 - \frac{A_\lambda \sin 2\beta}{2\mu_{\rm eff}} \right| \ll 1 \,, \tag{2.17}$$

with m_S^2 being of the order of $M_{\rm SUSY}^2$. It is thus found that, if A_λ is larger than $2\mu_{\rm eff}$, the mixing can get a sizable suppression at some region of $\tan\beta$. One would otherwise need $\mu_{\rm eff}^2 \ll m_S^2$ to suppress the mixing.

In the PQ-NMSSM, a stringent constraint on λ comes from the experimental bound on the Z-boson invisible decay rate because the PQ symmetry makes $\tilde{\chi}_1^0$ light. The singlino mixes with neutral Higgsinos to induce the interaction $\bar{\tilde{\chi}}_1^0 \sigma^\mu \tilde{\chi}_1^0 Z_\mu$ [41, 42], through which Z can invisibly decay into pairs of the lightest neutralino. The coupling for this interaction is given by

$$g_{Z\tilde{\chi}_1^0\tilde{\chi}_1^0} = \frac{g}{2\cos\theta_W} \left(|N_1^{\tilde{H}_d^0}|^2 - |N_1^{\tilde{H}_u^0}|^2 \right) \approx \frac{g}{2\cos\theta_W} \frac{\lambda^2 v^2 \cos 2\beta}{\mu_{\rm eff}^2} \,, \tag{2.18}$$

JHEP04(2012)022

where the last approximation is valid for small $\lambda v/\mu_{\rm eff}$. Hence, at large $\tan\beta$, the interaction gets strong while the mass of $\tilde{\chi}_1^0$ becomes small. The above coupling mediates the Z decay into $\tilde{\chi}_1^0$ with

$$\Gamma_{Z\to\tilde{\chi}_1^0\tilde{\chi}_1^0} = \frac{g^2_{Z\tilde{\chi}_1^0\tilde{\chi}_1^0}}{24\pi} M_Z {\beta_Z}^3 \simeq 25{\beta_Z}^3 \left(\frac{\lambda}{0.8}\right)^4 \left(\frac{\cos 2\beta}{0.8}\right)^2 \left(\frac{200\,\mathrm{GeV}}{\mu_{\rm eff}}\right)^4 \mathrm{MeV}, \tag{2.19}$$

if $M_Z > 2m_{\tilde{\chi}_1^0}$. Here $\beta_Z = (1 - 4m^2_{\tilde{\chi}_1^0}/M_Z^2)^{1/2}$ is the velocity of $\tilde{\chi}_1^0$ in the rest frame of Z. The process $Z \to \tilde{\chi}_1^0\tilde{\chi}_1^0$ contributes to the invisible Z decay and is tightly constrained by the LEP data to occur with a small rate, $\Gamma_{Z\to\tilde{\chi}_1^0\tilde{\chi}_1^0} \lesssim 2\,\mathrm{MeV}$ [43]. This translates into

$$\lambda \lesssim 0.4 \left(\frac{\mu_{\rm eff}}{200\,\mathrm{GeV}}\right)\left(\frac{0.8}{|\cos 2\beta|}\right)^{1/2}. \tag{2.20}$$

The above constraint on λ around the weak scale becomes important for large values of $\tan\beta$. To kinematically forbid the mode $Z \to \tilde{\chi}_1^0\tilde{\chi}_1^0$, we need

$$\lambda \gtrsim 0.7 \left(\frac{\mu_{\rm eff}}{200\,\mathrm{GeV}}\right)^{1/2}\left(\frac{0.6}{\sin 2\beta}\right)^{1/2}, \tag{2.21}$$

which is possible for $\lambda \lesssim 1$ at low $\tan\beta$. For instance, at small $\tan\beta$ around 2, the LEP limits on the Z invisible width exclude values of $\mu_{\rm eff}$ in the range between 196 GeV and 260 GeV for $\lambda \approx 0.6$ [32].

On the other hand, for the theory to remain perturbative up to $M_{\rm GUT}$, λ should be small enough at the weak scale. NMSSM models with $\lambda S H_u H_d$ usually require λ less than 0.7–0.8 for $\tan\beta \gtrsim 2$. In models with a superpotential term S^3, the upper bound on λ decreases as the coupling for S^3 increases. However, the situation in the PQ-NMSSM is different because S^3 is absent and the PQ messengers with mass $M_\Psi \propto |X|$ affect the running of gauge couplings. Above the scale M_Ψ, gauge couplings have larger values than in the MSSM and slow down the running of Yukawa couplings. This results in the increase of the perturbativity bound on λ by $\delta\lambda \lesssim 0.1$ [44]. A large number of light PQ messengers are favored by raising the bound, but disfavored by the requirement of the perturbativity of gauge couplings up to $M_{\rm GUT}$. If there exists an extra gauge interaction, the perturbation theory would be valid below $M_{\rm GUT}$ for a larger value of λ at the weak scale.

Though we do not discuss it here in detail, there is also a constraint placed by cosmology. If $\tilde{\chi}_1^0$ is the lightest sparticle, its relic abundance should not exceed the measured amount of the dark matter. In the present model, the production of dark matter relies on the cosmological evolution of the saxion, which has a very flat potential generated after SUSY breaking and thus can play some non-trivial role in cosmology. On the other hand, the gravitino or axino can be lighter than $\tilde{\chi}_1^0$ depending on the mediation mechanism of SUSY breaking and on how the saxion is stabilized.

3 Low energy Higgs sector

In this section, we study the low energy Higgs sector. To see the impact of the PQ-NMSSM specific Higgs properties, we consider the decoupling limit of the MSSM where all heavy

JHEP04(2012)022

Higgs states decouple below $M_{\rm SUSY}$ and thus one combination of $H_{u,d}$ behaves exactly like the SM Higgs scalar H. In such a situation, we include the singlet S and construct a low energy effective theory below $M_{\rm SUSY}$ to examine how much the model departs from the MSSM. The modification is mainly due to (i) the extra contribution to the Higgs quartic coupling, which is a general property of NMSSM models, and (ii) the presence of a light neutralino that is singlino-like, which is a consequence of the PQ symmetry.

3.1 Effective theory below the SUSY breaking scale

For $0.1 \lesssim \lambda \lesssim 1$ at the weak scale, $\mu_{\rm eff}^2 \ll m_S^2$ is favored to suppress the mixing between H and the singlet scalar. Here we consider such a case and assume that the MSSM sparticles other than Higgsinos obtain masses of the order of $M_{\rm SUSY}$. The singlet scalar is also assumed to have $m_S^2 \sim M_{\rm SUSY}^2$. For $\mu_{\rm eff}$ less than $M_{\rm SUSY}$, the low energy effective theory below $M_{\rm SUSY}$ contains $\tilde{H}_{u,d}$ and $\tilde{S}$ in addition to the ordinary SM particles. The Lagrangian relevant to our analysis is given by[4]

$$-\mathcal{L}_{\rm eff} = \frac{\lambda_H}{2}(|H|^2 - v^2)^2 + (y_t \bar{t}_R Q_L H^c + \mu_{\rm eff}\tilde{H}_u\tilde{H}_d + y'_u H\tilde{H}_u\tilde{S} + y'_d H^c\tilde{H}_d\tilde{S} + \text{h.c.})\,, \tag{3.1}$$

where $H^c = -i\sigma_2 H^*$, and y_t is the top-Yukawa coupling. The singlino Yukawa couplings at the SUSY breaking scale are

$$y'_u(M_{\rm SUSY}) = \lambda\cos\beta\,, \qquad y'_d(M_{\rm SUSY}) = \lambda\sin\beta\,, \tag{3.2}$$

while the Higgs quartic coupling is given by

$$\lambda_H(M_{\rm SUSY}) = \frac{g^2+g'^2}{4}\cos^2 2\beta + \frac{\lambda^2}{2}\sin^2 2\beta + \delta\lambda_H|_{\rm tree} + \delta\lambda_H|_{\rm loop}\,, \tag{3.3}$$

where $\delta\lambda_H|_{\rm tree}$ is the threshold correction coming from tree-level exchange of the singlet scalar, and $\delta\lambda_H|_{\rm loop}$ is from the loops involving the stops:

$$\delta\lambda_H|_{\rm tree} \simeq -\frac{\lambda^2(2\mu_{\rm eff} - A_\lambda \sin 2\beta)^2}{2m_S^2}\,, \tag{3.4}$$

$$\delta\lambda_H|_{\rm loop} \simeq \frac{3y_t^4}{8\pi^2}\left(X_t - \frac{X_t^2}{12}\right), \tag{3.5}$$

where $X_t = (A_t - \mu_{\rm eff}\cot\beta)^2/M_{\rm SUSY}^2$ with A_t being the A-parameter for $H_u\tilde{t}_R\tilde{Q}_L$.

[4] To obtain the couplings of the SM-like Higgs boson more precisely, one needs to know the mixing between the SM-like Higgs boson and singlet scalar. To this end, one can replace the scalar part of (3.1) by

$$\begin{aligned}-\mathcal{L}_{\rm eff}|_{\rm scalar} =\ & \frac{\lambda_H - \delta\lambda_H|_{\rm tree}}{2}(|H|^2 - v^2)^2 + (m_S^2 + \lambda^2 v^2)|S - v_S|^2 \\ & - \left\{\frac{\lambda(2\mu_{\rm eff} - A_\lambda\sin 2\beta)}{2}(|H|^2 - v^2)(S - v_S) + \text{c.c.}\right\},\end{aligned}$$

and $\mu_{\rm eff}$ by λS. The small mixing with the singlet scalar reduces the couplings of the Higgs boson h. The reduced couplings can be obtained by taking the replacement

$$h \to \left(1 - \frac{\lambda v|2\mu_{\rm eff} - A_\lambda\sin 2\beta|}{m_S^2}\right)h\,.$$

JHEP04(2012)022

The physical mass of the CP-even neutral Higgs boson h can be obtained using the relation $m_h^2 = 2\lambda_H v^2$. For this, we need λ_H renormalized at the weak scale. In the effective theory, a low energy value of λ_H is determined by the renormalization group (RG) running equation:

$$\mu\frac{d\lambda_H}{d\mu} = \frac{1}{16\pi^2}\left(12\lambda_H^2 + 4(3y_t^2 + y_u'^2 + y_d'^2 - 3A)\lambda_H + 3B - 12y_t^4 - 4(y_u'^2 + y_d'^2)^2\right), \quad (3.6)$$

with the parameters A and B defined by

$$4A = 3g^2 + g'^2, \qquad 4B = 3g^4 + 2g^2g'^2 + g'^4. \quad (3.7)$$

Here one should note that the mixing between the neutral Higgs boson and singlet scalar would slightly modify the running equations.

To see the qualitative properties of the Higgs mass, we make an approximation taking into account that the dominant effects on the RG running come from the term y_t^4, and also from the terms $y_{u,d}'^4$ if λ is not small. The Higgs boson mass is found to be approximately given by

$$\begin{aligned} m_h^2 \approx\ & M_Z^2\cos^2 2\beta + \frac{3m_t^4}{4\pi^2 v^2}\left(\ln\left(\frac{M_{\rm SUSY}^2}{m_t^2}\right) + X_t - \frac{X_t^2}{12}\right) \\ & + M_Z^2\frac{2\lambda^2}{g^2+g'^2}\left(\sin^2 2\beta - \frac{(2\mu_{\rm eff} - A_\lambda\sin 2\beta)^2}{m_S^2} + \frac{\lambda^2}{4\pi^2}\ln\left(\frac{M_{\rm SUSY}^2}{\mu_{\rm eff}^2}\right)\right), \end{aligned} \quad (3.8)$$

for $m_t = y_t v$ and $\mu_{\rm eff} \gtrsim m_h$. The first line is the well-known result for the Higgs boson mass in the MSSM [45–48]. On the other hand, those in the second line correspond to the additional contributions arising due to S, i.e. as a consequence of the extra Higgs quartic coupling $\lambda^2|H_u H_d|^2$, the mixing between the singlet scalar and neutral Higgs boson, and the singlino Yukawa interactions affecting the running of the Higgs quartic coupling at low energy scales. The last two contributions are approximately estimated as

$$\delta m_h|_{\rm mix} \approx -10\left(\frac{130\,{\rm GeV}}{m_h}\right)\left(\frac{30}{m_S^2/\mu_{\rm eff}^2}\right)\left(1 - \frac{A_\lambda\sin 2\beta}{2\mu_{\rm eff}}\right)^2\left(\frac{\lambda}{0.8}\right)^2{\rm GeV}, \quad (3.9)$$

$$\delta m_h|_{\rm rad} \approx 4.1\left(\frac{130\,{\rm GeV}}{m_h}\right)\left(\frac{\ln(M_{\rm SUSY}^2/\mu_{\rm eff}^2)}{\ln 30}\right)\left(\frac{\lambda}{0.8}\right)^4{\rm GeV}. \quad (3.10)$$

A negative contribution to m_h from the mixing with the singlet scalar is present in any NMSSM model. In the PQ-NMSSM, $\mu_{\rm eff}^2 \ll m_S^2$ leads to a large suppression of this effect for $A_\lambda \lesssim \mu_{\rm eff}$. For $A_\lambda \gtrsim 2\mu_{\rm eff}$, small mixing can still be obtained at some values of $\tan\beta$. One should also note that there is a PQ-NMSSM specific contribution $\delta m_h|_{\rm rad}$ arising because the PQ symmetry makes the lightest neutralino get a relatively small mass.[5] This positive contribution is insensitive to $\tan\beta$, and becomes important for a small value of $\mu_{\rm eff}/M_{\rm SUSY}$ contrary to $\delta m_h|_{\rm mix}$.

[5] See also [20] for a similar discussion in a singlet extension of the MSSM having a relatively light neutralino. However, in our situation, the LEP bound on the invisible Z-boson decay width excludes large values of λ at large $\tan\beta$.

JHEP04(2012)022

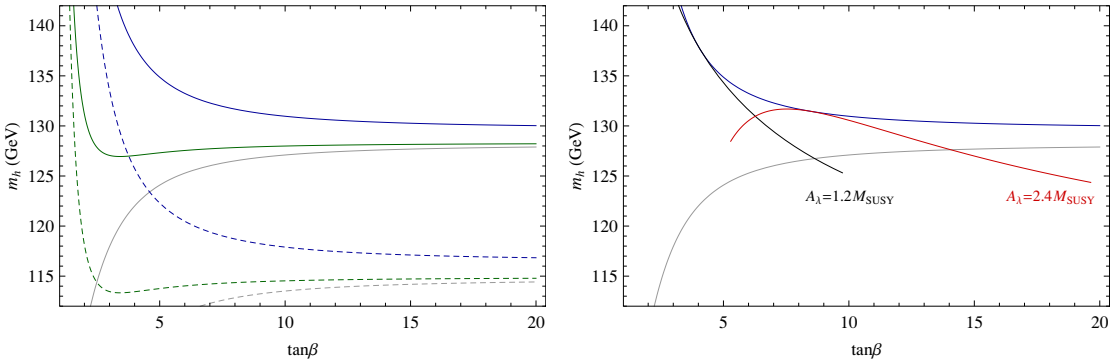

Figure 1. The mass of the SM-like Higgs boson for $M_{\rm SUSY} = 1.5\,\text{TeV}$ in the PQ-NMSSM. Here λ is taken to be the maximum value satisfying the bound $\Gamma_{Z\to\tilde{\chi}_1^0\tilde{\chi}_1^0} \lesssim 2\,\text{MeV}$. The solid curve in the left panel is the upper bound on m_h for $\mu_{\rm eff} = 240\,\text{GeV}$ (green) and $\mu_{\rm eff} = 420\,\text{GeV}$ (blue), which is obtained for no mixing case $\delta m_h|_{\rm mix} = 0$. The gray line is the MSSM value of m_h. In the left panel, the dashed lines are for $X_t = 0$ while the solid ones for $X_t = 6$. Meanwhile, the right panel shows m_h for $X_t = 6$, $\mu_{\rm eff} = 420\,\text{GeV}$ and a given value of A_λ: the black curve is for $A_\lambda = 1.2M_{\rm SUSY}$ while the red one for $A_\lambda = 2.4M_{\rm SUSY}$.

In figure 1, we show the upper bound on m_h in the PQ-NMSSM, which is obtained taking the maximum value of λ allowed by the constraint (2.20) from the Z invisible decay. Here we have solved the RG equation to get λ_H at the weak scale, and restricted λ to be less than unity as would be necessary to maintain its perturbativity up to $M_{\rm GUT}$. In the left panel, the value of m_h is shown for $\delta m_h|_{\rm mix} = 0$. While the MSSM generates $m_h \simeq 115\,\text{GeV}$ ($128\,\text{GeV}$) at $\tan\beta \gtrsim 10$ for $X_t = 0$ (6) and $M_{\rm SUSY} = 1.5\,\text{TeV}$, the additional contribution from λ can lead to m_h larger than $115\,\text{GeV}$ also at low $\tan\beta$ as in other NMSSM models. The loops of stops involving A_t can further increase m_h. The maximum comes at $X_t = 6$. It is also important to note that, when $\mu_{\rm eff} \gtrsim 400\,\text{GeV}$, m_h can be raised by a few GeV from the MSSM value even at large $\tan\beta$ owing to the PQ-NMSSM specific contribution $\delta m_h|_{\rm rad}$. On the other hand, the right panel shows the value of m_h for a given value of A_λ. For $A_\lambda \gtrsim 2\mu_{\rm eff}$, the mixing effect is suppressed only at some limited region of $\tan\beta$. In the figure, we consider values of $\tan\beta$ giving $(2\mu_{\rm eff} - A_\lambda \sin 2\beta)^2/m_S^2$ less than 0.1.

3.2 Phenomenological aspects

Since there appears a light neutralino as a consequence of the PQ symmetry, the Higgs boson h can invisibly decay into pairs of the lightest neutralino. This process is mediated by the Yukawa interaction $h\tilde{\chi}_1^0\tilde{\chi}_1^0$, which is generated due to the mixing between $\tilde{S}$ and $\tilde{H}_{u,d}^0$ and has a coupling given by

$$y_{h\tilde{\chi}_1^0\tilde{\chi}_1^0} = -\sqrt{2}\lambda\left(N_1^{\tilde{H}_d^0}\sin\beta + N_1^{\tilde{H}_u^0}\cos\beta\right) \approx \frac{\sqrt{2}\lambda^2 v\sin 2\beta}{\mu_{\rm eff}}\,, \tag{3.11}$$

where the approximation is valid for small $\lambda v/\mu_{\rm eff}$. The above coupling becomes negligible at large $\tan\beta$. If dominates, such non-standard invisible decay would make the Higgs discovery at hadron colliders much more difficult.

JHEP04(2012)022

Recent LHC data have excluded the Higgs boson with SM properties in the mass range between 141 GeV and 476 GeV at the 95% confidence level [49]. For h with mass lighter than 141 GeV, the main processes for its decay are $h \to b\bar{b}$ and $h \to WW^*$, ZZ^* [50–52]. The Higgs boson h in the PQ-NMSSM, which would have a small singlet component for $\mu_{\rm eff}^2/m_S^2 \ll 1$, can decay through a non-standard mode $h \to \tilde{\chi}_1^0\tilde{\chi}_1^0$ [33]. If it is kinematically accessible, the process $h \to \tilde{\chi}_1^0\tilde{\chi}_1^0$ takes place with the relative decay strength

$$\frac{\Gamma_{h\to\tilde{\chi}_1^0\tilde{\chi}_1^0}}{\Gamma_{h\to b\bar{b}}} \simeq \frac{1}{3}\left(\frac{y_{h\tilde{\chi}_1^0\tilde{\chi}_1^0}}{m_b/v}\right)^2 \simeq 128\left(\frac{\lambda}{0.8}\right)^4\left(\frac{\sin 2\beta}{0.6}\right)^2\left(\frac{200\,\text{GeV}}{\mu_{\rm eff}}\right)^2, \tag{3.12}$$

$$\frac{\Gamma_{h\to\tilde{\chi}_1^0\tilde{\chi}_1^0}}{\Gamma_{h\to WW^*}} \simeq \frac{32\pi^2}{3R(x)}\left(\frac{y_{h\tilde{\chi}_1^0\tilde{\chi}_1^0}}{g^2}\right)^2 \simeq 440\left(\frac{0.3}{R(x)}\right)\left(\frac{\lambda}{0.8}\right)^4\left(\frac{\sin 2\beta}{0.6}\right)^2\left(\frac{200\,\text{GeV}}{\mu_{\rm eff}}\right)^2, \tag{3.13}$$

where we have ignored the masses of the final states, and $R(x)$ is defined by

$$\begin{aligned} R(x) = {} & \frac{3(1-8x+20x^2)}{(4x-1)^{1/2}}\arccos\left(\frac{3x-1}{2x^{3/2}}\right) \\ & - \frac{1-x}{2x}(2-13x+47x^2) - \frac{3}{2}(1-6x+4x^2)\ln x\,, \end{aligned} \tag{3.14}$$

with $x = M_W^2/m_h^2$. The decay rate for the process $h \to ZZ^*$ is similar to $\Gamma_{h\to WW^*}$. When h has a sizable singlet component, the Higgs decay width for each process is modified, but the ratio between decay widths remains the same up to small correction arising due to that $y_{h\tilde{\chi}_1^0\tilde{\chi}_1^0}$ receives contribution not only from $H^0\tilde{H}_{u,d}^0\tilde{S}$ but also from $S\tilde{H}_u^0\tilde{H}_d^0$. The Higgs invisible decay to neutralinos would not dominate the SM decay processes either if λ is strong enough to make $\tilde{\chi}_1^0$ heavier than $m_h/2$:

$$\lambda \gtrsim 0.85\left(\frac{m_h}{130\,\text{GeV}}\right)^{1/2}\left(\frac{\mu_{\rm eff}}{200\,\text{GeV}}\right)^{1/2}\left(\frac{0.6}{\sin 2\beta}\right)^{1/2}, \tag{3.15}$$

or if λ is small enough to suppress the Yukawa coupling of $\tilde{\chi}_1^0$ to the Higgs boson: $\text{Br}(h \to \tilde{\chi}_1^0\tilde{\chi}_1^0)$ is less than 0.5 for

$$\lambda \lesssim 0.27\left(\frac{\mu_{\rm eff}}{200\,\text{GeV}}\right)^{1/2}\left(\frac{0.6}{\sin 2\beta}\right)^{1/2}. \tag{3.16}$$

Here we have naively estimated the value of λ required for $m_{\tilde{\chi}_1^0} > m_h/2$ by taking the leading term in (2.14), which is expanded in powers of $\lambda^2 v^2/\mu_{\rm eff}^2$. It is interesting to see that, in a low $\tan\beta$ region, the Higgs boson decays mainly through the invisible channel $h \to \tilde{\chi}_1^0\tilde{\chi}_1^0$ for $\lambda \gtrsim 0.4$ and $\mu_{\rm eff} \lesssim 400\,\text{GeV}$. A large $\mu_{\rm eff}$ can weaken this decay mode, but would lead to large mixing between H^0 and S. On the other hand, for $\tan\beta \gtrsim 10$, the constraint from the invisible Z-boson decay (2.20) requires $\lambda \lesssim 0.36 \times (\mu_{\rm eff}/200\,\text{GeV})$. Thus, in this case, $\text{Br}(h \to \tilde{\chi}_1^0\tilde{\chi}_1^0)$ cannot be larger than 0.5 if $\mu_{\rm eff}$ is smaller than about 360 GeV.

Figure 2 shows the branching ratio for the invisible Higgs decay $h \to \tilde{\chi}_1^0\tilde{\chi}_1^0$ in the $(\tan\beta, \lambda)$ plane. In the figure, the yellow region is excluded by the experimental bound $\Gamma_{Z\to\tilde{\chi}_1^0\tilde{\chi}_1^0} \lesssim 2\,\text{MeV}$, and the black contour is the value of m_h obtained for $M_{\rm SUSY} = 1.5\,\text{TeV}$

JHEP04(2012)022

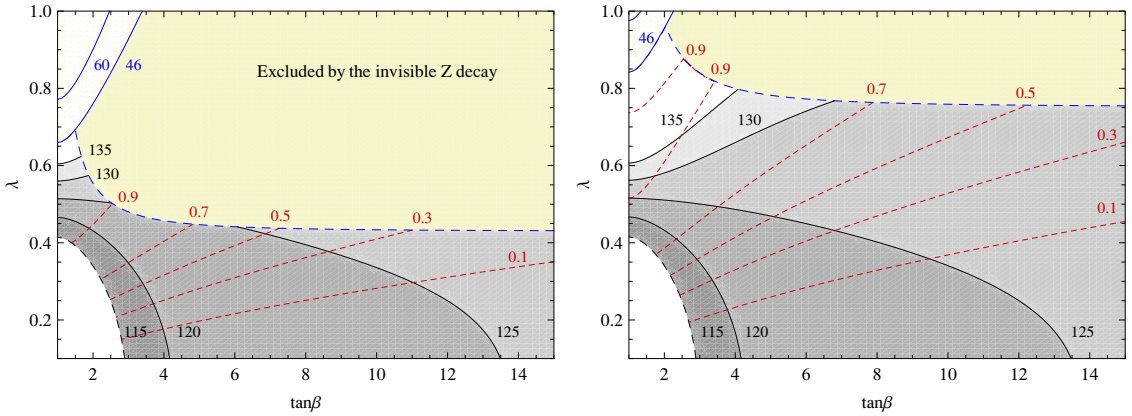

Figure 2. The branching ratio of non-standard mode $h \to \tilde{\chi}_1^0\tilde{\chi}_1^0$ for $\mu_{\rm eff} = 240\,{\rm GeV}$ (left) and $\mu_{\rm eff} = 420\,{\rm GeV}$ (right). The dashed red line is the contour for ${\rm Br}(h \to \tilde{\chi}_1^0\tilde{\chi}_1^0)$. We also show a contour plot for $m_{\tilde{\chi}_1^0}$ larger than $M_Z/2$, which is given in blue. The yellow region is excluded by the experimental bound on the invisible Z decay width. Meanwhile, the black contour shows the value of m_h obtained for $\delta m_h|_{\rm mix} = 0$ in the case with $M_{\rm SUSY} = 1.5\,{\rm TeV}$ and $X_t = 6$. The Higgs boson has a mass larger than 115 GeV above the dashed black line. In the figure, masses are given in the GeV unit.

and $X_t = 6$ with $\delta m_h|_{\rm mix} = 0$. Here we have taken $\mu_{\rm eff} = 240\,{\rm GeV}$ for the left plot, and $\mu_{\rm eff} = 420\,{\rm GeV}$ for the right plot. Since there is an extra contribution to m_h from λ as (3.8), the Higgs mass can be raised above 115 GeV at low $\tan\beta$. Notice also that the contribution $\delta m_h|_{\rm rad}$ raises m_h by a few GeV even at $\tan\beta \gtrsim 10$ compared to the MSSM value that corresponds to the $\lambda = 0$ case. The process $h \to \tilde{\chi}_1^0\tilde{\chi}_1^0$ can be the dominant mode of the Higgs decay at $\tan\beta \lesssim 10$, but is suppressed at large $\tan\beta$.

On the other hand, for small $\mu_{\rm eff}$ less than λv, the lightest neutralino is a sizable mixture of $\tilde{S}$ and $\tilde{H}_{u,d}^0$ at low $\tan\beta$. In this case, it can acquire a mass larger than $M_Z/2$ so that the invisible decay $Z \to \tilde{\chi}_1^0\tilde{\chi}_1^0$ is kinematically forbidden. For some parameter region, it is possible for $\tilde{\chi}_1^0$ to get a mass even larger than $m_h/2$. Otherwise, h would decay dominantly through the invisible process $h \to \tilde{\chi}_1^0\tilde{\chi}_1^0$ at low $\tan\beta$ because $\tilde{\chi}_1^0$ has a sizable Higgsino component. One should also note that the contribution from λ can raise m_h well above 115 GeV for $M_{\rm SUSY} \lesssim 1\,{\rm TeV}$ at $\tan\beta \lesssim 3$. In figure 3, we show the region of λ and $\tan\beta$ where $\tilde{\chi}_1^0$ has a mass larger than $M_Z/2$. The Higgs boson mass is also shown for the case with $M_{\rm SUSY} = 1\,{\rm TeV}$.

4 UV completion

When one considers GUT models to UV complete the PQ-NMSSM, an important issue is how the GUT partners of the MSSM Higgs doublets, which also carry a PQ charge, acquire heavy masses. We point out that the PQ-NMSSM can emerge as a low energy effective theory of a missing-partner model for supersymmetric SU(5) GUT [14].[6] The missing-

[6] A 5 dimensional SU(5) unified theory can also yield the PQ-NMSSM when compactified on $S^1/(Z_2 \times Z_2')$ orbifold [53, 54]. For instance, one can introduce a pair of Higgs hypermultiplet $\mathcal{H} + \bar{\mathcal{H}}$ which form $5 + \bar{5}$

JHEP04(2012)022

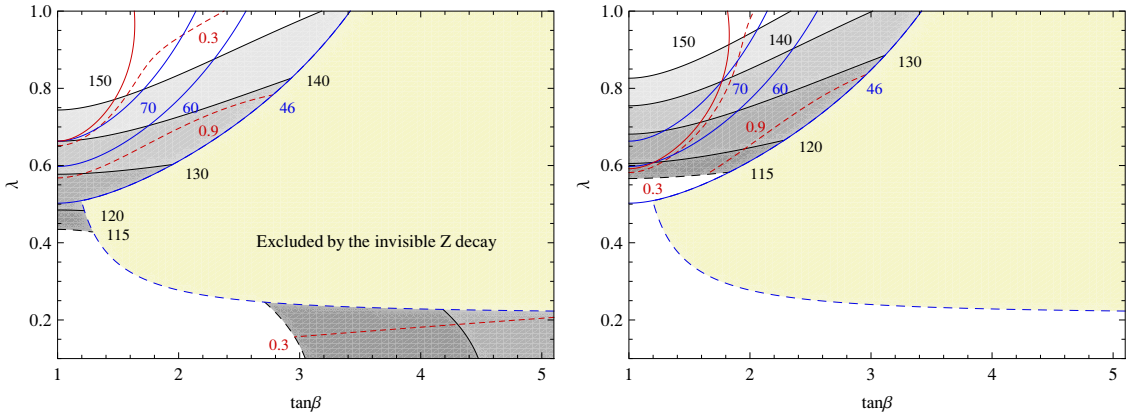

Figure 3. The parameter region where $Z \to \tilde{\chi}_1^0 \tilde{\chi}_1^0$ is kinematically forbidden. The blue contour shows the value of $m_{\tilde{\chi}_1^0}$ for $\mu_{\rm eff} = 120\,{\rm GeV}$. We also show the value of m_h by a black contour for the case with $M_{\rm SUSY} = 1\,{\rm TeV}$, $X_t = 6$ (left) and $X_t = 0$ (right). The masses are given in the GeV unit. The dashed red line is a contour for ${\rm Br}(h \to \tilde{\chi}_1^0 \tilde{\chi}_1^0)$. Above the solid red line, the lightest neutralino obtains a mass larger than $m_h/2$.

partner model has been considered to explain a large mass splitting of the SU(2) doublet and color triplet Higgses. The idea is to introduce higher dimensional representations that contain Higgs triplets but no doublets. Then, if a mass term $H_5 \bar{H}_{\bar{5}}$ for $\mathbf{5} + \bar{\mathbf{5}}$ Higgs multiplets is absent in the superpotential, the doublet-triplet splitting can be achieved without fine-tuning from the interactions of H_5 and $\bar{H}_{\bar{5}}$ with the higher dimensional Higgs multiplets. This is possible because the superpotential is not renormalized in perturbation theory.

The Higgs sector of the original model consists of the chiral multiplets, $\Sigma(\mathbf{75})$, $\theta(\mathbf{50}) + \bar{\theta}(\overline{\mathbf{50}})$ and $H(\mathbf{5}) + \bar{H}(\bar{\mathbf{5}})$. To incorporate the PQ symmetry without spoiling the missing-partner mechanism, we modify the model by introducing three pairs of $\mathbf{50} + \overline{\mathbf{50}}$ and $\mathbf{5} + \bar{\mathbf{5}}$ multiplets, and also three SU(5) singlets:

$$\Sigma(\mathbf{75})\,, \qquad \theta_i(\mathbf{50}) + \bar{\theta}_i(\overline{\mathbf{50}})\,, \qquad H_i(\mathbf{5}) + \bar{H}_i(\bar{\mathbf{5}})\,, \qquad X_i(\mathbf{1})\,, \tag{4.1}$$

where $i = (1, 2, 3)$, and $\mathrm{U}(1)_{\rm PQ}$ charges are assigned as

$$\begin{aligned}
&\Sigma(0)\,, \quad X_1(q)\,, \quad X_2(-3q)\,, \quad X_3(2q)\,, \\
&\theta_1(-p) + \bar{\theta}_1(p)\,, \qquad \theta_2(-3q-p) + \bar{\theta}_2(3q+p)\,, \qquad \theta_3(-q-p) + \bar{\theta}_3(q+p)\,, \\
&H_1(p) + \bar{H}_1(-q-p)\,, \qquad H_2(3q+p) + \bar{H}_2(-p)\,, \qquad H_3(q+p) + \bar{H}_3(-3q-p)\,.
\end{aligned} \tag{4.2}$$

This model seems similar to the minimal model with $\mathrm{U}(1)_{\rm PQ}$ considered in [15], but it turns out that more than two pairs of chiral multiplets are needed to obtain the PQ-NMSSM as

representation of SU(5) and carry a PQ charge -1. Then, doublet-triplet splitting is achieved taking the orbifold projection such that $\mathcal{H}$ ($\bar{\mathcal{H}}$) has a SU(2) doublet Higgs chiral multiplet transforming as $(+,+)$ under $Z_2 \times Z_2'$ and a triplet Higgs with $(+,-)$. This also leads to the terms (2.1) for the PQ-NMSSM below the compactification scale.

JHEP04(2012)022

an effective theory below $M_{\rm GUT}$. The missing-partner mechanism is implemented by the following PQ-invariant superpotential terms

$$W = \frac{1}{2}M\mathrm{Tr}(\Sigma^2) + \frac{1}{3}a\mathrm{Tr}(\Sigma^3) + b_i\theta_i\Sigma H_i + c_i\bar{\theta}_i\Sigma\bar{H}_{i+1} + \tilde{M}_i\bar{\theta}_i\theta_i\,, \tag{4.3}$$

with the identification $\bar{H}_4 = \bar{H}_1$. As in the original model, the vacuum expectation value of Σ breaks SU(5) to the SM gauge groups, and gives rise to the triplet mass terms. This becomes clear after integrating out the heavy triplets in $\theta_i + \bar{\theta}_i$, which leads to

$$W_{\rm eff} = M_i^c H_i^c \bar{H}_{i+1}^c\,, \tag{4.4}$$

where $M_i^c \sim M_{\rm GUT}^2/\tilde{M}_i$, and H_i^c denotes the color-triplet from H_i. Because the **50** representation does not contain Higgs doublets, no doublet mass terms are generated from the superpotential (4.3), and the three pairs of doublet Higgses remain massless. Mass terms for these doublet Higgses arise from

$$W = \lambda_i X_i H_i \bar{H}_i + \frac{\xi}{M_{\rm Pl}} X_1^3 X_2\,, \tag{4.5}$$

where we have chosen a basis of X_3 such that $X_1^2 H_3\bar{H}_3$ is removed in the superpotential. Including soft SUSY breaking terms for the gauge singlet scalars

$$-\mathcal{L}_{\rm soft} = m_{X_i}^2|X_i|^2 + \left(A_\xi \frac{\xi}{M_{\rm Pl}} X_1^3 X_2 + \mathrm{h.c.}\right), \tag{4.6}$$

the second term in the above superpotential fixes $X_{1,2}$ at

$$|X_{1,2}|^2 \approx \frac{M_{\rm Pl}(-m_{X_1}^2)^{1/2}}{\xi} \sim \frac{M_{\rm Pl}M_{\rm SUSY}}{\xi}\,, \tag{4.7}$$

thereby leading to that $\mathrm{U}(1)_{\rm PQ}$ is spontaneously broken around 10^{11} GeV for $\xi \sim 1$, and there appears the axion which is a mixture of $\arg(X_{1,2})$. Here we have assumed $m_{X_1}^2 < 0$. Hence, the doublet Higgses in $H_{1,2} + \bar{H}_{1,2}$ obtain large masses from the vacuum expectation value of $X_{1,2}$, respectively. On the other hand, the doublet Higgses in $H_3 + \bar{H}_3$ remain massless until X_3 acquires a nonzero vacuum expectation value.

Notice that the PQ charge assignment (4.2) allows direct mass terms $H_i\bar{H}_{i+1}$ and the Yukawa term $X_1X_2X_3$ in the renormalizable superpotential. These terms should be absent in order for the missing-partner mechanism to work and for only one pair of Higgs doublets to remain light. Once we do not put these superpotential terms, radiative corrections will not change the situation owing to supersymmetry.[7] It is also important to note that the model possesses two global U(1) symmetries associated with the independent charges p and q. To eliminate one of them, as was considered in [15], we introduce three right-handed neutrino multiplets $N(\mathbf{1})$ that implement the conventional see-saw mechanism through the superpotential terms $NLH_u + X_iNN$ with $i = 1$ or 2. The PQ charges are then fixed

[7] One can assign a different PQ charge to X_2 and the Higgs multiplets to forbid a superpotential term $X_1X_2X_3$. Then, other mechanism is needed to fix the PQ breaking scale because the term $X_1^3X_2$ in the scalar potential (4.6) is not allowed.

JHEP04(2012)022

as $5p = -8q$ when the Majorana masses for N arise from $X_1 NN$, and $5p = -12q$ if one instead chooses $X_2 NN$.

It now becomes apparent that the missing-partner model with the superpotential terms (4.3) and (4.5) leads to the PQ-NMSSM. The doublet Higgses in $H_3 + \bar{H}_3$ correspond to the ordinary MSSM Higgses, while $X_{1,2}$ and X_3 play the role of X and S, respectively. In the model, the higher dimensional operators

$$\mathcal{L} = \int d^4\theta \left(\kappa_1 \frac{X_1^{*2} X_3}{M_{\rm Pl}} + \kappa_2 \frac{X_1 X_2 X_3}{M_{\rm Pl}} \right) + \text{h.c.} \tag{4.8}$$

can generate an effective tadpole term for X_3 as

$$W_{\rm eff} = \tilde{m}_0^2 X_3 \,, \tag{4.9}$$

where $\tilde{m}_0^2 \sim M_{\rm SUSY}^2$ for $\kappa_{1,2} \sim 1$ and $\xi \sim 1$. Then, X_3 is naturally expected to get a vacuum expectation value around the weak scale for $M_{\rm SUSY} \sim 1\,\text{TeV}$. However, if PQ-breaking mass terms $\theta_i \bar{\theta}_j$ with $i \neq j$ are present, the loops of heavy triplets would generate large tadpoles for X_3. This implies that $\mathrm{U}(1)_{\rm PQ}$ is crucial to avoid the tadpole problem. The PQ symmetry plays an important role also in suppressing dangerous higher dimensional operators leading to too rapid proton decays. The triplet Higgses mediate dimension 5 operators violating the baryon number [55, 56], which carry a nonzero PQ charge and therefore are further suppressed by a small factor $X_1 X_2/(M_1^c M_2^c) \sim M_{\rm SUSY} M_{\rm Pl}/(M_1^c M_2^c)$ compared to those in the minimal SU(5) GUT model.

Let us finally discuss the difference from the model of [15]. That model contains two pairs of Higgs doublets $H_f + \bar{H}_f$ and $H'_f + \bar{H}'_f$ which are vector-like also under $\mathrm{U}(1)_{\rm PQ}$. One pair of them becomes heavy through $P H_f \bar{H}'_f$ for P being a $\mathrm{U}(1)_{\rm PQ}$ breaking gauge singlet field, and the other remains light. If one introduces an additional singlet P' having a term $P' H'_f \bar{H}_f$ in the superpotential, P' necessarily carries a PQ charge such that PP' is invariant under $\mathrm{U}(1)_{\rm PQ}$ transformations. Thus, even if one omits PP' in the superpotential, a Kähler potential term PP' would induce too large tadpole term for P'. This makes it difficult for P' to play the role of S in the PQ-NMSSM.

5 Conclusions

Extended to incorporate the PQ mechanism solving the strong CP problem, the NMSSM becomes compatible with the grand unification since the PQ symmetry forbids large tadpoles for the SM singlet S to be generated from loops of heavy fields coupling to S. Another important property of the PQ-NMSSM is that all the mass parameters are determined by the SUSY breaking scale $M_{\rm SUSY}$ and $F_a^2/M_{\rm Pl}$ with F_a being the axion decay constant. Thus, the electroweak symmetry breaking is naturally achieved at the correct scale. Furthermore, the model can avoid the domain wall problem in the presence of the PQ messengers.

An important consequence of the PQ symmetry is that the lightest neutralino is singlino-like with a small Higgsino admixture, and is relatively light compared to other sparticles. The Higgsino component is determined by the coupling of S to the Higgs doublets, which is constrained by the LEP bound on the invisible Z-boson decay width. This

JHEP04(2012)022

constraint becomes severe at large $\tan\beta$. Meanwhile, the SM-like Higgs boson decays mainly through the conventional decay modes at large $\tan\beta$ and in a portion of parameter space for small values of $\tan\beta$. The decay of the Higgs boson into a pair of the lightest neutralino can be the main mode at low $\tan\beta$, for which case the Higgs search at colliders will be modified. Also important is that the SM-like Higgs mass receives an additional positive contribution from the loops involving the singlino Yukawa coupling. This PQ-NMSSM specific contribution can lead to a significant increase of the Higgs boson mass by a few GeV even at large $\tan\beta$ compared to the MSSM.

We found that the PQ-NMSSM is realized as a low energy effective theory of a missing-partner model for supersymmetric SU(5) GUT with the PQ symmetry, which solves the doublet-triplet splitting problem and the proton decay problem. It is interesting to note that such a UV completion achieves the relation $F_a \sim \sqrt{M_{\rm SUSY} M_{\rm Pl}}$. Hence, all the mass parameters of the resulting PQ-NMSSM have values of the order of $M_{\rm SUSY}$.

Note added. After submitting the manuscript, the ATLAS and CMS collaborations at the LHC reported their updated results in the Higgs search [57, 58], which may indicate a SM-like Higgs boson with mass around 125 GeV. To explain a 125 GeV Higgs mass within the MSSM, we need large stop mixing or heavy stops with mass larger than about 10 TeV. The PQ-NMSSM improves the situation because the Higgs mass receives an additional positive contribution, which can be of a few GeV even at large $\tan\beta$.

A Mass matrix

In this appendix, we present the tree-level mass matrices for the neutral scalar fields. After rotating the upper left 2×2 submatrix of the mass matrix for the CP even scalars, one obtains

$$\begin{aligned}
(M_H^2)_{11} &= M_Z^2 \cos^2 2\beta + \lambda^2 v^2 \sin^2 2\beta \,, \\
(M_H^2)_{22} &= \frac{2 b_{\rm eff}}{\sin 2\beta} + (M_Z^2 - \lambda^2 v^2) \sin^2 2\beta \,, \\
(M_H^2)_{33} &= m_S^2 + \lambda^2 v^2, \\
(M_H^2)_{12,21} &= \frac{1}{2}(M_Z^2 - \lambda^2 v^2) \sin 4\beta \,, \\
(M_H^2)_{13,31} &= \lambda v (2\mu_{\rm eff} - A_\lambda \sin 2\beta) \,, \\
(M_H^2)_{23,32} &= \lambda v A_\lambda \cos 2\beta \,.
\end{aligned} \tag{A.1}$$

JHEP04(2012)022

The mass matrix for the pseudoscalar fields is given by

$$M_A^2 = \begin{pmatrix} b_{\rm eff}\cot\beta & b_{\rm eff} & \lambda v A_\lambda \cos\beta \\ b_{\rm eff} & b_{\rm eff}\tan\beta & \lambda v A_\lambda \sin\beta \\ \lambda v A_\lambda \cos\beta & \lambda v A_\lambda \sin\beta & m_S^2 + \lambda^2 v^2 \end{pmatrix}. \tag{A.2}$$

It is easy to see that there are one massless mode, which is absorbed into gauge boson, and two massive CP odd scalars:

$$M_{A_{1,2}}^2 = \frac{b_{\rm eff}}{\sin 2\beta} + \frac{1}{2}(m_S^2 + \lambda^2 v^2) \pm \sqrt{\left(\frac{b_{\rm eff}}{\sin 2\beta} - \frac{1}{2}(m_S^2 + \lambda^2 v^2)\right)^2 + A_\lambda^2 \lambda^2 v^2}\,. \tag{A.3}$$

Using the stationary condition (2.7), one can find that $M_{A_1} = 0$ if $\kappa = 0$.

B Global structure of the Higgs potential

In the PQ-NMSSM, where the Higgs sector is extended to include the singlet S, the Higgs potential may develop another minimum away from the weak scale. The model parameters are constrained to avoid such a minimum since it would generally appear at a field value similar to or larger than $M_{\rm SUSY}$ and thus be deeper than the electroweak vacuum. For the case with $m_S^2 > 0$ and $\lambda \lesssim 1$, we shall show that the region $\lambda^2(|H_u^0|^2 + |H_d^0|^2) \sim M_{\rm SUSY}^2$ somewhat near the D-flat direction is potentially dangerous for much of the parameter space. This argues that the condition to avoid a deeper minimum can approximately be examined by looking at the shape of the potential along the D-flat direction.

After integrating out S by the minimization condition, the Higgs potential reads

$$\begin{aligned} V = &\left(\frac{g^2 + g'^2}{2}\cos^2 2\theta + \lambda^2 \sin^2 2\theta\right)\phi^4 - \frac{(A_\lambda \lambda \phi^2 \sin 2\theta + B_\kappa m_0^2)^2}{2\lambda^2\phi^2 + m_S^2} \\ &+ 2(m_{H_u}^2 \sin^2\theta + m_{H_d}^2 \cos^2\theta - \lambda m_0^2 \sin 2\theta)\phi^2 + \text{constant}\,, \end{aligned} \tag{B.1}$$

where $|H_u^0| = \sqrt{2}\phi\sin\theta$ and $|H_d^0| = \sqrt{2}\phi\cos\theta$ with $0 \le \theta < \pi/2$ and $0 \le \phi$. At very large values of ϕ, the first term becomes dominant and lifts the potential along the ϕ-direction. It is also straightforward to see that $\partial_\phi V = 0$ when $\phi = 0$ or when

$$\begin{aligned} &\left(\sin^2 2\theta + \frac{g^2 + g'^2}{2\lambda^2}\cos^2 2\theta\right)(2\lambda^2\phi^2 + m_S^2)^3 - k m_S^2 (2\lambda^2\phi^2 + m_S^2)^2 \\ &\qquad + 2\left(\frac{A_\lambda m_S^2}{2}\sin 2\theta - \lambda B_\kappa m_0^2\right)^2 = 0\,, \end{aligned} \tag{B.2}$$

where k is a function of θ,

$$k = \left(1 + \frac{A_\lambda^2}{2m_S^2}\right)\sin^2 2\theta + \frac{g^2 + g'^2}{2\lambda^2}\cos^2 2\theta - 2\frac{m_{H_u}^2 \sin^2\theta + m_{H_d}^2 \cos^2\theta - \lambda m_0^2 \sin 2\theta}{m_S^2}\,. \tag{B.3}$$

The above relation shows that the potential can have at most one local minimum at $\phi \neq 0$ along the ϕ-direction for a given θ, which would appear at $2\lambda^2\phi^2 + m_S^2 \sim M_{\rm SUSY}^2$. On the other hand, along the angular direction, the slope of the potential vanishes when

$$\sin 2\theta = -\left(r\frac{\phi^2}{\Lambda_1^2}\sin 2\theta + \frac{\Lambda_2^2}{\Lambda_1^2}\right)\cos 2\theta\,, \tag{B.4}$$

JHEP04(2012)022

for which

$$\partial_\theta^2 V = 4\left(-\cos 2\theta + \frac{\Lambda_2^2}{\Lambda_1^2}\sin 2\theta\right)\Lambda_1^2\phi^2\tan^2 2\theta\,. \tag{B.5}$$

Here r is defined by

$$r = g^2 + g'^2 - 2\left(1 - \frac{A_\lambda^2}{2\lambda^2\phi^2 + m_S^2}\right)\lambda^2, \tag{B.6}$$

and $\Lambda_{1,2}^2$ are given by

$$\begin{aligned}\Lambda_1^2 &= m_{H_d}^2 - m_{H_u}^2\,,\\ \Lambda_2^2 &= 2\left(1 + \frac{A_\lambda B_\kappa}{2\lambda^2\phi^2 + m_S^2}\right)\lambda m_0^2\,,\end{aligned} \tag{B.7}$$

both of which are generally of $\mathcal{O}(M_{\rm SUSY}^2)$, and positive. For $r > 0$, one can find (i) $\partial_\theta V = 0$ can have a solution at $\tan\theta > 1$ with a positive curvature $\partial_\theta^2 V > 0$, implying that there is only one minimum along the angular direction for a given ϕ, and (ii) for large values of ϕ, $\phi^2 \gg \Lambda_1^2 \sim M_{\rm SUSY}^2$, a minimum along the angular direction is located near $\tan\theta = 1$, i.e. near the D-flat direction.

Let us examine further the case with $r > 0$ and $m_S^2 \sim M_{\rm SUSY}^2$. Note that r is positive at $2\lambda^2\phi^2 + m_S^2 \sim M_{\rm SUSY}^2$ if $\lambda \lesssim 0.5$ for small A_λ, and if $\lambda \lesssim 1$ for $A_\lambda \sim M_{\rm SUSY}$ and $B_\kappa \sim M_{\rm SUSY}$. At the electroweak vacuum, which lies at $\phi^2 \sim M_W^2 \ll M_{\rm SUSY}^2$ and $\theta = \beta$, the condition (B.4) gives

$$\frac{\Lambda_2^2}{\Lambda_1^2} \simeq -\tan 2\beta\,. \tag{B.8}$$

The extremum condition (B.4) can then be written

$$\left(1 - \frac{r\phi^2}{\Lambda_1^2}\frac{\tan^2\theta - 1}{\tan^2\theta + 1}\right)\tan 2\theta \approx \tan 2\beta\,, \tag{B.9}$$

for $\phi^2 \lesssim M_{\rm SUSY}^2$. This tells that a minimum along the angular direction arises at $1 < \tan\theta < \tan\beta$ for a given ϕ, and approaches the D-flat direction, $\tan\theta = 1$, as ϕ increases. Thus it is useful to first analyze the potential along the D-flat direction though the actual another minimum, if exists, appears somewhat away from the D-flat direction.

On the other hand, in the case with $r < 0$, the potential is minimized along the angular direction at $\tan\theta > \tan\beta$ or at $\tan\theta < 1$ for $\phi^2 \gtrsim M_{\rm SUSY}^2$. In the former case, making the potential develop no other minimum in the region near the D-flat direction is not enough to guarantee the absence of a deeper minimum.

JHEP04(2012)022

C RG running equations

For the low energy effective theory (3.1) below $M_{\rm SUSY}$, the RG running equations for the Yukawa couplings read

$$\begin{aligned}
8\pi^2\mu\frac{dy_t^2}{d\mu} &= \left(\frac{9}{2}y_t^2 + y_u'^2 + y_d'^2 - \frac{17}{20}g_1^2 - \frac{9}{4}g_2^2 - 8g_3^2\right)y_t^2\,,\\
8\pi^2\mu\frac{dy_u'^2}{d\mu} &= \left(3y_t^2 + \frac{5}{2}y_u'^2 + 4y_d'^2 - \frac{9}{20}g_1^2 - \frac{9}{4}g_2^2\right)y_u'^2\,,\\
8\pi^2\mu\frac{dy_d'^2}{d\mu} &= \left(3y_t^2 + 4y_u'^2 + \frac{5}{2}y_d'^2 - \frac{9}{20}g_1^2 - \frac{9}{4}g_2^2\right)y_d'^2\,,
\end{aligned} \tag{C.1}$$

at the one-loop, and those for SM gauge couplings are

$$\begin{aligned}
8\pi^2\mu\frac{d}{d\mu}\frac{1}{g_1^2} &= -\frac{103}{30} - \frac{1}{10}\theta(\mu - m_h) - \frac{17}{30}\theta(\mu - m_t) - \frac{2}{5}\theta(\mu - \mu_{\rm eff})\,,\\
8\pi^2\mu\frac{d}{d\mu}\frac{1}{g_2^2} &= \frac{13}{3} - \frac{1}{6}\theta(\mu - m_h) - \theta(\mu - m_t) - \frac{2}{3}\theta(\mu - \mu_{\rm eff})\,,\\
8\pi^2\mu\frac{d}{d\mu}\frac{1}{g_3^2} &= 8 - \theta(\mu - m_t)\,,
\end{aligned} \tag{C.2}$$

with $g_1 = \sqrt{5/3}g'$ and $g_2 = g$. Here $\theta(x) = 1$ for $x > 0$ and $\theta(x) = 0$ for $x < 0$.

Abstract: We study the implications of the LHC Higgs signals on the Higgs mixing in the next-to-minimal supersymmetric standard model (NMSSM). The Higgs couplings can depart from their values in the standard model (SM) due to mixing effects. However the Higgs signal rate in the WW and ZZ channels can remain close to the SM values, as observed at the LHC, even if the SM-like Higgs boson with a mass near 125 GeV has a large singlet component. This allows to get a sizable enhancement in the Higgs to diphoton rate through the charged-higgsino loop contribution, as well as a sizable reduction of the Higgs to $b\bar{b}$ and $\tau\tau$ rates through the mixing effects, with little deviation in the WW and ZZ signal rates from the SM prediction. We find that an enhancement of diphoton signals by a factor of 1.5 or more, and also a reduction of $b\bar{b}$ and $\tau\tau$ signals by a factor of 0.5, can be obtained in the region of parameter space consistent with the constraints on the higgsino mass parameter and the singlet coupling to the Higgs doublets, which determine the Higgs mixing.

1 Introduction

The ATLAS and CMS collaborations have announced the discovery of a Higgs boson near 125 GeV with standard model (SM)-like properties [1, 2]. It is thus of importance to study if models with extended Higgs sector, which is motivated to solve various difficulties of the SM, can accommodate such a SM-like Higgs boson. In this paper we consider the next-to-minimal supersymmetric SM (NMSSM). The NMSSM maintains most of the nice features of the MSSM while allowing richer physics in the Higgs and neutralino sectors since it includes a SM singlet which couples to the Higgs doublets [3, 4].

In the NMSSM, the Higgs boson properties can significantly deviate from the SM ones due to Higgs mixing effects. Meanwhile the observed Higgs signal rate in the WW/ZZ channel, for which experimental uncertainties are small compared to those in other channels, is almost consistent with the SM predictions. This however does not necessarily demand small Higgs mixing, and it turns out that the observed signal rate in this channel can still be explained even if the SM-like Higgs boson has a large singlet component. It is then interesting to examine how the signal rate in other channels are modified when the Higgs boson mixes with the additional neutral scalars in such a way that the WW/ZZ rate remains close to the SM rate.

In particular we pay our attention to the possibility that the observed enhancement in the diphoton rate relative to the SM value, though we need more statistics to confirm

this observation, is accommodated in the presence of Higgs mixing effects.[1,2] Indeed this is achievable through the charged-higgsino loop contribution if the SM-like Higgs boson has a sizable singlet component. In such a case, the mixing effects generally reduce the $b\bar{b}$ and $\tau\tau$ rates below the SM values, because the Higgs couplings to $b\bar{b}$ and $\tau\tau$ are suppressed more strongly than those to the W/Z boson and the top quark. On the other hand, the mixing in the neutral Higgs sector depends on the higgsino mass parameter μ and the singlet coupling λ to the Higgs doublets. This implies that the size of mixing effects is subject to the LEP bound on the chargino mass, and the perturbativity limit on λ, as well as to the requirement on the mass of the SM-like Higgs boson. Thus one should consider these, and also other possible constraints on the model parameters, in order to see how large enhancement can be obtained in the diphoton channel through the charged-higgsino contribution. It turns out that an enhancement of diphoton rate, for instance, by a factor 1.5 or larger, as well as a reduction of $b\bar{b}$ and $\tau\tau$ rates by a factor of 0.5, can be achieved while having little deviation in the WW/ZZ rate from the SM value.

This paper is organized as follows. In section 2, we will briefly review how the Higgs boson couples to the SM particles when it mixes with other neutral scalars, and then examine the Higgs signal rate. We will focus on the question which mixing angles are allowed for the SM-like Higgs boson whose signal rates in the WW/ZZ channel are close to those predicted by the SM. In section 3, we will discuss the possible enhancement of the diphoton rate through the charged-higgsino loop contribution. The constraints on the model parameters will be explored in detail in section 4, where we present some examples to see the mixing effects on the Higgs signal rate in the viable region of parameter space. Section 5 is devoted to the conclusion.

2 Higgs sector of the NMSSM

In the supersymmetric SM, the properties of the SM-like Higgs boson crucially depend on the mixing in the neutral Higgs sector. So an important question is if it is possible to arrange a SM-like Higgs boson whose properties are consistent with the observation, in the presence of mixing effects. We will see that the Higgs signal rate observed at the LHC can have interesting implications on the Higgs mixing in the NMSSM.

2.1 Higgs boson with SM-like properties

We start by discussing how to describe the deviation of Higgs properties from the SM behavior. The interactions of a SM-like Higgs boson h at energy scales around 125 GeV

[1] It has been noticed that Higgs mixing effects can increase the diphoton rate above the SM value in the supersymmetric models [5–9], for which case the WW/ZZ rate is also enhanced by a similar amount, assuming that the MSSM superparticles are heavy.

[2] There have been many works studying how to get a large enhancement in the diphoton signal, see e.g. refs. [10–16] for general discussion. In the supersymmetric SM, charged superparticles can give a sizable contribution to the Higgs coupling to photons if they are light. For instance, in refs. [17–22], light third generation sfermions with large left-right mixing have been considered to achieve this. It is also possible to consider the contribution from light charginos or charged Higgs scalar [23–27]. Alternatively, one may extend the supersymmetric SM to include extra charged-particles with light masses [28–30]. In this case, if colored particles are added, the Higgs production rate at the LHC would be affected significantly.

JHEP02(2013)090

can be examined using the effective action [31],

$$\mathcal{L}_{\rm eff} = C_V \frac{\sqrt{2}m_W^2}{v} h W_\mu^+ W_\mu^- + C_V \frac{m_Z^2}{\sqrt{2}v} h Z_\mu Z_\mu - C_f \frac{m_\psi}{\sqrt{2}v} h\bar{\psi}\psi + C_g \frac{\alpha_s}{12\sqrt{2}\pi v} h G^a_{\mu\nu} G^a_{\mu\nu} + C_\gamma \frac{\alpha}{\sqrt{2}\pi v} h A_{\mu\nu} A_{\mu\nu} + \cdots , \tag{2.1}$$

for ψ denoting the SM fermions, and $v \simeq 174\,\text{GeV}$. Here the custodial symmetry is assumed for the Higgs couplings to W and Z bosons as suggested by the electroweak precision measurements, and the ellipsis denotes Higgs interactions with non-SM particles. In the SM, the Higgs boson has $C_V = C_f = 1$, while its couplings to gluons and photons are induced only radiatively with the dominant contribution coming from the W-boson and top quark loops.

The Higgs signal rate in the decay channel, $h \to ii$, relative to the SM prediction is defined by

$$R_h^{ii} = \frac{\sigma(pp \to h)\,\text{Br}(h \to ii)}{\sigma(pp \to h)|_{\rm SM}\,\text{Br}(h \to ii)|_{\rm SM}}, \tag{2.2}$$

where $\sigma(h)$ and $\text{Br}(h \to ii)$ is the total Higgs production cross section and the branching ratio into the corresponding decay channel, respectively. The production of a SM-like Higgs boson at the LHC is dominated by the gluon-gluon fusion, which receives the main contribution from the top quark loop. Let us assume $C_b = C_\tau$ and $C_t = C_c$, which hold at the tree-level in the MSSM. Then, for $m_h = 125\,\text{GeV}$, using the well-known production and decay properties of the SM Higgs boson having the same mass, one finds the Higgs signal rate in the WW/ZZ channel to be

$$R_h^{VV} \simeq \frac{(0.94C_g^2 + 0.12C_V^2)C_V^2}{0.64C_b^2 + 0.24C_V^2 + 0.12C_t^2}, \tag{2.3}$$

under the assumption that new Higgs decay mode if kinematically allowed has a negligibly small decay width. The Higgs signal rate in other channels read

$$R_h^{b\bar{b}} = R_h^{\tau\tau} = \frac{C_b^2}{C_V^2} R_h^{VV}, \qquad R_h^{\gamma\gamma} \simeq \frac{1.52C_\gamma^2}{C_V^2} R_h^{VV}. \tag{2.4}$$

In the SM, the Higgs boson has $R_h^{ii} = 1$ by definition. Here one should note that the effective couplings C_g and C_γ receive only loop contributions in the MSSM. For the case that colored superparticles have masses well above the weak scale, which we will assume in this paper, the effective Higgs coupling to gluons and photons are written as

$$C_g \simeq 1.03C_t - 0.06C_b, \qquad C_\gamma \simeq 0.23C_t - 1.04C_V + \delta C_\gamma|_{\rm SUSY}, \tag{2.5}$$

for h having $m_h = 125\,\text{GeV}$. The loop correction from charged superparticles, $\delta C_\gamma|_{\rm SUSY}$, becomes important when they are light.

JHEP02(2013)090

The above shows that the signal rates for the decay processes relevant to Higgs searches are determined by the effective Higgs couplings C_V, C_t, C_b and $\delta C_\gamma|_{\rm SUSY}$. We will examine how C_V, C_t and C_b are modified by Higgs mixing effects in the NMSSM, and then move on to discuss how large correction to C_γ is possible from the loops of charged superparticles. In particular, we focus on the possibility to get a large enhancement of the Higgs coupling to photons through the contribution from the charged-higgsino loop, which requires the charged higgsino to have a relatively light mass and also the SM-like Higgs boson to have a sizable singlet component.

2.2 Higgs boson in the NMSSM

The Higgs boson in the supersymmetric SM can have properties which are significantly deviated from the SM properties due to Higgs mixing effects. In particular, NMSSM models have rich Higgs/neutralino physics as the Higgs sector is extended to include a SM singlet field S. The singlet couples to the Higgs doublets through,

$$W = \lambda S H_u H_d + f(S) + (\text{MSSM Yukawa terms}), \tag{2.6}$$

so that a higgsino mass parameter is dynamically generated after it gets a vacuum expectation value. The effective Higgs μ and $B\mu$ terms read

$$\begin{aligned} \mu &\equiv \lambda\langle S\rangle, \\ B\mu &\equiv A_\lambda \lambda\langle S\rangle + \lambda\langle \partial_S f\rangle, \end{aligned} \tag{2.7}$$

where A_λ is the soft SUSY breaking trilinear parameter, and we take a field basis such that a bare μ term if exists is absorbed into S. The superpotential $f(S)$ is necessary to avoid a phenomenologically unacceptable visible axion, and various models are classified according to its form. In this paper, we do not specify the exact form of $f(S)$, but will assume that there is no CP violation in the Higgs sector. Noting that H_u^0 and H_d^0 mix with the singlet scalar through the scalar potential terms,

$$V_{\rm mix} = \lambda^2|S|^2\left(|H_u|^2 + |H_d|^2\right) + \left(A_\lambda \lambda S H_u H_d + (\partial_S f)^* \lambda H_u H_d + \text{h.c.}\right), \tag{2.8}$$

we introduce a mass parameter,

$$\Lambda \equiv A_\lambda + \langle \partial_S^2 f\rangle, \tag{2.9}$$

for discussion on the Higgs mixing, and will treat μ, $B\mu$ and Λ as independent parameters as $f(S)$ is needed in any model for the Higgs sector not to possess a global symmetry, unless λ is extremely small.

The neutral Higgs sector of the NMSSM has three CP-even Higgs bosons:

$$\begin{aligned} \hat{h} &= \sqrt{2}\left((\text{Re}H_d^0 - v\cos\beta)\cos\beta + (\text{Re}H_u^0 - v\sin\beta)\sin\beta\right), \\ \hat{H} &= \sqrt{2}\left((\text{Re}H_d^0 - v\cos\beta)\sin\beta - (\text{Re}H_u^0 - v\sin\beta)\cos\beta\right), \\ \hat{s} &= \sqrt{2}\left(\text{Re}S - \langle S\rangle\right), \end{aligned} \tag{2.10}$$

JHEP02(2013)090

where $\langle H_u^0 \rangle = v \sin\beta$ and $\langle H_d^0 \rangle = v \cos\beta$. Among them, $\hat{h}$ behaves exactly like the SM Higgs boson if it does not mix with the others. However, since the mass matrix of the hatted fields is given by

$$\hat{M}^2 = \begin{pmatrix} m_{\hat{h}}^2 & \frac{1}{2}(m_Z^2 - \lambda^2 v^2)\sin 4\beta & \lambda v(2\mu - \Lambda \sin 2\beta) \\ \frac{1}{2}(m_Z^2 - \lambda^2 v^2)\sin 4\beta & m_{\hat{H}}^2 & \lambda v \Lambda \cos 2\beta \\ \lambda v(2\mu - \Lambda \sin 2\beta) & \lambda v \Lambda \cos 2\beta & m_{\hat{s}}^2 \end{pmatrix}, \tag{2.11}$$

the SM-like Higgs boson generally appears as a mixture of CP-even Higgs bosons:

$$h = c_{\theta_1} c_{\theta_2} \hat{h} - s_{\theta 1} \hat{H} - c_{\theta_1} s_{\theta_2} \hat{s}, \tag{2.12}$$

which we assume to be the resonance near 125 GeV observed at the LHC. Here $s_\theta = \sin\theta$ and $c_\theta = \cos\theta$, for $-\pi/2 < \theta_i \leq \pi/2$ $(i = 1, 2, 3)$ being the mixing angles in the orthogonal matrix diagonalizing $\hat{M}^2$ (see eq. (4.3)). There are also two other mass eigenstates, s and H with mass m_s and m_H, respectively, where we define H to be the heaviest Higgs boson and fix the mass of h to be $m_h \simeq 125\,\text{GeV}$.

Let us summarize the properties of the SM-like Higgs boson in the presence of mixing effects. The Higgs couplings are determined by

$$\begin{aligned} C_V &= c_{\theta_1} c_{\theta_2}, \\ C_t &= c_{\theta_1} c_{\theta_2} + s_{\theta_1} \cot\beta, \\ C_b &= C_\tau = c_{\theta_1} c_{\theta_2} - s_{\theta_1} \tan\beta, \end{aligned} \tag{2.13}$$

at the tree-level. The branching fraction of h for each decay process deviates from the SM value if the above effective couplings have values different from each other. This is indeed the case due to the second term in the effective coupling to the quarks, which relies on $\tan\beta$ and θ_1. Note that the sign of θ_1 is also important. For instance, if θ_1 has a positive value, it is possible to reduce the Higgs coupling to the bottom quark relative to the SM value, more significantly than those to the W/Z boson and top quark. This does not happen in the MSSM unless there are large radiative corrections to the mixing between two doublet Higgs bosons. Here we only consider $\tan\beta > 1$ as required for the top Yukawa coupling to remain perturbative at high energy scales. However the situation changes in the NMSSM, where one can consider $\lambda v > m_Z$ for which $\hat{M}_{12}^2$ is positive, or sizable mixing between the singlet and doublets. As we will see soon, mixing with $\theta_1 > 0$ has an interesting implication for the modification in the Higgs signal rate.

On the other hand, mixing effects on the Higgs boson mass can be examined using the relation,

$$m_h^2 = m_{\hat{h}}^2 - \frac{(s_{\theta_2} s_{\theta_3} - s_{\theta_1} c_{\theta_2} c_{\theta_3})^2}{c_{\theta_1}^2 c_{\theta_2}^2}(m_H^2 - m_{\hat{h}}^2) - \frac{(s_{\theta_2} c_{\theta_3} + s_{\theta_1} c_{\theta_2} s_{\theta_3})^2}{c_{\theta_1}^2 c_{\theta_2}^2}(m_s^2 - m_{\hat{h}}^2). \tag{2.14}$$

The above relation imposes a constraint on m_H, m_s and the mixing angles because $m_{\hat{h}}$ is restricted to be less than a certain value:

$$m_{\hat{h}}^2 = m_0^2 + (\lambda^2 v^2 - m_Z^2)\sin^2 2\beta, \tag{2.15}$$

JHEP02(2013)090

where m_0 is equal to m_Z at the tree-level, and can be regarded as the SM-like Higgs boson mass in the decoupling limit of the MSSM at large $\tan\beta$. The NMSSM contribution raises $m_{\hat{h}}$ above m_0 for $\lambda v > m_Z$, but the amount decreases as $\tan\beta$ increases. Including radiative corrections, one finds [32, 33]

$$m_0^2 = m_Z^2 + \frac{3m_t^4}{4\pi^2 v^2} \ln\left(\frac{m_{\tilde{t}}^2}{m_t^2}\right) + \frac{3m_t^4}{4\pi^2 v^2}\left(X_t^2 - \frac{1}{12}X_t^4\right) + \cdots , \tag{2.16}$$

where $m_{\tilde{t}}$ is the stop mass, and $X_t = (A_t - \mu\cot\beta)/m_{\tilde{t}}$ denotes the stop mixing parameter. For the stop masses at the TeV scale, m_0 is around 115 GeV. The stop mixing raises m_0 further approximately by the amount, $5\,\text{GeV} \times (X_t^2 - X_t^4/12)$, which is about 5 GeV at $X_t = 1$. The stop mixing contribution is maximized at $X_t = \sqrt{6}$, where m_0 can reach about 130 GeV for stop masses around TeV. In section 4, taking the value of m_0 in the range between 95 and 135 GeV, we will examine in detail the region of parameter space consistent with various constraints on the Higgs mixing.

2.3 Mixing effects on the Higgs signal rate

The observed Higgs signal rate in the WW/ZZ channel, which has a relatively small experimental error compared to other decay processes, is in good agreement with the SM predictions. However this does not necessarily imply small mixing in the neutral Higgs sector. It is thus of importance to examine the signal rate in other channels when the SM-like Higgs boson has $R_h^{VV} \approx 1$ in the presence of Higgs mixing. The signal rate for $h \to b\bar{b}$ and $h \to \gamma\gamma$ are modified according to the relation (2.4).

Plugging the effective Higgs couplings (2.13) into the relation (2.3), we find that Higgs mixing leaves the signal rate R_h^{VV} close to 1 at two different positive values of θ_1 for given $\tan\beta$ and θ_2. The larger solution of $R_h^{VV} \approx 1$ is approximately given by

$$\theta_1|_{\text{large}} \approx \frac{2.1 - 1.9\sin^2\theta_2}{\tan\beta}, \tag{2.17}$$

for moderate and large values of $\tan\beta$. It is also straightforward to see that the smaller solution reads

$$\theta_1|_{\text{small}} \approx \frac{\tan\beta}{1.4\tan^2\beta + 1.7}\sin^2\theta_2, \tag{2.18}$$

for $\tan\beta \gtrsim 2$. Thus C_V and C_t are positive for both solutions, while C_b is found to be positive only for $\theta_1|_{\text{small}}$. This results in that the $b\bar{b}$ signal rate can also remain close to the SM value for $\theta_1|_{\text{large}}$ if $C_V \approx -C_b$, which we find the case in the region around $\sin^2\theta_2 = 0.15$. Note also that the gluon-gluon fusion for the Higgs boson production occurs through the coupling C_g, and thus depends on the relative sign of C_t and C_b since the quarks have masses, $2m_b < m_h < 2m_t$. On the other hand, for the smaller solution $\theta_1|_{\text{small}}$, the SM-like Higgs boson contains non-SM Higgs doublet component whose fraction is much smaller than the singlet fraction. In this case, $R_h^{b\bar{b}}$ is always smaller than R_h^{VV}.

Figure 1 shows the region of parameter space leading to $R_h^{VV} = 1 \pm 0.1$, for $\tan\beta = 2, 5, 8$. One sees that the Higgs signal rate in the WW/ZZ channel can remain consistent

JHEP02(2013)090

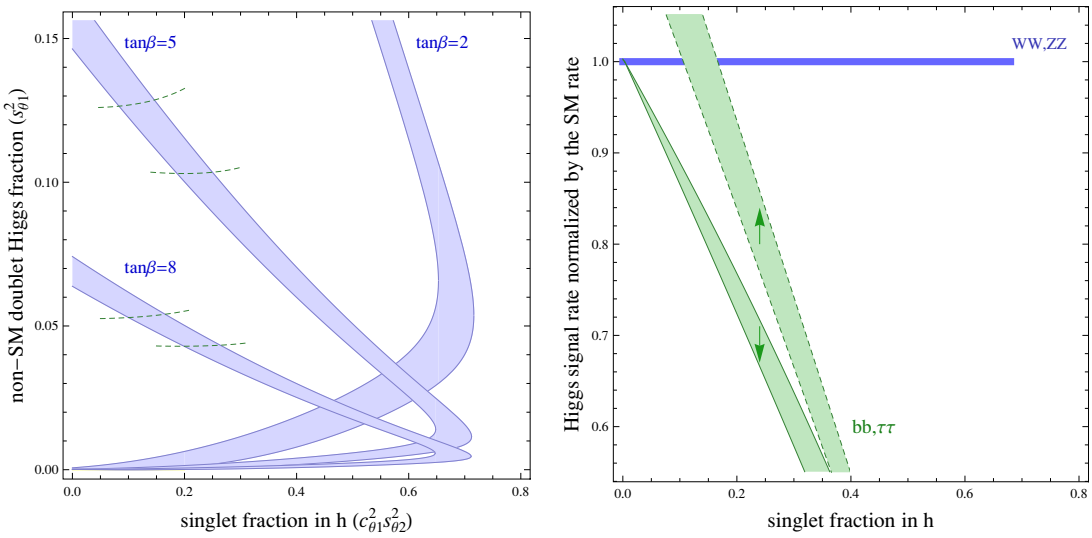

Figure 1. Mixing effects on the signal rate of the SM-like Higgs boson, $h = c_{\theta_1} c_{\theta_2} \hat{h} - s_{\theta_1} \hat{H} - c_{\theta_1} s_{\theta_2} \hat{s}$ with mass $m_h = 125\,\text{GeV}$. The left panel shows the region of parameter space where the signal rate in the WW/ZZ channel is $R_h^{VV} = 1 \pm 0.1$, for $\tan\beta = 2, 5, 8$, respectively. The $b\bar{b}$ channel also has $R_h^{b\bar{b}} = 1 \pm 0.1$ in the region between two dashed green lines, in the blue band. The right panel illustrates how the signal rates in $h \to b\bar{b}$ and $h \to \tau\tau$ are affected by mixing effects when the Higgs boson has $R_h^{VV} = 1$. The green band is $R_h^{b\bar{b}} (= R_h^{\tau\tau})$ obtained for $2 \leq \tan\beta \leq 5$, where the colored arrow indicates its behavior for increasing $\tan\beta$. The lower (upper) band corresponds to the $b\bar{b}$ rate for θ_1 fixed at the smaller (larger) solution of the equation $R_h^{VV}(\theta_1) = 1$.

with the observation even if the SM-like Higgs boson has a large singlet fraction. In the right panel of the figure, we illustrate how the $b\bar{b}$ and $\tau\tau$ rates are modified when the Higgs mixing leads to $R_h^{VV} = 1$. The green band gives $R_h^{b\bar{b}} (= R_h^{\tau\tau})$ for $2 \leq \tan\beta \leq 5$, where the colored arrow shows how the signal rate changes as $\tan\beta$ increases. The lower (upper) green band corresponds to $R_h^{b\bar{b}}$ for θ_1 fixed at the smaller (larger) solution of the equation $R_h^{VV}(\theta_1) = 1$. The $b\bar{b}$ and $\tau\tau$ rates are reduced relative to the SM case for the smaller solution, however this is not necessarily the case for the other solution. On the other hand, the mixing also affects the diphoton rate, which will be examined in section 3 by including the contribution from the charged higgsino.

3 Enhanced diphoton rate by higgsino effects

The Higgs signal in the $h \to \gamma\gamma$ process has been observed at the rate, 1.5 to 1.8 times larger than the value predicted in the SM. Although the statistics is small yet compared to the WW/ZZ channel, this may be a hint for physics beyond the SM. In particular, it is interesting to see if the observed enhancement of the diphoton rate can be explained within the NMSSM, where the deviation in the WW/ZZ channel is small even if the Higgs mixing is sizable. Indeed the Higgs coupling to photons can receive a significant contribution from the charged-higgsino loop when the Higgs boson has a large singlet component.

Let us examine the higgsino effects on the diphoton rate in the presence of Higgs mixing. Since the singlet scalar couples to the higgsinos through the Yukawa term $\lambda S \tilde{H}_u \tilde{H}_d$ in the

JHEP02(2013)090

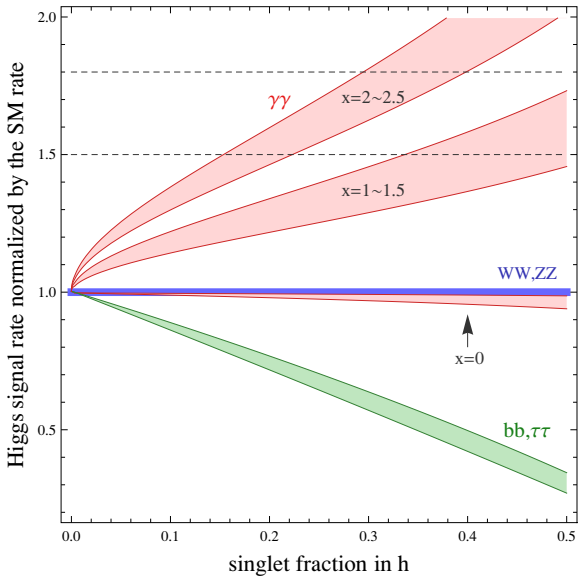

Figure 2. Enhanced diphoton rate via the charged-higgsino loop contribution, in the presence of Higgs mixing with positive θ_1 and θ_2. We fix the value of θ_1 at the smaller solution of $R_h^{VV}(\theta_1) = 1$, for which the diphoton rate is determined by θ_2 and $x \equiv \lambda v/|\mu|$, almost independent of $\tan\beta$. The red band corresponds to $R_h^{\gamma\gamma}$ for $x = 0$, $1 \le x \le 1.5$, and $2 \le x \le 2.5$ from below, respectively. Here we take $2 \le \tan\beta \le 8$. The figure also shows the signal rate in other channels, which are rarely affected by the charged-higgsino loop. The green band gives $R_h^{b\bar{b}}$ obtained for $\tan\beta$ in the same range.

NMSSM, the SM-like Higgs boson has the interaction,

$$\mathcal{L} = \frac{\lambda c_{\theta_1} s_{\theta_2}}{\sqrt{2}} h \tilde{H}_u^+ \tilde{H}_d^- + \cdots . \tag{3.1}$$

Thus the Higgs coupling to photons is radiatively generated by the charged-higgsino loop. The contribution to C_γ is found to be [31],

$$\delta C_\gamma|_{\rm SUSY} \simeq -0.17 A_f(\tau_{\tilde{H}^\pm}) \frac{\lambda v}{m_{\tilde{H}^\pm}} c_{\theta_1} s_{\theta_2}, \tag{3.2}$$

where $\tau_i = m_h^2/4m_i^2$, and the charged higgsino has mass $m_{\tilde{H}^\pm} \simeq |\mu|$ simply assuming that the Wino is heavy so that the mixing in the chargino sector is small. The loop function is given by $A_f(\tau) = 3(\tau + (\tau - 1)\arcsin^2\sqrt{\tau})/2\tau^2$ for $\tau \le 1$, and is approximated as $A_f(\tau) \simeq 1 + 7\tau/30$ for small values of τ. On the other hand, the effective couplings C_V, C_t and C_b are negligibly affected by the charged higgsino.

The SM-like Higgs boson can have $R_h^{VV} \approx 1$ for the Higgs mixing (2.17) or (2.18), for which the diphoton signal rate will be reduced a bit below the SM value if $\delta C_\gamma|_{\rm SUSY} = 0$. However, including the radiative correction from $\tilde{H}^\pm$, the diphoton rate reads

$$R_h^{\gamma\gamma} \simeq \frac{1.52 C_\gamma^2}{C_V^2} R_h^{VV} \simeq \left(1 - 0.28 \frac{s_{\theta_1}}{c_{\theta_1} c_{\theta_2}} \frac{1}{\tan\beta} + 0.21 \frac{s_{\theta_2}}{c_{\theta_2}} \frac{\lambda v}{|\mu|}\right)^2 R_h^{VV}, \tag{3.3}$$

JHEP02(2013)090

for $|\mu| \gtrsim 100\,\mathrm{GeV}$, and thus an enhancement of diphoton signals relative to the SM case is achievable for $R_h^{VV} \approx 1$, when θ_2 is positive. Note that, if $\delta C_\gamma|_{\rm SUSY} = 0$, the Higgs signal rate in each channel is modified by the mixing effects independently of the sign of θ_2. To get a large enhancement, the charged higgsino needs to have a small mass. In addition, we need a large value of θ_2, which determines the singlet fraction of the SM-like Higgs boson. Since Higgs mixing with positive θ_1 allows h to contain a large singlet component while having $R_h^{VV} \approx 1$, the second term in the bracket in (3.3) tells that a small value of θ_1 is favored to have $R_h^{\gamma\gamma}$ larger than R_h^{VV}. For the smaller solution (2.18) of $R_h^{VV}(\theta_1) \approx 1$, the diphoton rate becomes insensitive to $\tan\beta$, and is written

$$R_h^{\gamma\gamma} \approx \left(1 + 0.21 \frac{s_{\theta_2}}{c_{\theta_2}} \frac{\lambda v}{|\mu|}\right)^2 . \tag{3.4}$$

Thus the signal rate in $h \to \gamma\gamma$ can be larger than the SM expectation, but still with little deviation in the WW/ZZ channel. The enhancement crucially depends on the value of $\lambda v/|\mu|$, which is less than about 3.5 for $\lambda < 2$ and μ is larger than 100 GeV. In section 4, we will examine the value of $\lambda v/|\mu|$ consistent with various constraints.

Figure 2 illustrates the effect of the charged higgsino on the diphoton rate, where we have fixed the value of θ_1 to give $R_h^{VV} = 1$ for positive θ_1 and θ_2. Among the two solutions of $R_h^{VV}(\theta_1) = 1$, we choose the smaller one, for which the diphoton rate is almost independent of $\tan\beta$. The $R_h^{\gamma\gamma}$ is shown in the red band for $x = 0$, $1 \le x \le 1.5$ and $2 \le x \le 2.5$, where $x \equiv \lambda v/|\mu|$. In the absence of the charged-higgsino contribution, which is the case with $x = 0$, the diphoton rate is slightly below the SM value. However the higgsino effect can significantly enhance diphoton signals, which demands a large x and sizable singlet fraction in h. For instance, the diphoton rate is about 1.5 times larger than the SM value at $x = 1.2$ if the singlet fraction in h is 0.4. On the other hand, the green band indicates $R_h^{b\bar{b}}$ obtained for $2 \le \tan\beta \le 8$. The $b\bar{b}$ rate is reduced relative to the SM value. Meanwhile, one may consider Higgs mixing such that R_h^{VV} is a bit larger than 1. Then the diphoton rate will be increased by the similar amount, whereas $R_h^{b\bar{b}}$ will decrease further.

4 Constraints on Higgs mixing

In this section, we discuss various constraints on the mass spectrum of Higgs bosons and the mixing angles which arise because of their relations to the model parameters in $\hat{M}^2$. Then we will consider several examples to explore the region of parameter space where the SM-like Higgs boson has $R_h^{VV} \approx 1$ while satisfying the constraints. The WW/ZZ rate remains close to the SM value at the two solutions of $R_h^{VV}(\theta_1) \approx 1$, among which the smaller one is favored to get a large enhancement in the diphoton rate through the charged-higgsino contribution. So we will focus on the smaller solution, and examine the diphoton rate in the explicit examples.

4.1 Relation with the Lagrangian parameters

Let us first discuss the constraints on Higgs mixing related to the model parameter μ and λ, which determine the off-diagonal components of $\hat{M}^2$. Their values are determined once

JHEP02(2013)090

we fix the mass eigenvalues and mixing angles. This implies that μ and λ are written as functions of

$$\xi \equiv (\tan\beta, m_H, m_s, \theta_1, \theta_2, \theta_3). \tag{4.1}$$

Meanwhile the LEP bound on the chargino mass requires μ larger than about 100 GeV [34]. In addition, in order for the model to remain perturbative up to at least 10 TeV, λ should be less than about 2 at the weak scale. For NMSSM models with λ larger than about 0.7 [35], there should appear new physics, such as strong dynamics involving S, at an intermediate scale below the conventional GUT scale $\sim 10^{16}$ GeV. The above bounds on μ and λ translate into the constraints on ξ.

Here we present the relation between ξ and the model parameters appearing in the off-diagonal elements of $\hat{M}^2$:

$$\begin{aligned}
\lambda^2 v^2 &= m_Z^2 + \frac{1}{\sin 4\beta}\Big((m_H^2 - m_s^2)s_{\theta_2}s_{2\theta_3} + 2(m_h^2 - m_H^2 c_{\theta_3}^2 - m_s^2 s_{\theta_3}^2)s_{\theta_1}c_{\theta_2}\Big)c_{\theta_1}, \\
\lambda v\mu &= -\frac{1}{4}m_h^2 c_{\theta_1}^2 s_{2\theta_2} - \frac{1}{4}(m_H^2 - m_s^2)s_{\theta_1}c_{2\theta_2}s_{2\theta_3} \\
&\quad + \frac{1}{4}\Big((m_H^2 - m_s^2 s_{\theta_1}^2)s_{\theta_3}^2 - (m_H^2 s_{\theta_1}^2 - m_s^2)c_{\theta_3}^2\Big)s_{2\theta_2} \\
&\quad - \frac{\tan 2\beta}{4}\Big((m_H^2 - m_s^2)c_{\theta_2}s_{2\theta_3} - 2(m_h^2 - m_H^2 c_{\theta_3}^2 - m_s^2 s_{\theta_3}^2)s_{\theta_1}s_{\theta_2}\Big)c_{\theta_1}, \\
\lambda v\Lambda &= -\frac{1}{2\cos 2\beta}\Big((m_H^2 - m_s^2)c_{\theta_2}s_{2\theta_3} - 2(m_h^2 - m_H^2 c_{\theta_3}^2 - m_s^2 s_{\theta_3}^2)s_{\theta_1}s_{\theta_2}\Big)c_{\theta_1},
\end{aligned} \tag{4.2}$$

where we have used that the orthogonal matrix U which diagonalizes $\hat{M}^2$ is parameterized in terms of three mixing angles,

$$U = \begin{pmatrix} c_{\theta_1}c_{\theta_2} & -s_{\theta_1} & -c_{\theta_1}s_{\theta_2} \\ s_{\theta_1}c_{\theta_2}c_{\theta_3} - s_{\theta_2}s_{\theta_3} & c_{\theta_1}c_{\theta_3} & -c_{\theta_2}s_{\theta_3} - s_{\theta_1}s_{\theta_2}c_{\theta_3} \\ s_{\theta_1}c_{\theta_2}s_{\theta_3} + s_{\theta_2}c_{\theta_3} & c_{\theta_1}s_{\theta_3} & c_{\theta_2}c_{\theta_3} - s_{\theta_1}s_{\theta_2}s_{\theta_3} \end{pmatrix}, \tag{4.3}$$

for $c_\theta = \cos\theta$ and $s_\theta = \sin\theta$.

4.2 Higgs boson mass

There are also constraints related to the mass spectrum of the Higgs bosons. The SM-like Higgs boson has a mass which is written as a function of m_0 and ξ, as is given by (2.14). Thus, requiring $m_h \simeq 125$ GeV constrains the parameter space of m_0 and ξ. Here the value of m_0 has an upper bound, crucially depending on the radiative corrections. For instance, m_0 is less than about 120 GeV for the stop with mass around or smaller than 1 TeV and small stop mixing. One can also arrange m_0 around or larger than 130 GeV by considering stop masses above a few TeV or invoking large stop mixing. It is worth noting that, in the NMSSM, m_0 can receive an additional sizable contribution from the higgsino loops. The superpotential $f(S)$ provides mass to the singlino, $m_{\tilde{S}} = \langle \partial_S^2 f \rangle$. If $m_{\tilde{S}}$ is around or below μ, the interactions of the higgsinos ($\tilde{H}_u$ and $\tilde{H}_d$) and the singlino ($\tilde{S}$),

$$-\mathcal{L}_{\rm int} = \lambda H_u \tilde{H}_d \tilde{S} + \lambda H_d \tilde{H}_u \tilde{S} + \mu \tilde{H}_u \tilde{H}_d + \frac{1}{2}m_{\tilde{S}}\tilde{S}\tilde{S} + \text{h.c.}, \tag{4.4}$$

JHEP02(2013)090

will remain relevant at low energy scales. Then the mass of $\hat{h}$ receives additional radiative corrections, analogously to that from the top Yukawa coupling. The correction is estimated naively to be [36]

$$\delta m_0^2 \approx \frac{\lambda^4 v^2}{4\pi^2} \ln\left(\frac{m_s^2}{|\mu|^2}\right), \tag{4.5}$$

for $m_s^2 \gg |\mu|^2$. The above contribution is quite sensitive to λ, but is almost independent of $\tan\beta$. In the analysis, we will consider $95\,\mathrm{GeV} \leq m_0 \leq 135\,\mathrm{GeV}$, while keeping in mind that larger values can be allowed depending on models.

On the other hand, the experimental constraints from the $b \to s\gamma$ process require the charged Higgs scalar to be heavier than about 350 GeV [37] unless there are cancellations with superparticle contributions. The charged Higgs scalar obtains a mass according to $m_{H^\pm}^2 = m_{\hat{H}}^2 + m_W^2 - m_Z^2 \sin^2 2\beta$ at the tree-level, while $m_{\hat{H}}^2$ is given by

$$m_{\hat{H}}^2 = s_{\theta_1}^2 m_h^2 + c_{\theta_1}^2 c_{\theta_3}^2 m_H^2 + c_{\theta_1}^2 s_{\theta_3}^2 m_s^2, \tag{4.6}$$

implying that an addition constraint will be imposed if one requires a large value of $m_{H^\pm}$ to avoid the constraint from $b \to s\gamma$.

For a large value of m_H, the mixing angle θ_3 needs to be small since otherwise mixing between $\hat{h}$ and $\hat{H}$ will decrease the mass of the SM-like Higgs boson significantly. Suppose that θ_3 is similar to or smaller than θ_1 in size. Then the Higgs mass reads

$$m_h^2 \approx m_{\hat{h}}^2 - \frac{1}{\tan^2\beta}\frac{s_{\theta_2}^4}{1-s_{\theta_2}^2}(m_H^2 - m_{\hat{h}}^2) - \frac{s_{\theta_2}^2}{1-s_{\theta_2}^2}(m_s^2 - m_{\hat{h}}^2), \tag{4.7}$$

for $\theta_1 = \theta_1|_{\mathrm{small}}$, where the coefficients of order unity have been neglected in the last two terms. We see that the second term, which is a result of mixing between two doublet Higgs bosons, is much suppressed compared to the third term. Indeed one can find that the second term lowers the mass of h by less than about 10 GeV even for H having mass around or above 350 GeV, if

$$s_{\theta_2}^2 \lesssim 0.15 \times \left(\frac{m_H}{350\mathrm{GeV}}\right)^{-1} \tan\beta. \tag{4.8}$$

for $\tan\beta \gtrsim 2$. On the other hand, the third term arises due to mixing with the singlet, and can have either sign. This contribution will compensate the mass decrease by the second term if s has a mass smaller than $m_{\hat{h}}$. The relation $m_{\hat{h}}^2 = m_0^2 + (\lambda^2 v^2 - m_Z^2)\sin^2 2\beta$ tells that the sign of the third term depends m_0, λ and $\tan\beta$. It is clear that m_s much larger than m_0 will make it difficult to get $m_h \simeq 125\,\mathrm{GeV}$ unless the NMSSM contribution to $m_{\hat{h}}$ is large enough.

Let us discuss further the properties of s, which is singlet-like in most of the parameter space of interest. Since it couples to the SM particles through the doublet Higgs components, it may be possible to detect s at hadron colliders when Higgs mixing is large. The production and decay rate of s depend on its mass and the fraction of the Higgs doublets. However, if the invisible decay into neutralinos is kinematically allowed, the discovery of the

JHEP02(2013)090

singlet-like Higgs boson will become very difficult. This is the case for $m_h < 2m_{\chi_1^0} < m_s$, where the lower bound on $m_{\chi_1^0}$ would be necessary to suppress the invisible decay of the SM-like Higgs boson.[3] On the other hand, if $m_s < m_h$, one should take into account the LEP constraints on the signal rate of s in $e^+e^- \to Zs \to Zb\bar{b}$ [41]. In this case, it may still be possible to have sizable mixing if m_s lies in the range between about 90 and 110 GeV.

Before proceeding to the analysis, we briefly mention about the property of the lightest neutralino, which we assume the lightest superparticle (LSP). For $\lambda v/|\mu|$ around one, the lightest neutralino χ_1^0 is a sizable mixture of the neutral higgsinos and singlino, simply assuming that all the gauginos are heavy. If χ_1^0 is heavier than the W-boson, the annihilation among LSPs takes place with a large cross section, dominantly through the t-channel charged-higgsino exchange with W bosons in the final state. Then thermal relic density of χ_1^0 would be too small to account for the observed dark matter density. To avoid this, one may consider light gauginos so that χ_1^0 has a sizable Bino component. Another way would be to implement non-thermal production of LSPs, or to consider the QCD axion as a dark matter.

On the other hand, for $m_{\tilde{s}} \gg |\mu|$ and $\lambda v/|\mu|$ around one, the mixing decreases the mass of a higgsino-like neutralino, and thus it is possible to have χ_1^0 lighter than m_W but heavier than $m_h/2$. In such a case, the annihilation via the s-channel Z-boson exchange into SM fermions is not so effective due to the suppressed $Z\chi_1^0\chi_1^0$ coupling, and the coannihilation effect [42] is also suppressed because the charged-higgsino still has a mass equal to μ. However, since the $h\chi_1^0\chi_1^0$ coupling can be sizable in the NMSSM, it would be possible to get the correct dark matter density from thermally produced LSPs. A detailed analysis will be given elsewhere.

4.3 Examples

We have discussed the constraints and the favored values of model parameters. Let us now examine the diphoton rate in the region of parameter space where such requirements are satisfied. In the analysis, we impose the constraints,

$$m_h \simeq 125\,\text{GeV}, \quad |\mu| \geq 105\,\text{GeV}, \quad \lambda \leq 2, \tag{4.9}$$

by taking m_0 in the range

$$95\,\text{GeV} \leq m_0 \leq 135\,\text{GeV}. \tag{4.10}$$

For given m_H, m_s and θ_3, three parameters of ξ in (4.1) remain unfixed. Among them, θ_1 is fixed if one requires the signal rate in the WW/ZZ channel to be close to the SM value. Then we can examine the above constraints by scanning over $\tan\beta$ and θ_2, or equivalently in terms of $\tan\beta$ and the singlet fraction in the SM-like Higgs boson. The Higgs signal rate in $h \to \gamma\gamma$ is determined by $x = \lambda v/|\mu|$ and the singlet fraction in h.

[3] In models where $f(S)$ contains only a linear term of S [36, 38–40], the singlino has no Majonara mass term, and the mass and the coupling to h of χ_1^0 are proportional to $\lambda^2 v \sin 2\beta/\mu$. One would thus need small $\tan\beta$ and large λ to kinematically forbid the invisible decay of h into neutralinos.

JHEP02(2013)090

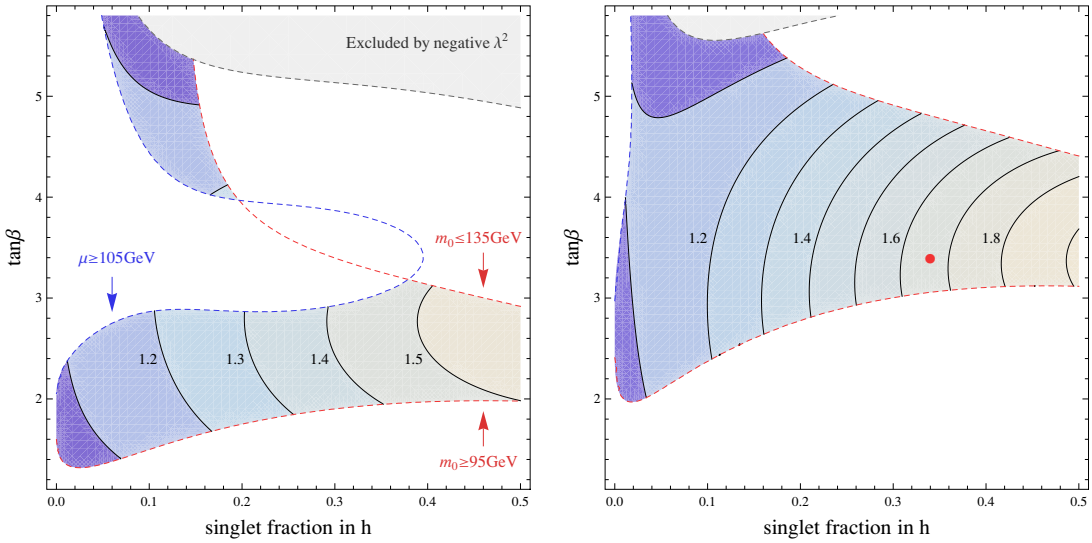

Figure 3. Enhanced diphoton rate in the region of parameter space allowed by $|\mu| \geq 105\,\text{GeV}$ and $\lambda \leq 2$, where we have fixed θ_1 at the smaller solution of $R_h^{VV}(\theta_1) = 1.05$. The left panel is for the case with $(m_H, m_s, \theta_3) = (480\text{GeV}, 160\text{GeV}, 0.1)$, while the right one is for $(m_H, m_s, \theta_3) = (780\text{GeV}, 160\text{GeV}, 0.07)$. In both figures, μ is larger than 105 GeV in the right side of the blue-dashed curve, and $m_h = 125\,\text{GeV}$ is obtained for $95\,\text{GeV} \leq m_0 \leq 135\,\text{GeV}$ in the region between two red-dashed curves. The gray-shaded region is excluded due to negative λ^2. The contours of $R_h^{\gamma\gamma}$ are indicated by black lines, with the contour interval equal to 0.1. To see the detailed Higgs properties, we take an example point as given by the red-filled circle.

In figure 3, we show the diphoton rate relative to the SM value in the region of parameter space allowed by the requirements mentioned above, for two examples,

$$\begin{aligned} &\text{example 1} \;:\; (m_H, m_s, \theta_3) = (480\text{GeV}, 160\text{GeV}, 0.10), \\ &\text{example 2} \;:\; (m_H, m_s, \theta_3) = (780\text{GeV}, 160\text{GeV}, 0.07), \end{aligned}$$

with θ_1 fixed at the smaller solution of $R_h^{VV}(\theta_1) = 1.05$. For both examples, the parameter space is mainly constrained by the requirements, $m_h = 125\,\text{GeV}$ and $|\mu| \geq 105\,\text{GeV}$. The right side of the blue-dashed curve gives μ larger than 105 GeV, and h has $m_h = 125\,\text{GeV}$ between two red-dashed curves if one considers $95\,\text{GeV} \leq m_0 \leq 135\,\text{GeV}$. The gray-shaded region is excluded since $\lambda^2 < 0$. The diphoton rate relative to the SM value is shown in black lines. We see that an enhancement by a factor of 1.5 or larger can be accommodated through the charged-higgsino contribution, when $\tan\beta$ is about $2-3$ and the singlet fraction in h is larger than 0.39 in the left panel. For the other example, this is achieved at $3 \lesssim \tan\beta \lesssim 4.8$ when the singlet fraction in h is larger than 0.26. On the other hand, the mixing effects reduce the $b\bar{b}$ rate below the SM value.

To see the relation between ξ and the model parameters, we take an example point at

$$(\tan\beta, m_H, m_s, \theta_1, \theta_2, \theta_3) = (3.4,\ 780\,\text{GeV},\ 160\,\text{GeV},\ 0.07,\ 0.62,\ 0.07), \tag{4.11}$$

which corresponds to the red-filled circle in the figure. The above set of parameters trans-

JHEP02(2013)090

lates into

$$(\lambda, \mu, \Lambda, m_0) \simeq (1.03, 112\,\text{GeV}, 376\,\text{GeV}, 110\,\text{GeV}), \tag{4.12}$$

together with $m_{\hat{H}} \simeq 776\,\text{GeV}$ and $m_{\hat{s}} \simeq 167\,\text{GeV}$. The Higgs signal rate in the WW/ZZ channel is $R_h^{VV} = 1.05$ at the example point, and the $b\bar{b}/\tau\tau$ channel has $R_h^{b\bar{b}} = R_h^{\tau\tau} \simeq 0.51$. Finally, the diphoton rate is found to be $R_h^{\gamma\gamma} \simeq 1.66$, as a result of the charged-higgsino loop contribution combined with the Higgs mixing effects.

5 Conclusions

We have examined how to arrange a SM-like Higgs boson in the NMSSM, in a way consistent with the LHC results on the Higgs boson search. The observed WW/ZZ signal rate can be compatible with the model even when the SM-like Higgs boson has a large singlet component. This leads to an interesting possibility that the Higgs to diphoton signal rate is enhanced by the loops of charged higgsino which couples to the SM-like Higgs boson through mixing with the singlet scalar. A large enhancement is achievable when there is a large singlet fraction in the SM-like Higgs boson and the charged higgsino is light.

The Higgs mixing depends on the higgsino mass parameter μ and the singlet coupling λ to the Higgs doublets. Hence there are constraints on the Higgs mixing angles coming from the LEP bound on the chargino mass, and the perturbativity limit on λ. In addition, the model should provide a mass near 125 GeV to the SM-like Higgs boson. Taking into account these constraints, we find that the charged-higgsino loop contribution, combined with the mixing effects, can enhance the diphoton signal rate above the SM expectation by a factor of 1.5 or more, while having little deviation in the WW/ZZ rate.

On the other hand, the Higgs mixing effects reduce the $b\bar{b}$ and $\tau\tau$ signals below the SM values, if the mixing between two doublet Higgs bosons $\hat{h}$ and $\hat{H}$ is relatively small, which is favored to get a sizable enhancement of the diphoton signal rate while keeping the WW/ZZ rate similar to the SM prediction. Indeed we could see that the $b\bar{b}$ and $\tau\tau$ rates can be reduced by a factor of 0.5, or even less, for the mixing parameters which would enhance the diphoton signal by a factor of 1.5.

ABSTRACT

Recent LHC data showed excesses of Higgs-like signals at the Higgs mass of around 125 GeV. This may indicate supersymmetric models with relatively heavy scalar fermions to enhance the Higgs mass. The desired mass spectrum is realized in the anomaly-mediated supersymmetry breaking model, in which the Wino can naturally be the lightest superparticle (LSP). We discuss possibilities for confirming such a scenario, particularly detecting signals from Wino LSP at direct detection experiments, indirect searches at neutrino telescopes and at the LHC.

© 2012 Elsevier B.V. Open access under CC BY license.

Higgs mass contains very important information about low-energy supersymmetry (SUSY) models, which is well motivated because it provides a viable candidate of dark matter (DM) and also because it realizes the gauge coupling unification. In particular, in the minimal SUSY standard model (MSSM), the lightest Higgs boson cannot be heavier than the Z-boson at the tree level, while a sizable radiative correction may enhance the Higgs mass [1]. The size of the radiative correction depends on the masses (and other parameters) of superparticles. The lightest Higgs mass becomes larger as superparticles (in particular, stops) become heavier. Thus, once the lightest Higgs mass is known, mass scale of superparticles is constrained.

Recently, the ATLAS Collaboration reported 3.6σ local excess of the standard model (SM) Higgs-like event at $m_h \simeq 126$ GeV [2]. In addition, the CMS Collaboration also showed more than 2σ local excess at $m_h \simeq 124$ GeV [3].[1] In order to achieve such a value of the lightest Higgs mass in the MSSM, relatively large values of the superparticle masses are required; the typical scale of the sfermion masses to realize $m_h \simeq 125$ GeV is 10 TeV–10^3 TeV [4,5]. Then, if the masses of all the superparticles are of the same order, it is difficult to find experimental signals of low-energy SUSY and the existence of SUSY is hardly confirmed.

Although the sfermion masses are much larger than the electroweak scale, gauginos may be much lighter than sfermions and within the reach of collier and other experiments. One interesting possibility is the model in which the SUSY breaking scalar masses are from direct coupling to the SUSY breaking field while the gaugino masses are generated by the anomaly-mediation mechanism [6,7]; in this Letter, we call such a model as anomaly-mediated SUSY breaking (AMSB) model. Even in the AMSB model, however, if the pure anomaly-mediation relation holds among the gaugino masses, gluino mass is about 8 times larger than the mass of Wino. Thus, if the Wino mass is a few hundred GeV, which is the lower bound on it from astrophysical and cosmological considerations as will be reviewed later, the gluino mass becomes multi-TeV; with such a heavy gluino, the discovery of the SUSY signal at the LHC becomes challenging because we consider the case that all the squarks are extremely heavy.

Even so, there still exist possibilities of discovering signals of the AMSB scenario. In particular, in the present framework, the neutral Wino is the lightest superparticle (LSP) and may be DM. In such a case, pair annihilation cross section of the LSP and the scattering cross section of the LSP off the nuclei are both enhanced compared to the Bino LSP case, which has significant implications to direct and indirect detection of DM. Because the search of the superparticles at the LHC may be difficult, it is important to pursue these possibilities and explore how well we can study the AMSB scenario with these procedures.[2]

In this Letter, motivated by the recent Higgs searches at the LHC, we discuss the detectability of the signals of AMSB scenario. We pay particular attention to the case of the Wino LSP. We focus on direct/indirect detection of the Wino DM at underground laboratories and neutrino telescopes. We also comment on the LHC reach for the direct Wino production. Since superparticles except gauginos are heavy, standard methods for SUSY searches may not work. Even in this case, we will show that there are some windows for the confirmation of the SUSY.

doi:10.1016/j.physletb.2012.02.058

Let us first briefly discuss important properties of the AMSB scenario. We assume that the soft SUSY breaking scalar masses are generated by the direct coupling between the scalars and the SUSY breaking hidden sector field, while the gaugino masses are generated by the anomaly mediation mechanism. Adopting the pure AMSB relation, the gaugino masses are given by [6,7]

$$M_a^{(\mathrm{AMSB})} = \frac{b_a}{16\pi^2} g_a^2 m_{3/2}, \tag{1}$$

where g_a ($a = 1$–3) are gauge coupling constants of the SM gauge groups, $m_{3/2}$ is the gravitino mass, and $(b_1, b_2, b_3) = (11, 1, -3)$. Then, the Wino becomes the lightest among the gauginos, and gaugino masses largely separate: $m_{\tilde{B}} : m_{\tilde{W}} : m_{\tilde{g}} \simeq 3 : 1 : 8$. Although the AMSB relation may be affected by Higgs and Higgsino loop diagrams [7,9], we adopt the pure AMSB mass relation. With the gaugino masses being of $O(100)$ GeV–$O(1)$ TeV, the gravitino mass becomes of $O(10)$ TeV–$O(100)$ TeV. The sfermion masses are expected to be of the same order of the gravitino mass, which is preferred from the point of view of realizing $m_h \simeq 125$ GeV. In particular, if the scalar masses are (almost) equal to the gravitino mass, $m_h \simeq 125$ GeV requires relatively small value of $\tan\beta \sim$ a few (where $\tan\beta$ is the ratio of the vacuum expectation values of up- and down-type Higgs bosons) [5].

Before discussing the detectability of the signals of AMSB model, we comment on the supersymmetric Higgs mass parameter (so-called μ-parameter). In the present setup, the soft SUSY breaking scalar mass parameters of up- and down-type Higgs bosons are expected to be of $O(10)$ TeV–$O(100)$ TeV. In order to have viable electroweak symmetry breaking, the μ-parameter (as well as heavy Higgs boson masses) is also expected to be of the same order; then, the Higgsinos become extremely heavy and the Wino becomes the LSP. Thus, we pay particular attention to the case of Wino LSP in the following. In some of our following analysis, however, we consider the case with $\mu \sim O(100)$ GeV–$O(1)$ TeV taking account of the possibility of an accidental tuning of the parameters. This is because detection rates of some of signals (in particular, the direct detection rates) strongly depend on the value of μ.

Taking account of the radiative correction due to the gauge boson loops, the neutral Wino becomes lighter than the charged one. Therefore, we focus on the case of neutral Wino LSP. In addition, we assume that the LSP (i.e., the neutral Wino) is the dominant component of DM. The Wino LSP accounts for the present DM density for $m_{\tilde{W}} \simeq 3$ TeV if it is produced only from thermal bath [10]. In the AMSB scenario, however, the Wino LSP can be non-thermally produced from the gravitino or moduli decay [7,11]. If the reheating temperature takes an appropriate value, for example, the decay of gravitino produces the Wino LSP with correct relic density [12], while thermal leptogenesis [13] works successfully [14]. Thus the Wino is a good DM candidate in the present setup. Hereafter, we assume that the right amount of Wino is somehow produced in the early universe to be DM.

We start with discussing direct detection experiments of DM. The scattering cross section of the Wino LSP off the nucleon significantly depends on μ. Since all scalars except for the lightest Higgs boson are expected to be heavy enough, it is only the lightest Higgs boson that mediates the spin-independent (SI) scattering. The DM–proton scattering cross section is given by [15]

$$\sigma = \frac{4}{\pi}\left(\frac{m_{\tilde{\chi}^0} m_N}{m_{\tilde{\chi}^0} + m_N}\right)^2 \times \left[(n_p f_p + n_n f_n)^2 + 4\frac{J+1}{J}\left(a_p\langle s_p\rangle + a_n\langle s_n\rangle\right)^2\right], \tag{2}$$

where the first and the second terms in the bracket are the contributions of SI and spin-dependent (SD) interaction, respectively. Here $m_{\tilde{\chi}^0}$ is the LSP mass, m_N is the mass of the target nucleus, $n_p(n_n)$ is the number of proton (neutron) in the target nucleus, J is the total nuclear spin, a_p and a_n are the effective DM–nucleon SD couplings, and $\langle s_{p(n)}\rangle$ are the expectation values of the spin content of the proton and neutron groups within the nucleus. We refer to Ref. [15] for definitions of these quantities. The effective DM–proton coupling, f_p, is given by

$$f_p = \sum_{q=u,d,s} \frac{f_q^H}{m_q} m_p f_{T_q}^{(p)} + \frac{2}{27} f_{T_G} \sum_{q=c,b,t} \frac{f_q^H}{m_q} m_p, \tag{3}$$

where $f_{T_G} = 1 - \sum_{u,d,s} f_{T_q}^{(p)}$, m_p and m_q denote the proton and quark masses, respectively, and f_q^H is the effective DM–quark coupling obtained by the exchange of the Higgs boson. Since the DM–Higgs coupling is proportional to the magnitude of Wino–Higgsino mixing,[3] the cross section is enhanced if the Wino–Higgsino mixing is large. In Fig. 1 we plot the Wino–proton SI and SD scattering cross section. In this plot we have used the following values for the quark contents in the proton [17]: $f_{T_u}^{(p)} = 0.023$, $f_{T_d}^{(p)} = 0.034$, $f_{T_s}^{(p)} = 0.025$ and taken $\tan\beta = 3$ and $\tan\beta = 20$. The XENON100 experiment [18] most severely constrains the SI cross section. The sensitivity is improved by a few orders of magnitude for the next generation 1 ton scale detectors, and then broad parameter regions up to $m_{\tilde{W}} \sim \mu \sim 1$ TeV will be explored. The IceCube searches for neutrino events arising from the DM annihilation in the Sun. Since the efficiency for the DM trapping into the Sun depends on the DM–proton scattering cross section, the high-energy neutrino observations give limits on it. For the SD cross section, the IceCube gives the most stringent limit, and it will be further improved by about one order of magnitude with the DeepCore instrument [19].

We have also calculated the detection rate at the IceCube DeepCore, arising from high-energy neutrinos produced by the Wino annihilation at the galactic center (GC). We distinguish two event classes following Refs. [20–22]: contained muon events and shower events. The contained muons correspond to those emerge inside the instrumental volume through the high-energy neutrino interactions with nucleons. The shower events are caused by charged current interactions of electron and tau neutrinos, and neutral current interactions of all neutrino species. They leave electromagnetic/hadronic shower inside the instrumental volume. The event rate of the contained muons is given by

$$N_{\mu^+\mu^-} = \int dE_{\nu_\mu} \int_{E_{\mathrm{th}}}^{E_{\nu_\mu}} dE_\mu \left[\frac{d\Phi_{\nu_\mu}}{dE_{\nu_\mu}}\left(\frac{d\sigma_{\nu_\mu p}^{(\mathrm{CC})}}{dE_\mu} n_p + \frac{d\sigma_{\nu_\mu n}^{(\mathrm{CC})}}{dE_\mu} n_n\right) + (\nu_\mu \leftrightarrow \bar{\nu}_\mu)\right] V_{\mathrm{eff}}(E_\mu), \tag{4}$$

where E_{ν_μ} is the incident neutrino energy, E_μ is the muon energy resulting from the neutrino–proton (neutron) interactions, E_{th} is the threshold energy above which the muon can be detected, $d\Phi_{\nu_\mu}/dE_{\nu_\mu}$ is the neutrino flux at the Earth, $d\sigma_{\nu_\mu p(n)}^{(\mathrm{CC})}/dE_\mu$ denotes the neutrino–proton (neutron) charged current cross section for producing the muon energy with E_μ, $n_p(n_n)$ is the proton (neutron) number density in the detector material, and V_{eff} is the effective volume for the muon detection. The incident neutrino flux generated by DM annihilation from the GC within cone half angle of θ is given by

[3] In the limit of pure Wino DM, the Wino–nucleon scattering cross section is too small to be detected [16].

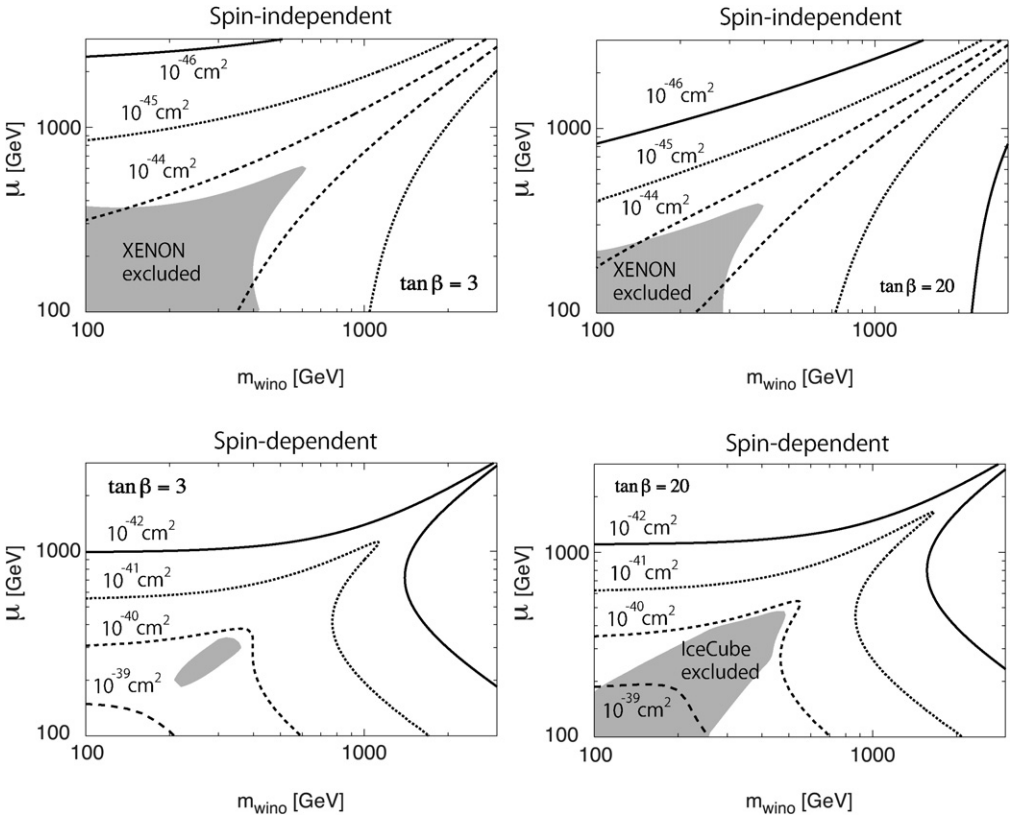

Fig. 1. Contours of spin-independent (SI) and spin-dependent (SD) Wino–proton scattering cross sections are plotted on the plane of $m_{\rm wino}$ and μ. Shaded regions are excluded by the XENON100 experiment for SI, and IceCube experiment for SD.

$$\frac{d\Phi_{\nu_i}}{dE_{\nu_i}} = \frac{R_\odot \rho_\odot^2}{8\pi m_{\tilde{W}}^2} \left(\sum_{j=e,\mu,\tau} \langle \sigma v \rangle \frac{dN_{\nu_j}}{dE_{\nu_j}} P_{j\to i} \right) \langle J_2 \rangle_\Omega \Delta\Omega . \tag{5}$$

Here $R_\odot = 8.5$ kpc and $\rho_\odot = 0.3\ \mathrm{GeV\,cm^{-3}}$, $\langle \sigma v \rangle$ is the Wino self-annihilation cross section including the non-perturbative effect [23], and dN_{ν_j}/dE_{ν_j} is the energy spectrum of the neutrino produced by DM annihilation, which is calculated by the PYTHIA package for the WW final state [24], $P_{j\to i}$ is the probability that the ν_j at the production is converted to ν_i because of the neutrino oscillation effect, $\Delta\Omega = 2\pi(1-\cos\theta)$, and $\langle J_2 \rangle_\Omega$ includes the information about the DM density profile in the Galaxy [25]. The shower event is evaluated in a similar way to the contained muon events (4), except that the charged current interactions from ν_e and ν_τ as well as the neutral current interactions for all neutrino flavors are included. The background event is evaluated by inserting the atmospheric neutrino flux into the expression (4).

Fig. 2 shows the signal-to-noise ratio at the IceCube DeepCore as a function of the Wino mass. Sensitivities for contained muon events (upper panel) and shower events (lower panel) with 1 year and 10 year observations are shown. We have adopted the NFW density profile and considered the neutrino flux from the cone half angle $\theta = 10^\circ$ and $\theta = 25^\circ$ around the GC. As noted in Ref. [22], the sensitivity is maximized for $\theta \simeq 10^\circ$. For this cone half angle, the flux dependence on the DM density profile is not large: it is within a factor of 2 [25]. The effective volume for the contained and shower events are set to be 0.04 km^3 and 0.02 km^3, respectively [20]. The atmospheric background is taken from Ref. [26]. It is seen that the signal-to-noise ratio is at most of order one for the Wino mass of a few hundred GeV. We have also checked that the upward muon events expected at the KM3NeT detector [27], assuming the effective area of 1 km^2 and taking account of the energy loss of muons [28], provide similar sensitivities to the DeepCore.

The Wino DM annihilation may leave characteristic signatures on astrophysical observations. Gamma-ray observations by Fermi-LAT and HESS severely restrict the DM annihilation cross section (see, e.g., Refs. [29,30] for recent works). The non-observations of DM-induced gamma-rays from dwarf galaxies excludes the Wino mass below ~ 400 GeV [29].[4] On the other hand, the cosmic-ray positron excess observed by PAMELA satellite [31] may be explained by the Wino DM annihilation with mass of 200 GeV [32,33] although it may confront the constraints from gamma-rays and anti-protons. The observations of light element abundances also give stringent bound on the DM annihilation cross section so as not to destroy light elements during big-bang nucleosynthesis (BBN). It gives a lower bound on the Wino mass as $m_{\tilde{W}} \gtrsim 200$ GeV [34,32]. It may be encouraging that the cosmic lithium problem may be solved for the Wino mass of around this bound, which simultaneously may explain the PAMELA anomaly. DM annihilation also affects the recombination history of the Universe, which results in the modification on the cosmic microwave background (CMB) anisotropy [35–37]. The constraint is comparable to that from BBN. Taking these constraints into account, we conservatively consider that the Wino must be heavier than ~ 200 GeV if it is the dominant component of DM.

Finally, we comment on a possibility of discovering a signal of AMSB model at the LHC. If we adopt the AMSB mass relation among gauginos, gluino becomes relatively heavy. Then, colored

[4] Ref. [29] derived this constraint by analyzing dwarf galaxies in a statistical way. The observations of each dwarf galaxy put a less severe limit on the cross section by a factor of ~ 2 compared with that derived by the statistical method.

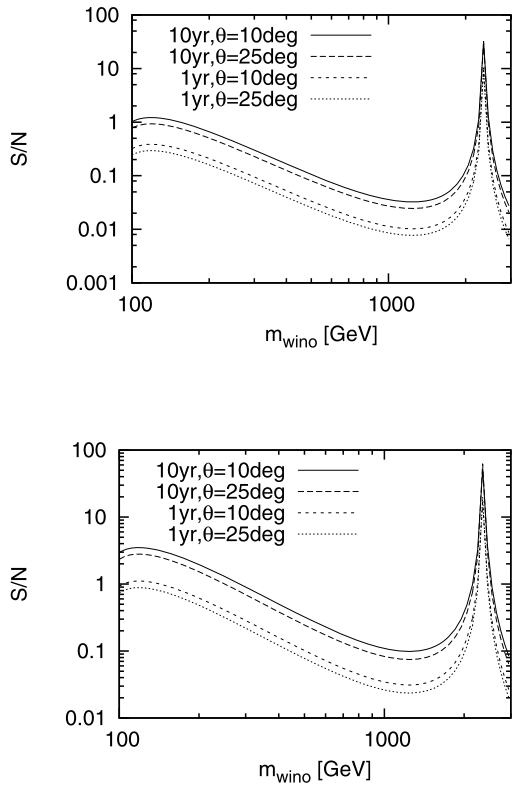

Fig. 2. Signal-to-noise ratio at the IceCube DeepCore as a function of the Wino mass. Sensitivities for contained muon events (upper panel) and shower events (lower panel) with 1 year and 10 year observations are shown. We have considered the neutrino flux from the cone half angle $\theta = 10^\circ$ and $\theta = 25^\circ$ around the GC.

superparticles are hardly produced at the LHC. Thus, we focus on the detection of a Wino signal.

If the neutral Wino $\tilde{W}^0$ is the LSP, we have a chance to observe the track of charged Wino $\tilde{W}^\pm$ [38,39]. This is because the mass difference between charged and neutral Winos is so small (~ 160 MeV) that the decay length of $\tilde{W}^\pm$ becomes macroscopic ($c\tau_{\tilde{W}^\pm} \simeq 5$ cm). Some of the produced charged Winos may travel through several layers of inner trackers and their track may be reconstructed. In the ATLAS experiment, for example, the charged Wino track can be reconstructed with almost 100% efficiency if $\tilde{W}^\pm$ hits the third layer of the semiconductor tracker (SCT) before it decays [40]. Then, because of the smallness of $c\tau_{\tilde{W}^\pm}$ compared to the detector size, $\tilde{W}^\pm$ decays before going through the whole detector. Such a charged Wino is identified as a high p_T track which disappears in the middle of the detector. Such a signal does not exist in the SM, and hence is a smoking gun evidence of the production of $\tilde{W}^\pm$.

The Wino pair can be produced by the Drell–Yan process at the LHC. However, there is no high p_T jet nor track in the final state in such an event, and hence the event cannot be recorded. In order to trigger on the Wino production events, one can use the event with high p_T jet; such a jet can be from the initial state radiation. Then, at the parton level, the Wino production processes relevant for the present study are the following:

$$q\bar{q} \to \tilde{W}^+\tilde{W}^- g, \qquad gq \to \tilde{W}^+\tilde{W}^- q, \qquad g\bar{q} \to \tilde{W}^+\tilde{W}^- \bar{q},$$
$$q\bar{q}' \to \tilde{W}^\pm\tilde{W}^0 g, \qquad gq \to \tilde{W}^\pm\tilde{W}^0 q', \qquad g\bar{q} \to \tilde{W}^\pm\tilde{W}^0 \bar{q}'.$$

We calculate the cross section of the process $pp \to \tilde{W}\tilde{W}j$; we perform the parton level calculation, and we approximate the p_T of jet by that of final-state quark or gluon. In the calculation of the

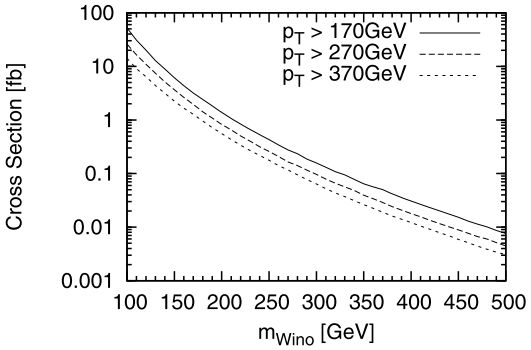

Fig. 3. Cross section for the process $pp \to \tilde{W}\tilde{W}j$ (with $j = q$ or g), for $\sqrt{s} = 14$ TeV. The transverse momentum of j is required to be larger than 170, 270, and 370 GeV from above.

cross section, the helicity amplitude package HELAS [41] and the CT10 parton distribution functions [42] are used. For the phase space integration, we use the BASES package [43]. In the calculation, we require that the transverse momentum of the jet be larger than 170, 270, and 370 GeV, and that at least one charged Wino travels more than 44.3 cm which is the distance to the third layer of SCT from the beam pipe in the ATLAS detector [44].

In Fig. 3, the cross section is plotted as a function of the Wino mass. In the high luminosity run with $\mathcal{L} = 2 \times 10^{33}$ cm^{-2} s^{-1}, for example, the so-called j370 trigger is planned to be available, which requires a jet with $p_T > 370$ GeV [44]. Then, requiring 10 events with $p_T > 370$ GeV for the discovery, for example, Wino mass smaller than 270 GeV (330 GeV) is covered by the LHC with the luminosity of $\mathcal{L} = 100$ fb^{-1} (300 fb^{-1}), where we have assumed that the background is negligible. Thus, in particular when μ is large, the LHC experiment still have a chance to cover the parameter region which has not been excluded yet by the current direct and indirect DM searches. If the p_T of the jet for the trigger can be reduced, the LHC can cover the region with larger Wino mass.

So far, we have assumed the pure AMSB relation among gaugino masses. However, as we have mentioned, such a relation may be largely affected by the Higgs and Higgsino loop diagrams. With such an effect, the gluino mass may become ~ 1 TeV even when the Wino mass is a few GeV. In such a case, the conventional procedures of the SUSY search using the missing energy distribution may work.

In summary, motivated by the recent report on the Higgs searches at the LHC, which indicated excesses of Higgs-like events at around $m_h \simeq 125$ GeV, we have investigated prospects for confirmation of the AMSB scenario, particularly the detection of Wino LSP. We have considered the situation that the scalars except for gauginos and Higgsinos are heavy enough so that they cannot be produced at colliders. Even in this unfortunate case, the Wino DM may be detected through direct/indirect detection experiments. Direct detection efficiency crucially depends on the Higgsino mass, and if the Wino and Higgsino masses happen to be close, future experiments may find their signals. The neutrino telescopes such as IceCube DeepCore and KM3NeT also have a potential to discover the Wino LSP through the observation muon and/or shower events induced by high-energy neutrinos from DM annihilation at GC.

ABSTRACT

Recently the AMS-02 experiment reported an excess of cosmic ray antiprotons over the expected astrophysical background. We interpret the excess as a signal from annihilating or decaying dark matter and find that the observed spectrum is well fitted by adding contributions from the annihilation or decay of dark matter with mass of $\mathcal{O}$(TeV) or larger. Interestingly, Wino dark matter with mass of around 3 TeV, whose thermal relic abundance is consistent with present dark matter abundance, can explain the antiproton excess. We also discuss the implications for the decaying gravitino dark matter with R-parity violation.

1. Introduction

The existence of the dark matter (DM) has been confirmed by various cosmological observations [1], yet its identity is a complete mystery. The DM provides the most robust evidence for physics beyond the Standard Model.

Recently, the AMS-02 collaboration has reported their latest results of the cosmic-ray antiproton measurement [2], which may be indirect signatures of annihilating/decaying DM in our Universe. Although recent studies [3,4] have claimed that the AMS-02 antiproton flux is within the uncertainties of the astrophysical secondary antiproton flux, the predicted secondary antiproton flux still tends to be smaller than the observed one at higher energy $\gtrsim 100$ GeV, which may indicate a DM contribution in that energy range. Refs. [3–5] also derived upper bound on the DM signal, but the conservative bound [4] is still weak, which allows a large DM contribution.

In this letter, we consider annihilating and decaying DM as a possible source of the AMS-02 antiproton flux. We show that annihilating/decaying DM with a mass of $\mathcal{O}$(TeV) can explain the antiproton flux in the high energy range. We also investigate the implications for supersymmetric (SUSY) DM. It is shown that the AMS-02 antiprotons may originate from Wino DM with a mass of 2–3 TeV. Surprisingly, the Wino mass of around 3 TeV, which is suitable for the thermal relic DM scenario, can explain the observed antiproton data. Another interesting DM candidate is gravitino with an R-parity violation. It is shown that $\mathcal{O}$(TeV) gravitino DM with an R-parity violation can also be the source of the AMS-02 antiprotons.

2. Antiproton from annihilating and decaying DM

The flux of primary antiprotons from DM annihilation/decay at the Solar System, $\vec{r} = \vec{r}_\odot$, is given by[1]

$$\Phi_{\bar{p}}^{\rm DM}(T) = \frac{v(T)}{4\pi} f_{\bar{p}}(T, \vec{r}_\odot)\,, \tag{1}$$

where $v(T)$ is the velocity of the antiproton with kinetic energy T and $f_{\bar{p}}(T, \vec{r})$ is the antiproton number density per unit kinetic energy. The propagation of antiprotons is described by a cylindrical stationary diffusion model [6]

$$\begin{aligned} 0 &= \frac{\partial}{\partial t} f_{\bar{p}}(T, \vec{r}) \\ &= \nabla\left[K(T)\nabla f_{\bar{p}}(T, \vec{r})\right] - \frac{\partial}{\partial z}\left[\mathrm{sign}(z) V_c f_{\bar{p}}(T, \vec{r})\right] \\ &\quad - 2h\delta(z)\Gamma_{\rm ann}(T) f_{\bar{p}}(T, \vec{r}) + Q(T, \vec{r}), \end{aligned} \tag{2}$$

with boundary conditions $f_{\bar{p}}(T, \vec{r}) = 0$ at $r = R$ and $z = \pm L$, where (r, φ, z) are the galactic cylindrical coordinates. Here, the effects of energy losses, reacceleration, and tertiary antiprotons are neglected.

[1] We neglect the difference between the fluxes at the top of the Earth's atmosphere $\Phi_{\bar{p}}^{\rm TOA}$ and at the interstellar $\Phi_{\bar{p}}^{\rm IS}$ due to the solar modulation, since its effect is $\mathcal{O}(1)$% for $T \gtrsim 50$ GeV.

Table 1
Propagation parameters [9].

Model	R (kpc)	L (kpc)	K_0 (kpc^2/Myr)	δ	V_c (km/s)
MIN	20	1	0.0016	0.85	13.5
MED	20	4	0.0112	0.70	12
MAX	20	15	0.0765	0.46	5

In Eq. (2), $K(T)$ is the diffusion coefficient and assumed to be spatially constant. It is parametrized as $K(T,\vec{r}) = K(T) = K_0\beta(p/\mathrm{GeV})^\delta$, where p and $\beta = v(T)/c$ are the momentum and velocity of the antiproton, respectively. The V_c term represents the convective wind, which is assumed to be constant and perpendicular to the galactic plane. The third term represents the annihilation of the antiproton on interstellar protons in the galactic plane, where h represents the thickness of the galactic plane and $\Gamma_{\rm ann}(T) = (n_{\rm H} + 4^{2/3} n_{\rm He})\sigma^{\rm ann}_{p\bar{p}} v(T)$ is the annihilation rate. We take $h = 0.1$ kpc, $n_{\rm H} = 1\ \mathrm{cm}^{-3}$, $n_{\rm He} = 0.07 n_{\rm H}$, and $\sigma^{\rm ann}_{p\bar{p}}$ given in Refs. [7,8],

$$\sigma^{\rm ann}_{p\bar{p}} = \begin{cases} 661(1 + 0.0115T^{-0.774} - 0.948T^{0.0151})\ \mathrm{mb} \\ \quad T < 15.5\ \mathrm{GeV}, \\ 36T^{-0.5}\ \mathrm{mb} \\ \quad T \geq 15.5\ \mathrm{GeV}. \end{cases} \tag{3}$$

Lastly, $Q(T,\vec{r})$ is the source term of the antiprotons. We adopt the set of propagation parameters R, L, K_0, δ, and V_c in Ref. [9], which are shown in Table 1.

The source term for DM annihilation/decay is given by

$$Q(T,\vec{r}) = q(\vec{r})\frac{dN_{\bar{p}}(T)}{dT} \tag{4}$$

where $dN_{\bar{p}}(T)/dT$ is the energy spectrum of the antiproton per one annihilation/decay, and $q(\vec{r})$ is given by

$$q(\vec{r}) = \frac{1}{2}\langle\sigma v\rangle\left(\frac{\rho_{\rm DM}(|\vec{r}|)}{m_{\rm DM}}\right)^2 \qquad \text{for annihilating DM}, \tag{5}$$

$$q(\vec{r}) = \frac{1}{\tau_{\rm DM}}\left(\frac{\rho_{\rm DM}(|\vec{r}|)}{m_{\rm DM}}\right) \qquad \text{for decaying DM}. \tag{6}$$

Here, $m_{\rm DM}$ and $\rho_{\rm DM}(|\vec{r}|)$ are the mass and the density profile of the DM, respectively. In addition, $\langle\sigma v\rangle$ is the annihilation cross section for the annihilating DM case, while $\tau_{\rm DM}$ is the DM lifetime for the decaying DM case.

The differential equation (2) can be solved analytically, which leads to

$$\Phi^{\rm DM}_{\bar{p}}(T) = \frac{v(T)}{4\pi}\widetilde{G}(T)\frac{dN_{\bar{p}}(T)}{dT}. \tag{7}$$

For the source spectrum $dN_{\bar{p}}(T)/dT$, we consider the following DM annihilation and decay channels:

- annihilation: $\chi\chi \to W^+W^-$,
- decay: $\chi \to W^\pm \ell^\mp$,

where χ denotes the DM and ℓ is a charged lepton. In Fig. 1, we show the numerical result for the antiproton spectrum from $\chi\chi \to W^+W^-$ obtained by Pythia 6.4 [10]. Our results agree well with the fitting formula in Ref. [11], which we use in the following analysis.[2] The spectrum from the decaying DM with a mass of $m_{\rm DM}$ is given by that from the annihilating DM with a mass of $m_{\rm DM}/2$ rescaled by the factor of 1/2.

[2] As for the fitting parameters $p_i(m_{\rm DM})$ in Ref. [11], we used $p_i(m_{\rm DM} = 5\ \mathrm{TeV})$ for $m_{\rm DM} \geq 5$ TeV.

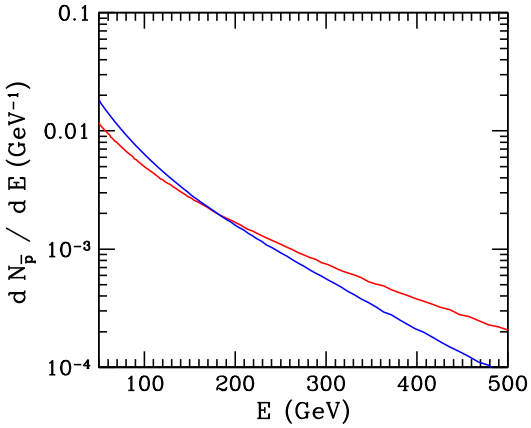

Fig. 1. Energy spectra of antiproton produced by non-relativistic annihilation of DM. Red and blue lines correspond to those for $\chi\chi \to W^+W^-$ and $b\bar{b}$, respectively. The DM mass is taken to be 2 TeV. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

In Fig. 1, we also show the antiproton spectrum from $\chi\chi \to b\bar{b}$. The source spectra for W^+W^- and $b\bar{b}$ are relatively close in the parameter range of our interest. We have checked that the resultant antiproton flux from $\chi\chi \to b\bar{b}$ is similar to the one from $\chi\chi \to W^+W^-$.

The analytic expression for $\widetilde{G}(T)$ is given by [6]

$$\widetilde{G}(T) = \sum_{i=1}^{\infty}\exp\left(\frac{-V_c L}{2K(T)}\right)\frac{y_i(T)}{A_i(T)\sinh(S_i(T)L/2)}J_0\left(\frac{\zeta_i r_\odot}{R}\right) \tag{8}$$

where

$$y_i(T) = \frac{4}{J_1^2(\zeta_i)R^2}\int_0^R r'dr' J_0\left(\frac{\zeta_i r'}{R}\right)\int_0^L dz'\exp\left(\frac{V_c(L-z')}{2K(T)}\right) \times \sinh\left(\frac{S_i(L-z')}{2}\right)q(\vec{r}),$$

$$A_i(T) = 2h\Gamma_{\rm ann}(T) + V_c + K(T)S_i(T)\coth\left(\frac{S_i(T)L}{2}\right),$$

$$S_i(T) = \sqrt{\frac{V_c^2}{K(T)^2} + \frac{4\zeta_i^2}{R^2}}.$$

Here, J_0 and J_1 are the zeroth and first order Bessel functions of the first kind, respectively, and ζ_i are the successive zeros of J_0. We have calculated the Green's function $\widetilde{G}(T)$ by using the NFW density profile [12]

$$\rho_{\rm DM}(|\vec{r}|) = \rho_\odot\frac{r_\odot}{|\vec{r}|}\left(\frac{1 + r_\odot/r_s}{1 + |\vec{r}|/r_s}\right)^2, \tag{9}$$

with $\rho_\odot = 0.3\ \mathrm{GeV/cm}^3$, $r_\odot = 8.5$ kpc and $r_s = 20$ kpc. We parametrize the result as

$$\widetilde{G}(T) = \frac{1}{2}\langle\sigma v\rangle\frac{\rho_\odot^2}{m_{\rm DM}^2}G_{\rm ann}(T) \qquad \text{annihilating DM}, \tag{10}$$

$$\widetilde{G}(T) = \frac{\rho_\odot}{m_{\rm DM}\tau_{\rm DM}}G_{\rm dec}(T) \qquad \text{decaying DM}. \tag{11}$$

For annihilating DM, our numerical result of $G_{\rm ann}(T)$ agrees well with the fitting formula given in Ref. [13]. For decaying DM, our numerical result is well reproduced with the following fitting function

$$G_{\rm dec}(T) = \exp\left(a_0 + a_1\tau + a_2\tau^2 + a_3\tau^3\right) \times 10^{14}\ \mathrm{s}, \tag{12}$$

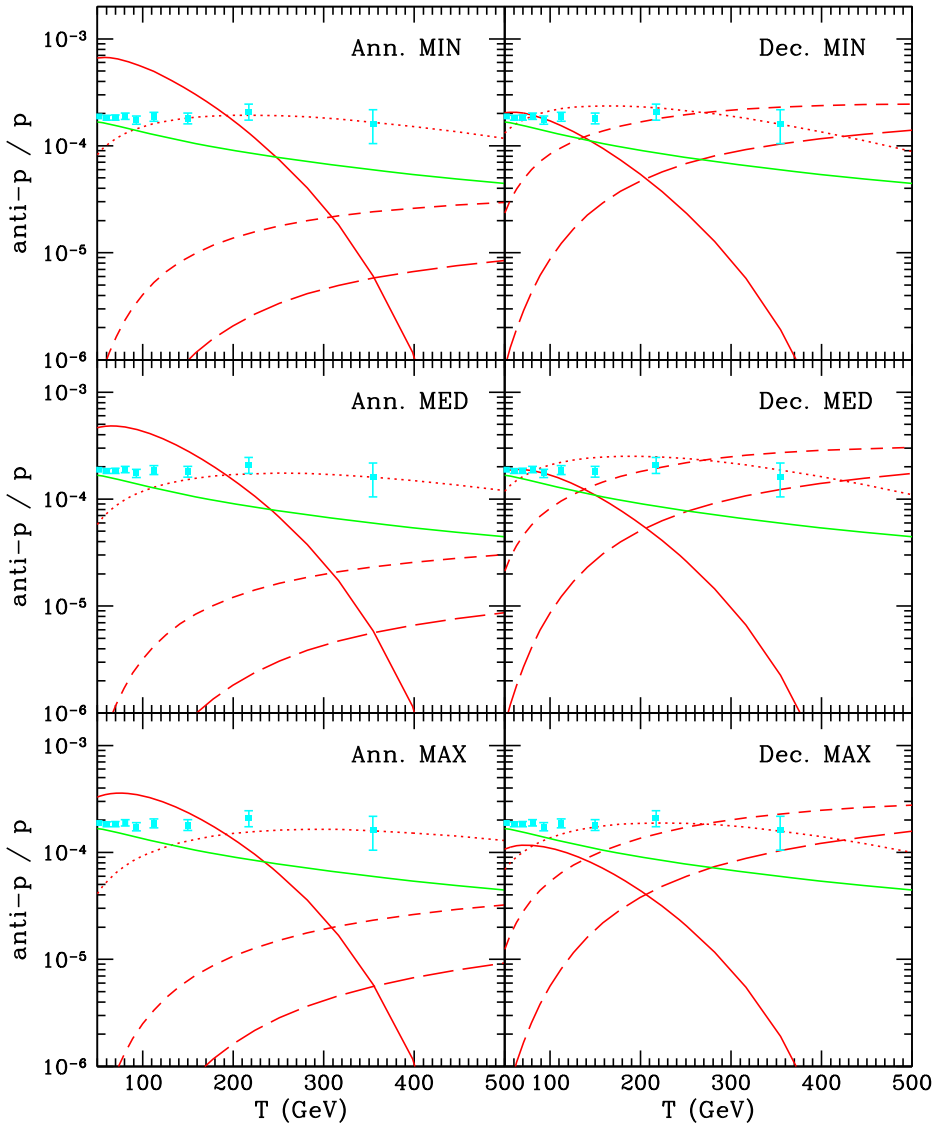

Fig. 2. The antiproton to proton ratio for MIN (top), MED (middle) and MAX (bottom) propagation models. The red lines are those predicted by the DM annihilation (left) and decay (right). For the annihilation case, the DM mass is taken to be 0.5 (solid), 2 (dotted), 10 (dashed), and 20 TeV (long-dashed), while the annihilation cross section is taken to be 2×10^{-23}, 2×10^{-24}, and 6×10^{-25} cm^3/s, for MIN, MED, and MAX propagation models, respectively. For the decay case, the DM mass is taken to be 1 (solid), 3 (dotted), 10 (dashed), and 30 TeV (long-dashed), while the lifetime is 1×10^{26}, 5×10^{26}, and 2×10^{27} s, for MIN, MED, and MAX propagation models, respectively. The background is shown in the green line, and the AMS-02 data are shown by the cyan points. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

Table 2
Fitting parameters for decaying DM.

Model	a_0	a_1	a_2	a_3
MIN	1.1127	1.7495	−1.2730	0.1412
MED	3.0662	0.8814	−0.8377	0.09178
MAX	4.5815	−0.3546	−0.2322	0.02524

where

$$\tau = \log_{10}(T/\mathrm{GeV}), \tag{13}$$

and the coefficients are shown in Table 2 for MIN, MED, and MAX propagation models.[3]

In Fig. 2, we show our numerical results of $\bar{p}/p$ ratio for annihilating and decaying DM. Here, for the proton flux, we adopt the following fitting formula

$$\frac{\Phi_p(T)}{\mathrm{m^{-2}\,sr^{-1}\,s^{-1}\,GeV^{-1}}} = [10.0 - \theta(-\tau_{300})3.0\,\tau_{300} - \theta(\tau_{300})0.6\,\tau_{300}] \times 10^3 \left(\frac{T}{\mathrm{GeV}}\right)^{-2.7}, \tag{14}$$

where $\tau_{300} = \log_{10}(T/300\ \mathrm{GeV})$, which reproduces the newly released proton flux by AMS-02 [2] well for $T \gtrsim 30$ GeV. In the figures, we also show the background spectrum represented by the fitting function in Ref. [13]:

$$\log_{10}\left(\frac{\Phi_{\bar{p}}^{\mathrm{bkg}}}{\mathrm{m^{-2}\,sr^{-1}\,s^{-1}\,GeV^{-1}}}\right) = -1.64 + 0.07\tau - \tau^2 - 0.02\tau^3 + 0.028\tau^4. \tag{15}$$

[3] Our result slightly differs from the fitting formula presented in Ref. [14] for high energy region, $T \gtrsim \mathcal{O}(100)$ GeV.

As can be seen from the figures, the antiproton flux can be explained by annihilating/decaying DM with masses of $\mathcal{O}$(TeV). Notice that the cross sections and lifetimes used in Fig. 2 are not the best-fit values, but just for presentation. The signal antiproton flux is proportional to $\langle\sigma v\rangle$ or $\tau_{\rm DM}^{-1}$, and hence the AMS-02 antiproton flux can be explained in a wide range of DM mass if $\langle\sigma v\rangle$ or $\tau_{\rm DM}$ is appropriately chosen.

3. Implications for supersymmetric DM

In this section, we briefly discuss the implications for some of SUSY DM candidates: annihilating Wino DM and decaying gravitino DM.

3.1. Wino dark matter

As shown in the previous section, if the antiproton flux is from the annihilating DM, it requires a mass of $\mathcal{O}$(TeV) and relatively large annihilation cross section of $\mathcal{O}(10^{-24}\ {\rm cm}^3\,{\rm s}^{-1})$. Such a parameter space is natural in the Wino DM scenario. In this case, the DM annihilation cross section is determined by its mass, and hence the antiproton flux depends only on the Wino mass.

In Fig. 3, we show the $\bar{p}/p$ ratio for several Wino masses for MIN, MED and MAX propagation models. Here, we adopt the annihilation cross section in Refs. [15,16]. As seen in the figure, Wino DM can account for the observed $\bar{p}/p$ ratio for several choices of masses. Interestingly, for the MED and MAX propagation models, Wino mass of 2.9 TeV can fit the antiproton data. Such a Wino mass is indeed predicted by the thermal relic abundance of Wino DM [17,18]. As can be seen in the figures, smaller Wino masses can also explain the data. In this case, a non-thermal production of Wino DM is necessary, such as gravitino [19–22], moduli [19,23], or Q-ball decay [24]. The antiproton flux at the AMS-02 may be the first hint of the Wino DM.

3.2. Gravitino DM with R-parity violation

In the scenario of gravitino DM with an R-parity violation [25,26], a small R-parity violating coupling and the Planck-suppressed interaction lead to a long DM lifetime. In the case of bilinear R-parity violation, its lifetime is given by [25,26]

$$\tau_{3/2} \simeq 10^{26}\ {\rm s}\left(\frac{\lambda}{10^{-7}}\right)^{-2}\left(\frac{m_{3/2}}{1\ {\rm TeV}}\right)^{-3}, \tag{16}$$

where $m_{3/2}$ is the gravitino mass and λ is the R-parity violating effective coupling.

As shown in Fig. 2, if the high energy antiproton flux is from decaying gravitino DM, it implies $m_{3/2} \gtrsim \mathcal{O}(1)$ TeV and $\tau_{3/2} \simeq 10^{26}$–$10^{27}$ s. This corresponds to an R-parity violating coupling of $\lambda \sim 10^{-7}$–10^{-8}. Such a value of R-parity violation is attractive from the cosmological point of view, since it is large enough to solve the constraint from the long-lived next-to-lightest SUSY particle (NLSP) while small enough to avoid the baryon erasure in combination with sphaleron (cf. [27]).

The gravitino abundance is given by [28–30][4]

$$\Omega_{3/2}h^2 \simeq 0.1 g_s^2 \ln\left(\frac{1.3}{g_s}\right)\left(1+\frac{m_{\tilde{g}}^2}{3m_{3/2}^2}\right)\left(\frac{m_{3/2}}{1\ {\rm TeV}}\right)\left(\frac{T_{\rm R}}{10^9\ {\rm GeV}}\right), \tag{17}$$

[4] Note that the NLSP quickly decays with R-parity violation without producing gravitinos.

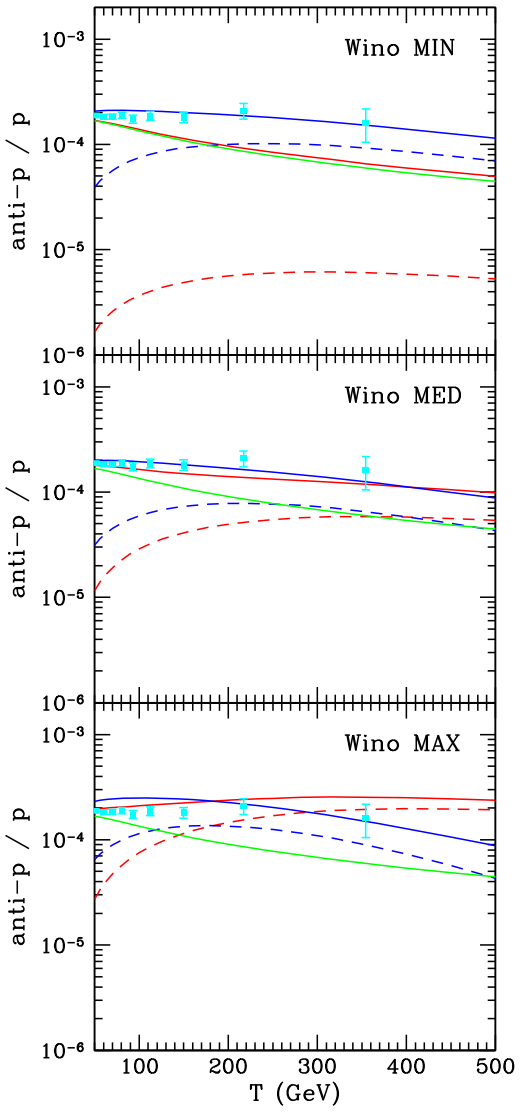

Fig. 3. The antiproton to proton ratio in the Wino DM scenario for MIN (top), MED (middle) and MAX (bottom) propagation models. Red lines are those for the Wino mass of 2.9 TeV, while blue lines are those for the Wino mass of 2.2 TeV (MIN), 1.7 TeV (MED), and 1.2 TeV (MAX). The solid lines are signal plus background, while the dashed lines are signal-only. The background is shown in the green line, and the AMS-02 data are shown by the cyan points. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

where g_s denotes the SU(3) gauge coupling constant, $m_{\tilde{g}}$ the gluino mass and $T_{\rm R}$ the reheating temperature after inflation. Therefore, for explaining the AMS-02 antiprotons with gravitino DM of $m_{3/2} \gtrsim$ (a few) TeV, we need $T_{\rm R} \lesssim 10^9$ GeV. This is slightly lower than the temperature required by the standard thermal leptogenesis scenario [31–33], while non-thermal leptogenesis [34] can explain the observed baryon asymmetry.

4. Discussion

Now let us discuss various observational constraints on the annihilating/decaying DM scenario for explaining the AMS-02 antiprotons.

- Cosmic microwave background (CMB): Recent Planck observation on the cosmic microwave background anisotropy constrains the DM annihilation cross section as $f_{\rm eff}\langle\sigma v\rangle/m_{\rm DM} \lesssim 4\times10^{-28}\ {\rm cm}^3\,{\rm s}^{-1}\,{\rm GeV}^{-1}$ [35], where $f_{\rm eff} \sim 0.3$ (in the case of

DM annihilation into W^+W^- or $b\bar{b}$) is the effective fraction of the energy per DM annihilation that ionizes the hydrogen at the epoch of recombination [36]. This leads to the following constraint

$$\langle \sigma v \rangle \lesssim 1 \times 10^{-24}\ \mathrm{cm}^3\,\mathrm{s}^{-1} \left(\frac{m_{\mathrm{DM}}}{1\ \mathrm{TeV}} \right). \tag{18}$$

For the MAX and MED model, this constraint is satisfied. For the MIN model, the required cross section is too large to satisfy this bound. This does not constrain the decaying DM model, because the energy injection around the recombination epoch is sufficiently small. Big-bang nucleosynthesis also constrains the annihilating DM model [37,16,38], but the constraint is weaker than that from CMB.

- Cosmic-ray positron: The annihilating/decaying DM also yields high-energy cosmic-ray positrons. We have explicitly checked that the typical annihilating/decaying DM models explaining the AMS-02 antiprotons do not conflict with the PAMELA [39] and AMS-02 [40] positron measurements for the MED and MAX models.
- Gamma-rays (continuum): Fermi satellite searches for gamma-rays from dwarf spheroidal galaxies and puts severe constraint on the DM annihilation cross section and decay rate. The constraint reads $\langle \sigma v \rangle \lesssim (0.2\text{–}10) \times 10^{-24}\ \mathrm{cm}^3\,\mathrm{s}^{-1}$ for DM mass of 1–10 TeV in the case of annihilating DM [41]. For decaying DM, the diffuse gamma-ray background gives stringent constraint [42–44] and the typical constraint reads $\tau_{\mathrm{DM}} \gtrsim 10^{27}$ s for DM mass of 1–10 TeV. For both annihilating and decaying DM cases to explain the AMS-02 antiproton data, the MED and MAX models can satisfy the constraint.
- Gamma-rays (line): Annihilating or decaying DM also produces line gamma. For example, the Wino DM annihilates into $Z\gamma$. For DM mass of $\mathcal{O}$(TeV), the HESS telescope gives stringent constraint on such line signals from the Galactic center in the case of DM annihilation [45]. However, the constraint significantly depends on the DM density profile. According to Ref. [46], in which constraint from the gamma-ray line from Galactic center is derived for the case of Wino DM, MED and MAX parameters are allowed for mild coring of the DM density profile around the Galactic center.

Finally, we comment on several possibilities to discriminate two scenarios to explain the anti-proton excess observed by the AMS-02, i.e., the annihilating Wino and decaying gravitino scenarios. As we have mentioned, in the annihilating Wino scenario, we expect sizable gamma-ray flux from high DM density regions. With future improvements in the observation of gamma-ray flux from dwarf spheroidal galaxies, for example, signal of Wino DM may be observed [47]. In addition, in the Wino DM scenario, sizable gamma-ray line flux is expected from the annihilation mode $\chi\chi \to Z\gamma$. The predicted gamma-ray line flux from the Galactic center is within the reach of future Cherenkov Telescope Array (CTA) experiment even for the cored density profile for the Wino mass of a few TeV [48,49]. This may be a smoking-gun signature of the Wino DM scenario. On the contrary, in the decaying DM scenario, gamma-ray emission is effective even at extragalactic region. Thus, detailed study of the extragalactic gamma-ray background may give us a hint about the decaying gravitino DM. Furthermore, in the case of gravitino DM decaying into $W^\pm e^\mp$ or $W^\pm \mu^\mp$, a sizable positron flux is also expected. In particular, when the gravitino decays into $W^\pm e^\mp$, a sharp edge of the positron spectrum at the energy around $m_{3/2}/2$ may be an interesting signature of the decaying gravitino scenario.

In summary, we studied the cosmic-ray antiproton flux from DM annihilation and decay in light of the recent AMS-02 result. It is possible to explain the observed $\bar{p}/p$ ratio by adding DM contributions to the typical astrophysical background. In particular, we found that Wino DM with mass of around 3 TeV can successfully account for the antiproton data, which is consistent with the present DM abundance in the standard thermal freezeout scenario. Decaying gravitino DM heavier than a few TeV can also explain the data.

5. Note added in proof

While finalizing this manuscript, Ref. [50] appeared which has some overlaps with the present work.

ABSTRACT

The effective potential for the Standard Model Higgs field allows two quasi-degenerate vacua; one is our vacuum at the electroweak scale, while the other is at a much higher scale. The latter minimum may be at a scale much smaller than the Planck scale, if the potential is lifted by new physics. This gives rise to a possibility of domain wall formation after inflation. If the high-scale minimum is a local minimum, domain walls are unstable and disappear through violent annihilation processes, producing a significant amount of gravitational waves. We estimate the amount of gravitational waves produced from unstable domain walls in the Higgs potential and discuss detectability with future experiments.

1. Introduction

The Standard Model (SM) of particle physics has been extremely successful, and the Higgs boson with a mass of 125 GeV discovered at the LHC [1,2] completed the last missing piece of the SM. So far there is no experimental hint for physics beyond the SM, and it may be that the Standard Model is valid up to very high energy scales beyond the reach of the current collider experiments.

In the SM framework, the measured values of the Higgs boson mass and top quark mass imply that the electroweak (EW) vacuum is likely metastable. This is because the Higgs self coupling becomes negative at some high energy scale as a result of the fact that its RGE (renormalization group equation) evolution is dominated by the top Yukawa coupling [3,4]. While such effective potential is acceptable as long as our vacuum is sufficiently long-lived, it may signal that new physics appears around that scale and lift the potential.[1] For example, higher dimensional operators may lift the effective potential so as to make these two vacua degenerate in energy, or even make the EW vacuum stable.

The existence of two quasi-degenerate minima in the Higgs potential has interesting cosmological implications. During inflation, either of the two vacua is randomly selected in each patch of the Universe, if the Higgs field acquires quantum fluctuations large enough to overcome the potential barrier between the two minima. Then, domain walls are formed after inflation. Domain walls are a sheet-like topological defect [5], and they are stable if the two vacua are exactly degenerate. Stable domain walls, however, are a cosmological catastrophe as they eventually dominate the Universe, generating unacceptably large inhomogeneities.[2] If there is an energy difference (bias) between the two vacua, domain walls are unstable and they eventually annihilate [11–14]. The EW vacua is realized in the whole Universe if it is energetically preferred. Interestingly, a significant amount of gravitational waves is emitted in the violent annihilation processes [15–18]. As we shall see shortly, such gravitational waves are within the sensitivity reach of future experiments such as advanced-LIGO [19], KAGRA [20,21], ET [22], LISA [23] and DECIGO [24], if the domain walls are sufficiently long-lived. Thus, gravitational waves can be a probe of another vacuum far beyond the EW scale.[3]

In this letter, we study the gravitational waves generated by collapsing domain walls in the Higgs potential with the quasi-degenerate vacua. In Section 2, we introduce the Higgs potential having the false vacuum at high energy scales and discuss the possibility of the domain wall formation. In Section 3, we calculate the gravitational wave abundance and discuss its detectability

[1] The scale sensitively depends on the top quark mass, and it will be around or beyond the Planck scale for the top quark mass about 171 GeV, the lower side of the experimental range [3,4].

[2] If the high-scale minimum is around or beyond the Planck scale, an eternal topological Higgs inflation may take place avoiding the cosmological disaster [6]. See Refs. [7,8] for the original works of topological inflation. The topological Higgs inflation may provide a dynamical explanation for the multiple-point criticality principle [9]. See also Ref. [10] for the related topics.

[3] The gravitational waves from domain wall annihilation can also be a probe of the SUSY breaking scale [25] or a thermal inflation scenario [26].

with future experiments. Section 4 is devoted to discussion and conclusions.

2. False vacuum in Higgs potential

Let us consider the following Higgs potential lifted by new physics at some high energy scale,

$$V_H = \frac{1}{4}\lambda(\varphi)\varphi^4 + \frac{\varphi^6}{\Lambda^2}, \tag{1}$$

where φ is the Standard Model Higgs scalar field, $\lambda(\varphi)$ is a scale-dependent self coupling constant and Λ is a cutoff scale for the dimension six operator. We have neglected the quadratic term of order the electroweak scale as we are interested in the behavior of the Higgs potential at high energy. Here we simply substitute the Higgs field value for the renormalization scale, $\lambda(\mu) = \lambda(\varphi)$.

The renormalization-group-improved effective potential including one-loop and two-loop corrections in Landau gauge is given in [3], and the gauge-dependence of the effective potential was examined in [4]. More recently, a treatment for higher dimensional operators in the Higgs potential was studied in [27]. For our order of magnitude estimate, however, the following crude approximation is sufficient. We leave further refinement of our analysis for future work, but we believe our main results will not be qualitatively changed.

The scale dependence of the Higgs self coupling $\lambda(\mu)$ is governed by the RGE,

$$(4\pi)^2\frac{d\lambda}{dt} = \beta_\lambda, \tag{2}$$

where $t = \ln(\mu/M_t)$ and

$$\beta_\lambda = 24\lambda^2 + 12\lambda y_t^2 - 6y_t^4 - 3\lambda(g'^2 + 3g^2) + \frac{3}{8}[2g^4 + (g'^2 + g^2)^2] \tag{3}$$

up to one loop order. Here y_t is the top Yukawa coupling, M_t is the top quark mass, g' and g are respectively the $U(1)_Y$ and the $SU(2)_L$ gauge coupling constants. The top Yukawa coupling gives a dominant contribution to the RGE up to a very high energy scale where the $U(1)_Y$ gauge coupling becomes large. As a result, the Higgs self coupling turns to negative, and the effective potential becomes negative at an intermediate scale in the absence of higher dimensional operators.

The effective potential can be lifted by higher dimensional operators such as the last term in the right-hand-side in Eq. (1).[4] In this case there are two potential minima; one is at the EW scale $\varphi = v_{\rm EW}$, and the other at a much higher scale $\varphi = \varphi_f$. Depending on the size of the higher dimensional operator, the high-scale minimum can be a local or global minimum. In particular, our main interest lies in the case when the two minima are quasi-degenerate and the EW vacuum is slightly energetically preferred:

$$V_H(v_{\rm EW}) \approx V_H(\varphi_f) \approx 0, \tag{4}$$

$$V_H(v_{\rm EW}) < V_H(\varphi_f). \tag{5}$$

If the Higgs field acquires a sufficiently large quantum fluctuations during inflation, both vacua may be populated in different patches of the Universe, leading to domain wall formation after inflation. In a later Universe, the EW vacuum will be selected after domain wall annihilation.

[4] Alternatively, one may lift the potential by introducing e.g. an additional singlet scalar field which gives a positive contribution to the beta function (3) [28–30]. Our results hold in this case too, without significant modifications.

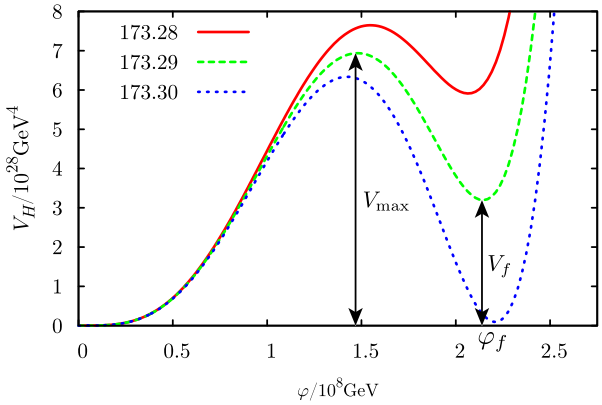

Fig. 1. The effective potential for the Higgs field, $V_H(\varphi)$. We have taken $M_t = 173.28$ (solid red), 173.29 (dashed green) and 173.30 GeV (dotted blue), $m_H = 125.6$ GeV, and $\Lambda = 10^{10}$ GeV. Note that the values of Λ and φ_f are for illustration purposes only. See the text for details.

In Fig. 1 we show the Higgs potential calculated in the present set-up for illustration purposes. We have taken the Higgs boson mass $m_H = 125.6$ GeV, $M_t = 173.28$ (solid (red)), 173.29 (dashed (green)), 173.30 GeV (dotted (blue)) and $\Lambda = 10^{10}$ GeV. One can see that the position of the high-scale minimum, $\varphi = \varphi_f$, is comparable to, but parametrically smaller than Λ because of the loop suppression factor in the RGE. The cut-off scale as well as φ_f increase for smaller values of M_t. For notational simplicity, let V_f and $V_{\rm max}$ denote the potential energy at the false vacuum and the local maximum, respectively, as shown in the figure for the middle line.

Note that the precise value of Λ obtained in Ref. [4] is about two orders of magnitude larger and it is about 10^{12} GeV for $M_t = 173.3$ GeV. Accordingly, φ_f will be larger by a similar amount. We emphasize here that our analysis in the next section does not depend on the detailed RGE evolution, because we express all the relevant quantities in terms of φ_f, $V_{\rm max}$ and V_f. One should simply use the result of e.g. Ref. [4] when one relates the value of φ_f to the top quark mass and the Higgs boson mass.

3. Gravitational waves from collapsing domain walls

As we have seen in the previous section, the Higgs potential allows two quasi-degenerate minima, especially if the potential is lifted by higher dimensional operators. This gives rise to a possibility of domain wall formation after inflation. A domain wall is characterized by its tension, σ, which is roughly estimated to be

$$\sigma \sim \left(\frac{\varphi_f^2}{w^2} + V_{\rm max}\right) w \sim V_{\rm max}^{1/2}\varphi_f, \tag{6}$$

where $V_{\rm max}$ is the height of the potential barrier between two minima, $w \sim \varphi_f/V_{\rm max}^{1/2}$ is the width of the domain wall, and we fix it to minimize the tension in the second equality. In order to avoid the cosmological domain wall problem, the energy bias between the two vacua is necessary to make domain walls unstable. In the presence of the bias, domain walls start to collapse when the energy density of the domain walls become comparable to the bias energy density. As is confirmed by numerical simulations, the evolution of the domain wall network exhibits a scaling behavior [31–34] and the energy density of the domain wall is roughly given by

$$\rho_{\rm dw} \sim \sigma H. \tag{7}$$

Then, the Hubble parameter at the domain wall decay is

$$H_{\rm dec} \sim \frac{V_f}{\sigma} \sim \frac{V_f}{V_{\rm max}^{1/2}\varphi_f}. \tag{8}$$

In order not to generate unacceptably large inhomogeneities, domain walls must decay before they dominate the Universe, which places a lower bound on the energy bias;

$$H_{\rm dec} > H_{\rm dom} \quad \Longleftrightarrow \quad \frac{V_f}{V_{\rm max}} > \left(\frac{\varphi_f}{M_P}\right)^2, \tag{9}$$

where $M_P \simeq 2.4 \times 10^{18}\,\text{GeV}$ is the reduced Planck mass, and $H_{\rm dom} \sim \sigma/M_P^2$ is the Hubble parameter when domain walls would start to dominate the energy density of the Universe if there were not for the bias.

The domain wall collapse is a violent processes, and some part of the energy stored in the domain walls is converted to gravitational waves. The spectrum of the gravitational waves is expected to be peaked at a frequency corresponding to the Hubble scale at the decay, as it is the typical curvature scale of the domain wall system. This was confirmed by detailed numerical calculations [18], and the density parameter of the gravitational waves at the peak frequency at the time of domain wall collapse is given by

$$\Omega_{\rm GW}(t_{\rm dec})|_{\rm peak} = \frac{8\pi\tilde{\epsilon}_{\rm gw}G^2\mathcal{A}^2\sigma^2}{3H_{\rm dec}^2} = \frac{\tilde{\epsilon}_{\rm gw}\mathcal{A}^2}{24\pi}\left(\frac{V_{\rm max}}{V_f}\right)^2\left(\frac{\varphi_f}{M_P}\right)^4, \tag{10}$$

where G is the Newton's gravitational constant and $\tilde{\epsilon}_{\rm gw}$ and $\mathcal{A}$ are numerical factors characterizing respectively the efficiency of the gravitational wave emission and the area of the domain walls. They are determined by the numerical calculations to be $\tilde{\epsilon}_{\rm gw} \simeq 0.7$ and $\mathcal{A} \simeq 0.8$ [18]. Then, the present time density parameter of the gravitational waves at the peak frequency is obtained as

$$\Omega_{\rm GW}h^2|_{\rm peak} \simeq 1.3 \times 10^{-5}\gamma\left(\frac{106.75}{g_*}\right)^{1/3}\Omega_{\rm GW}(t_{\rm dec})|_{\rm peak} \tag{11}$$

where g_* is the relativistic degrees of freedom at the domain wall decay and γ is the dilution factor after the domain wall decay, and it is given by

$$\gamma \simeq \begin{cases} 1 & \text{for } H_{\rm dec} < H_R \\ (H_R/H_{\rm dec})^{2/3} & \text{for } H_{\rm dec} > H_R \end{cases}. \tag{12}$$

Here H_R is the Hubble parameter at the reheating. The peak frequency corresponds to the Hubble parameter at domain wall decay, which is red-shifted by the cosmic expansion until today,

$$f_{\rm peak} = \frac{a(t_{\rm dec})}{a(t_0)}H_{\rm dec} \simeq 160\,\text{Hz}\,\gamma^{-1/2}\left(\frac{g_*}{106.75}\right)^{1/6}\left(\frac{T_X}{10^9\,\text{GeV}}\right) \tag{13}$$

where

$$T_X \simeq \begin{cases} T_{\rm dec} & \text{for } H_{\rm dec} < H_R \\ T_R & \text{for } H_{\rm dec} > H_R \end{cases}, \tag{14}$$

and $T_{\rm dec}$ and T_R are the cosmic temperature at $H = H_{\rm dec}$ and H_R, respectively.

Now let us turn to the domain walls in the SM Higgs potential lifted by new physics. We focus on the case in which the high-scale minimum is a false vacuum and it is quasi-degenerate with the EW vacuum. The position of the false vacuum is at intermediate energy scales, $10^8\ \text{GeV} \lesssim \varphi_f \lesssim 10^{12}\ \text{GeV}$, depending on the values of the top quark mass, the strong gauge coupling, and the Higgs boson mass [3,4]. The height of the potential barrier is determined by solving the RGE, which is roughly $V_{\rm max} \sim 10^{-4}\varphi_f^4$. The bias energy density is treated as a free parameter which is adjusted by tuning Λ.

In the case of the Higgs domain walls, there are generically finite temperature corrections to the Higgs potential, which give an extra contribution to the (time-dependent) energy bias. In the following we derive a condition for thermal effects to have a negligible impact on the domain wall dynamics. The condition can be relaxed in certain situations, and we shall give concrete examples later.

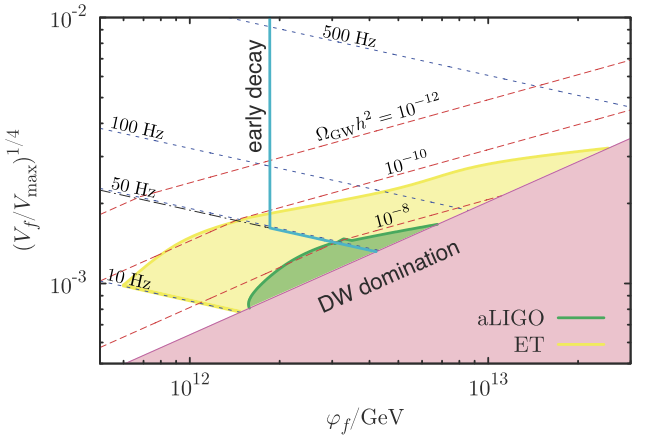
Throughout this letter, we focus on the case in which the position of the false vacuum is always much larger than the cosmic temperature, $\varphi_f \gg T$. Then the thermal mass correction to the effective potential is negligibly small at $\varphi = \varphi_f$. Even for $\varphi \gg T$, however, there is a logarithmic correction arising from the free energy of thermal plasma, the so-called *thermal log* potential [35], which is roughly given by

$$V_T(\varphi) = aT^4\ln\left(\frac{\varphi}{T}\right), \tag{15}$$

where a is a numerical constant of $O(0.1)$. In addition, there are background thermal plasma in the EW vacuum, while many of the SM particles are non-relativistic in the false vacuum because of $\varphi_f \gg T$. These thermal effects are considered to generate an extra energy bias of order T^4.

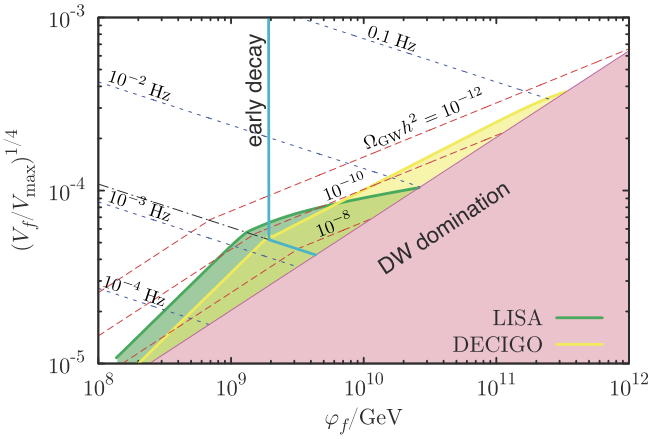
After reheating, the thermal energy bias $\sim T^4$ decreases faster than the energy density of domain walls in the scaling regime. Before reheating, both evolve in the same way since the dilute plasma energy density evolves as $T^4 \sim T_R^2 H M_P \propto \rho_{\rm dw}$ (see Eq. (7)) in the case of usual perturbative decay of the inflaton. Thermal effects do not induce the domain wall annihilation if $\rho_{\rm dw} \sim \sigma H \gtrsim T^4$. For a given reheating temperature, this gives a lower bound on the field value at the false vacuum:

$$T_R \lesssim 3 \times 10^8\ \text{GeV}\left(\frac{\varphi_f}{10^{12}\ \text{GeV}}\right)^{3/2} \lesssim V_f^{\frac{1}{4}}, \tag{16}$$



where the second inequality represents the condition for avoiding the domain wall domination (9). The condition (16) implies that the domain walls must annihilate before the reheating.

For the reheating temperature satisfying the condition (16), the thermal plasma energy is always much smaller than $V_{\rm max}$, and so, the use of the tension given in Eq. (6) is justified.[5] If the condition (16) is violated, domain walls will disappear soon after inflation and the resultant gravitational wave signal will be too weak to be detected by future experiments. Also the peak frequency tends to be extremely high.



We would like to emphasize that the bound (16) should be taken with care, because the thermal history after inflation is unknown. Indeed, it is possible to consider some complicated (and contrived) thermal history where thermal effects on the domain wall dynamics are negligible even if (16) is not satisfied. For instance, the inflaton may dominantly decay into hidden sector particles, and the SM sector is reheated when the coupling between the SM and hidden sectors freezes-in well after the domain wall annihilation.[6] We shall return to this issue in Section 4.

[5] The evolution of the domain wall network might deviate from the scaling regime in the presence of background plasma. The existence of plasma could also change the effective area of domain walls $\mathcal{A}$, which results in a shift of the peak frequency for the fixed tension and energy bias. We however expect that such thermal effect on the domain wall dynamics is small as long as thermal energy is much smaller than the energy stored in the domain walls, as we assume in the text.

[6] Our estimate (10) remains unchanged in this case.

(a) $T_R = 3 \times 10^8$ GeV

(b) $T_R = 10^4$ GeV

Fig. 2. The contours of $\Omega_{\rm GW}h^2|_{\rm peak}$ (dashed red) and $f_{\rm peak}$ (dotted blue) in the plane of φ_f–$(V_f/V_{\rm max})^{1/4}$. We have set $T_R = 3 \times 10^8$ GeV and $T_R = 10^4$ GeV in the upper and lower panel, respectively. The dash-dotted black line represents the border above (below) which the reheating takes place after (before) the wall decay (16). The lower right shaded (magenta) region is excluded by the domain wall domination (9) and the solid cyan line corresponds to the lower bound on φ_f due to the early domain wall decay by the thermal effect. The thick green and yellow lines represent the sensitivity curves for advanced-LIGO (LISA) and ET (DECIGO) respectively in the upper (lower) panel and the shaded region below the curves will be probed by each experiment.

In Fig. 2, we show the contours of the gravitational wave density parameter at the peak frequency, $\Omega_{\rm GW}h^2|_{\rm peak}$ (dashed (red) lines), as well as the peak frequency, $f_{\rm peak}$ (dotted (blue) lines), in the plane of $(\varphi_f, (V_f/V_{\rm max})^{1/4})$. We have set $T_R = 3 \times 10^8$ GeV in Fig. 2(a) and $T_R = 10^4$ GeV in Fig. 2(b). The shaded (magenta) lower-right triangle region is excluded by the domain wall domination (cf. Eq. (9)) and the solid cyan line is the lower bound on φ_f to avoid the early domain wall decay due to the thermal effects (cf. Eq. (16)). As mentioned earlier, thermal effects are negligible in the region right to the solid cyan line, but it does not necessarily preclude the region left to the solid cyan line because of large uncertainties of thermal history. The thick green and yellow lines represent the sensitivity curves of advanced-LIGO and ET respectively in Fig. 2(a), and LISA and DECIGO in Fig. 2(b), and the shaded region below the curves will be probed by each experiments. The sensitivity curve of KAGRA is expected to be similar to that of advanced-LIGO. Note that it is difficult to generate gravitational waves within the reach of pulsar timing observations such as IPTA [36] and SKA [37] which are sensitive to much lower frequencies ($\sim 10^{-9}$ Hz). It would require the tension of the domain walls to be close to $(10^5\,{\rm GeV})^3$, which cannot be realized within the SM framework.

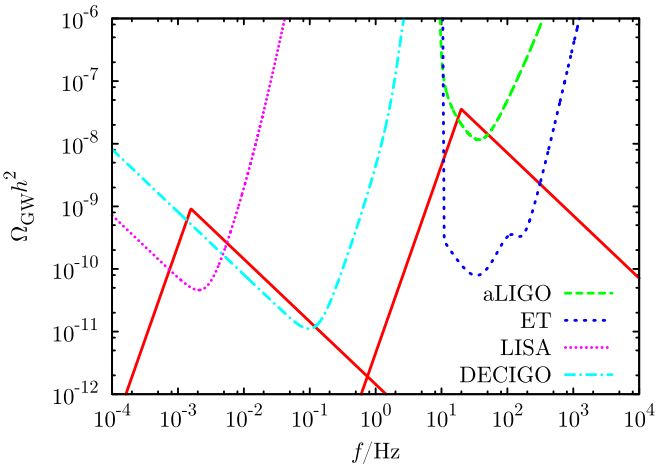


Fig. 3. The typical spectrum of the gravitational waves is shown by the solid (red) lines. We have taken $\varphi_f = 2 \times 10^9$ GeV and $(V_f/V_{\rm max})^{1/4} = 5 \times 10^{-5}$ for the left line and $\varphi_f = 2 \times 10^{12}$ GeV and $(V_f/V_{\rm max})^{1/4} = 10^{-3}$ for the right line.

We show in Fig. 3 the gravitational wave spectrum for certain parameters ($\varphi_f = 2 \times 10^9$ GeV and $(V_f/V_{\rm max})^{1/4} = 5 \times 10^{-5}$ for the left line and $\varphi_f = 2 \times 10^{12}$ GeV and $(V_f/V_{\rm max})^{1/4} = 10^{-3}$ for the right line). According to the precise numerical calculations [18], the gravitational wave spectrum scales as $(f/f_{\rm peak})^3$ for $f < f_{\rm peak}$ and $(f/f_{\rm peak})^{-1}$ for $f > f_{\rm peak}$.

4. Discussion and conclusions

In the previous section we have mentioned that the condition (16) can be relaxed in certain situations. Here we give concrete examples that relax the condition (16) so as to make the wider parameter available. As we shall see below, this requires a more involved thermal history of the Universe.

Suppose that the inflaton dominantly decays into a hidden sector, which is decoupled from the SM sector. This significantly suppresses thermal corrections to the Higgs potential, and the lower bound on φ_f (16) is no longer applied.[7] The SM particles can be thermally populated through various processes much later than the domain wall annihilation. For instance, the hidden sector may contain a U(1) gauge group, which has a small kinetic mixing with the SM U(1)$_Y$. For a sufficiently small kinetic mixing, the SM particles are thermalized through the kinetic mixing well after the domain wall annihilation but before nucleosynthesis, unless the hidden photon is extremely light. If the hidden photon is massless, we need to introduce hidden matter fields (e.g. a Dirac fermion) charged under the hidden U(1) gauge symmetry. The hidden matter fields behave as mini-charged particles, connecting the hidden sector and the SM sector. In this case, the massless hidden photon contributes to the effective neutrino species, $N_{\rm eff}$, whose precise value depends on the mass of the hidden matter fields [38]. Similarly, if one introduces a gauge singlet scalar field, the SM sector can be produced from the hidden sector through the Higgs portal coupling. In this case, the thermalization of the SM sector can be delayed for a sufficiently small Higgs portal coupling. It is worth noting that there is no

[7] Some amount of the SM plasma is necessarily generated by the Higgs domain walls, because they continuously annihilate in the scaling regime. We have numerically confirmed that the energy density of the SM plasma induced by the Higgs domain walls in the scaling regime is always smaller than that of domain walls, and therefore, it does not induce the domain wall annihilation.

entropy production when the SM sector is thermalized, and our analysis in the previous section can be applied without any modification even in the parameter space left to the solid cyan line in Fig. 2.

Alternatively, the SM sector can be reheated, if one introduces another field (e.g. a modulus field) which dominates the Universe for a short period and decays into the SM particles after the inflaton decay. In this case one has to take account of its thermal effects, the shift of the peak frequency, as well as an extra dilution due to the modified thermal history.

In the SM framework, the Higgs self coupling turns to negative, and the effective potential becomes negative at a high energy scale, based on the perturbative RGE analysis. The scale sensitively depends on the values of the top quark mass, but it is at an intermediate scale for the top quark mass, $M_t \simeq 173\,\mathrm{GeV}$. In such a case, the EW vacuum is metastable, which is acceptable as long as it is sufficiently long-lived. On the other hand, the negative effective potential may signal that new physics appears around that scale and lift the potential, creating a local minimum at an intermediate scale. In a limiting case, the two vacua, one at the EW scale and the other at an intermediate scale, are quasi-degenerate in energy. This requires a certain amount of fine-tuning of the parameters. Once the fine-tuning of the parameters is realized, it gives rise to a possibility of domain wall formation.

For domain walls to be formed after inflation, both vacua must be populated with more or less equal probability during inflation. Domain walls are not formed if one of the two vacua is preferred over the other. This is the case if the Higgs potential is significantly modified through its non-minimal coupling to gravity, or if the quantum fluctuations of the Higgs field is too small to overcome the barrier separating the two vacua. We have assumed that the Higgs field is minimally coupled to gravity as well as the inflaton sector so that the potential is not significantly modified, and that the quantum fluctuations of the Higgs field is sufficiently large to overcome the barrier between the two vacua.

The energy of domain walls is partially converted to gravitational waves through the violent annihilation processes. The gravitational waves are expected to be peaked at a frequency corresponding to the Hubble horizon size at the domain-wall annihilation. The gravitational-wave spectrum looks like that from a phase transition. In the latter case, the gravitational wave spectrum has a peak corresponding to the typical size of bubbles, a few orders of magnitude smaller than the Hubble horizon at the phase transition.

In order to generate gravitational waves within the reach of future experiments, the bias energy density must be so small that domain walls annihilate when they are about to dominate the Universe. While there is no compelling reason for the quasi-degeneracy of the two vacua, it may be due to the multiple-point principle [9] or an important cosmological role (e.g. dark matter, baryogenesis) of the decay products of domain walls. The violent domain wall annihilation processes produce not only gravitational waves but also a large amount of the SM Higgs bosons which soon decay into quarks, leptons and gauge bosons. If the SM Higgs boson is coupled to some heavy degrees of freedom such as right-handed neutrinos, a B–L Higgs field, and a singlet scalar, those heavy particles can be produced through non-perturbative processes, and they may contribute to dark matter, or baryogenesis, etc. [39].

In this letter we have investigated the domain wall formation in the Standard Model Higgs potential lifted by new physics and gravitational wave production due to the domain wall decay. We have shown that the gravitational waves can be within the reach of the future experiments such as advanced LIGO, KAGRA, ET, LISA and DECIGO, if the domain walls decay when their energy density is sizable. In this way, the direct detection experiments of the gravitational wave can be a powerful probe of another vacuum far beyond the EW scale.

計画研究 B02 班

課題名「テラスケール物理がもたらす新しい時空像」

研究組織

(1) 研究代表者

細谷　裕（HOSOTANI, Yutaka）
大阪大学・大学院理学研究科・教授
研究者番号：50324744

(2) 研究分担者

林　青司（LIM, C.S.）
東京女子大学・現代教養学部・教授
研究者番号：80201870

(3) 研究分担者

尾田欣也（ODA, Kin-ya）
大阪大学・大学院理学研究科・准教授
研究者番号：60442943

交付決定額

計画研究 B02 班に配分された交付額を表 1 に示す。

表 1. 交付決定額（配分額）　（金額単位：円）

年度	直接経費	間接経費	合計
平成 23 年度	5,400,000	1,620,000	7,020,000
平成 24 年度	7,000,000	2,100,000	9,100,000
平成 25 年度	7,100,000	2,130,000	9,230,000
平成 26 年度	6,700,000	2,010,000	8,710,000
平成 27 年度	6,700,000	2,010,000	8,710,000
総計	32,900,000	9,870,000	42,770,000

研究成果

１．研究開始当初の背景

標準模型は幾多の実験的テストに耐え、大きな成功を収めていたが、要のヒッグス粒子は未発見であった。その質量を電弱スケール(100 GeV)に保つためには理論のパラメター の不自然な微調整が必要であるという階層性問題や、クォーク・レプトンの質量や世代間混合を司る湯川結合が任意で、理論に多くの不定パラメター が存在するといった問題点を抱えている。この原因はヒッグス相互作用を制御する対称性原理の欠如にある。

ヒッグス相互作用を制御する方法として、余剰次元におけるゲージ・ヒッ グス統合を考える。これは、もともと代表者の細谷が 1983 年に提出したゲージ場とヒッグス場を 5 次元ゲージ理論のなかで統一し、量子効果により対称性を破るという細谷機構に基づいている。 我々の時空は 4 次元ではなく、 5 次元目， 6 次元目の余剰次元があり、余剰次元でのゲージ相互作用が、ヒッグス相互作用としてあらわれると考えるのである。分担者の林は 1998 年このゲージ・ヒッグス統合で階層性問題が解決できることを見いだし、電弱相互作用でのゲージ・ヒッグス統合理論の突破口を開いた。

余剰次元の歴史は古い。1920 年代に Kaluza と Klein は重力と電磁相互作用を 5 次元時空で統一することを提唱した。だが、それを確かめる術はなかった。1970 年ごろより、素粒子の基本相互作用は非可換ゲージ理論の形で統一されることになる。そして 1983 年、細谷は統一理論の柱となる対称性の自発的破れが 5 次元時空のゲージ相互作用の結果、 自然に起ることを発見した。更に、左右非対称でカイラルな弱い相互作用が、オービフォルドの余剰次元で自然に実現できることが見いだされ、電弱相互作用を記述する現実的な余剰次元理論、ゲージ・ヒッグス統合理論が構成されるに至った。

2．研究の目的

余剰次元が存在するという新しい時空描像のもと、ゲージ・ヒッグス統合理論を中心とする余剰次元理論から帰結されるテラスケールの物理を予言し、LHC や暗黒物質探索などの実験観測に直接結びつけ、検証することで新しい時空像を確立していく。

3．研究の方法

余剰次元と実験観測との接点をヒッグスボゾン、KK 励起粒子、暗黒物質、ブラックホール生成等に見極め、テラスケール加速器実験と観測で直接検証する形で時空描像を塗り替える。細谷が 28 年前明らかにした細谷機構を基礎とし、林が 13 年前に整備したゲージ・ヒッグス統合が、ようやく電弱相互作用を記述する現実的な理論となり、実験観測による検証が可能となる。1920 年代に始まった余剰次元による統一のシナリオが、単なる理論的可能性としてではなく、自然科学として実現できる。相対論の出現で時間と空間が融合し、量子論の出現でミクロの世界の基本原理が塗り替えられた。余剰次元の存在は、ミクロの彼方に潜む時空概念の大変革を意味し、我々は、新しい自然観の世界に突入する。

4．研究成果

(1) ゲージ・ヒッグス統合理論の構築

細谷は SO(5)xU(1) ゲージ・ヒッグス統合理論を Randall-Sundrum ワープ空間で構成した。このモデルは、低エネルギー領域では、標準模型とほぼ同じ結果を与える。ヒッグスボゾンがゲージ場の 5 次元目の成分として出現し、量子効果により、電弱対称性が自発的に破れる。ヒッグスボゾンの質量は有限に予言される。階層性問題が自動的に解決される。クォーク・レプトンはカイラルな相互作用を持つ零モードとして現れる。

ヒッグスボゾンは、5 次元目の空間でのアハロノフ・ボーム位相となる。ゲージ不変性により保証された位相として性質から、ヒッグスボゾンの相互作用係数は有限となる。

(2) ゲージ・ヒッグス統合理論の整合性

SO(5)xU(1) ゲージ・ヒッグス統合理論は驚くべき性質を持っていることが判明した。高次元で定義された理論では、各粒子に付随して 5 次元方向への励起モード（KK モード）が無限個出現する。2012 年に発見されたヒッグスボゾンは、例えば、2 光子に崩壊する。この崩壊過程には、無限個の KK モードの寄与があり、総和は発散してしまう危険性がある。ゲージ・ヒッグス統合理論では各モードの寄与の間に相殺が起こり、総和は有限で、かつ非常に小さいことが示された。

その後の実験結果と整合し、ゲージ・ヒッグス統合理論では、5 次元目の空間でのアハロノフ・ボーム位相がある程度小さい限り（つまり、0.1 より小さいかぎり）全てのヒッグスボゾンの崩壊モードのレートの標準模型からのずれは 1%以下になることが示された。

(3) ゲージ・ヒッグス統合理論の予言

SO(5)xU(1) ゲージ・ヒッグス統合理論はいくつか自由にとれるパラメータがある。にもかかわらず、多くの観測可能な物理量は、理論の詳細によらず、アハロノフ・ボーム位相の値でほぼ決まることが示された。この性質はユニバーサリティ（普遍性）と呼ばれる。何故、ユニバーサリティが成立するのかはまだ理解されていない。

例えば、光子や Z ボゾン、クォークの KK 励起モードの質量、クォーク・レプトンの湯川結合の大きさ、ヒッグスボゾンの 3 点、4 点自己相互作用の大きさなどは、すべてアハロノフ・ボーム位相の値でほぼ決まる。位相が 0.1 より小さいと、湯川結合の標準模型からのずれを実験的に観測するのは難しい。LHC 実験で探索可能なのは、光子や Z ボゾンの KK 励起モード（Z'と呼ばれる）で、その質量は 6 TeV から 8 TeV の領域に予言される。これが発見されれば、アハロノフ・ボーム位相の値が決まり、他の物理量（ヒッグスボゾンの 3 点、4 点自己相互作用の大きさなど）に対する予言となる。Z' 事象の発見は、余剰次元探索の要である。

(4) 暗黒物質

理論の詳細に依存するが、SO(5)xU(1) ゲージ・ヒッグス統合理論は暗黒物質の存在を予言する。現在 CMB（宇宙背景マイクロ波）等の観測データから決められた暗黒物質の残存量を説明し、かつ、暗黒物質直接探索の制限を満たすためには、アハロノフ・ボーム位相の値は 0.07 から 0.1 で、暗黒物質候補となる粒子の質量は 2 TeV から 3 TeV の領域に予言される。現在稼働中の、あるいは次期にプランされている暗黒物質直接探索実験で見つかる可能性がある。

(5) ゲージ・ヒッグス統合の理論的精密化

ゲージ・ヒッグス統合は新しい可能性として理論的にも更なる精密化が必要である。林は、ゲージ・ヒッグス統合理論におけるフレーバ混合の仕組みを明らかにした。世代間での FCNC を自然に抑制ための方法が開発された。また、SU(3)モデルで、125 GeV というヒッグス質量を古典レベルで再現することが可能であることも示した。

(6) 新分野の創造

ゲージ・ヒッグス統合理論の基礎となるのが細谷機構による対称性の自発的破れである。通常のヒッグス機構とは異なり、純粋なゲージ相互作用の枠内で、力学的に量子論的に、ゲージ対称性が自発的に破れる。このメカニズムは、これまで、摂動論的に確かめられ、ゲージ・ヒッグス統合理論に応用されてきた。

細谷は、この細谷メカニズムによるゲージ対称性の力学的破れを格子ゲージ理論による数値シミュレーションで非摂動論的に検証できることを示した。格子ゲージ理論の専門家との共同事業である。格子 QCD 理論の技術を応用し、スーパーコンピュータを使い、随伴表現のフェルミオンを含む 4 次元の SU(3)ゲージ理論で、温度やフェルミオン質量が変化させ、Polyakov ループの固有値分布を見ることで、SU(3)ゲージ対称性が SU(2)xU(1) や、U(1)xU(1) 対称性に破れることを示してみせた。

非摂動論的にゲージ対称性の自発的破れを示したことは、将来の物理学に大きな影響を及ぼすものと期待される。また、計算機科学の新しい分野を切り開いたことも貴重である。

(7) インフレーション

標準模型の枠内で、ヒッグス場と重力の間に新しい結合があれば、プランクスケール近傍でインフレーションが起こりえることを尾田は示した。さらに、超弦理論において、ヒッグス場を弦の無質量モードと同定すると、場の値が大きな領域においては、ヒッグス・ポテンシャルは逃避真空に繋がっていることを示した。その結果、ヒッグス場が永遠のインフレーションの起源となっていることを示した。ヒッグス場の物理がプランクスケールの物理に繋がる事を示したのは非常に興味深い。

The decay rate of the Higgs decay $H \to Z\gamma$ is evaluated at the one-loop level in the $SO(5) \times U(1)$ gauge-Higgs unification. Although an infinite number of loops with Kaluza-Klein states contribute to the decay amplitude, there appears the cancellation among the loops, and the decay rate is found to be finite and nonzero. It is found that the decay rate is well approximated by the decay rate in the standard model multiplied by $\cos^2\theta_H$, where θ_H is the Aharonov-Bohm phase induced by the vacuum expectation value of an extra-dimensional component of the gauge field.

I. INTRODUCTION

The Higgs boson of a mass about 125 GeV has been found at LHC [1,2]. The signal strength of each decay mode of the Higgs boson has been consistent with the standard model (SM) [3,4]. Though the decay mode $H \to Z\gamma$ has not been observed so far, it is expected to be seen in the Run 2 at LHC. The decay rate $\Gamma(H \to Z\gamma)$ has been evaluated in the SM, [5] the two Higgs doublet model, [6] the minimal supersymmetric standard model, [6] and the universal extra dimension model [7], and the type-II seesaw model [8].

The gauge-Higgs unification (GHU) is one of the scenarios beyond the SM [9–17]. In GHU the 4D Higgs boson appears as part of the extra-dimensional component of the gauge potentials. When the extra-dimensional space is not simply connected, it is identified with the 4D fluctuation mode of the Aharonov-Bohm (AB) phase θ_H along the extra-dimensional space. The gauge invariance protects the Higgs boson from acquiring divergent mass corrections. The Higgs boson mass is generated at the quantum level, being finite and independent of the cutoff scales in the theory. Especially the $SO(5) \times U(1)$ GHU in the Randall-Sundrum (RS) space-time is phenomenologically successful [18–22]. The Higgs doublet appears in the $SO(5)/SO(4)$ part of the fifth dimensional component of the vector potentials with the custodial symmetry. The model is consistent with the LHC results for $\theta_H < 0.1$. The deviation of the decay rate $\Gamma(H \to \gamma\gamma)$ from the SM, for instance, is less than 1% [23], despite the fact that an infinite number of Kaluza-Klein (KK) mode of the W boson and top quark contribute. Z' events are expected as the excitation of the first KK modes of γ, Z and the lowest mode of Z_R, the neutral $SU(2)_R$ gauge boson. Their masses are almost degenerate, and are estimated to be in the range 4 to 8.5 TeV for $\theta_H = 0.15 \sim 0.07$ [24]. There also exists a dark matter candidate in the model, the lowest KK mode of $SO(5)$-spinor fermion called dark fermions [25]. Its mass is in the range of 2.3–3.1 TeV and the spin-independent scattering cross section per nucleon is $\sigma_N \simeq O(10^{-44})$ cm^2. It may be detected in the 300 live days run of the LUX experiment.

In this paper we focus on the decay mode $H \to Z\gamma$ in the $SO(5) \times U(1)$ GHU. The decay width of $H \to Z\gamma$ has been evaluated in the $SU(3)$ GHU model on flat $M^4 \times (S^1/Z_2)$ by Maru and Okada [26]. They found that it vanishes at the one loop level, due to the group structure of the $SU(3)$ model. In the $SO(5) \times U(1)$ GHU in RS, on the other hand, it is known that the gauge couplings of the SM particles are almost the same as in the SM so that one expects that the process $H \to Z\gamma$ occurs. Furthermore, as in the case of $H \to \gamma\gamma$, one needs to worry about the contributions coming from an infinite number of KK modes running in the loops. The situation in the case of $H \to Z\gamma$ is more involved than that in the case of $H \to \gamma\gamma$. In $H \to \gamma\gamma$, the KK number of virtual particles running the inside loop is conserved. In contrast, in the case of $H \to Z\gamma$, the KK number of virtual particles may change, as both H and Z have off-diagonal couplings in RS. This gives rise to an interesting question whether or not the sum of all these contributions converges. It seems to require more subtle cancellation mechanism to have a finite result than in the case of $H \to \gamma\gamma$. We demonstrate in this paper by direct evaluation that miraculous cancellation takes place among KK-number-conserving and KK-number-violating loops. After all, the deviation of the decay width from that in the SM is $O(1)$%.

The paper is organized as follows. In Sec. II, the model of the $SO(5) \times U(1)$ GHU is explained. In Sec. III, we review the decay rate of the $H \to \gamma\gamma$ and evaluate the decay rate of the $H \to Z\gamma$ process in the $SO(5) \times U(1)$ GHU. In Sec. IV, the conclusion and discussions are given. In the appendix, we summarize Z and H couplings of various fields which are necessary in calculating the $H \to Z\gamma$ decay rate.

II. MODEL

We consider the $SO(5) \times U(1)$ gauge-Higgs unification in the Randall-Sundrum (RS) warped space [27], whose metric is given by $ds^2 = G_{MN}dx^M dx^N = e^{-2\sigma(y)}\eta_{\mu\nu}dx^\mu dx^\nu + dy^2$,

 © 2015 American Physical Society

where $\eta_{\mu\nu}=\mathrm{diag}(-1,1,1,1)$, $\sigma(y)=\sigma(y+2L)=\sigma(-y)$, and $\sigma(y)=k|y|$ for $|y|\le L$. The Planck and TeV branes are located at $y=0$ and $y=L$, respectively. The bulk region $0<y<L$ is anti-de Sitter (AdS) spacetime with a cosmological constant $\Lambda=-6k^2$. The warp factor is $z_L\equiv e^{kL}\gg 1$, and the Kaluza-Klein mass scale is given by $m_{\mathrm{KK}}=\pi k/(z_L-1)\sim\pi k z_L^{-1}$. The model consists of $SO(5)\times U(1)_X$ gauge fields (A_M,B_M), quark-lepton multiplets Ψ_a, $SO(5)$-spinor fermions (dark fermions) Ψ_{F_i}, brane fermions $\hat{\chi}_{\alpha R}$, and brane scalar $\hat{\Phi}$ [22,23]. The model has been specified in Refs. [24,25]. The bulk part of the action is given by

$$
\begin{aligned}
S_{\mathrm{bulk}} &= \int d^5x\sqrt{-G}\Big[-\mathrm{tr}\left(\frac{1}{4}F^{(A)MN}F^{(A)}_{MN}+\frac{1}{2\xi}(f^{(A)}_{\mathrm{gf}})^2+\mathcal{L}^{(A)}_{\mathrm{gh}}\right)-\left(\frac{1}{4}F^{(B)MN}F^{(B)}_{MN}+\frac{1}{2\xi}(f^{(B)}_{\mathrm{gf}})^2+\mathcal{L}^{(B)}_{\mathrm{gh}}\right)\\
&\quad+\sum_a\bar{\Psi}_a\mathcal{D}(c_a)\Psi_a+\sum_{i=1}^{n_F}\bar{\Psi}_{F_i}\mathcal{D}(c_{F_i})\Psi_{F_i}\Big],\\
\mathcal{D}(c) &= \Gamma^A e_A{}^M\left(\partial_M+\frac{1}{8}\omega_{\mathrm{MBC}}[\Gamma^B,\Gamma^C]-ig_A A_M-ig_B Q_X B_M\right)-c\sigma'(y).
\end{aligned}
\tag{2.1}
$$

The gauge fixing and ghost terms are denoted as functionals with subscripts gf and gh, respectively. $F^{(A)}_{MN}=\partial_M A_N-\partial_N A_M-ig_A[A_M,A_N]$, and $F^{(B)}_{MN}=\partial_M B_N-\partial_N B_M$. The color $SU(3)_C$ gluon fields and their interactions have been suppressed. The $SO(5)$ gauge fields A_M are decomposed as

$$
A_M=\sum_{a_L=1}^{3}A_M^{a_L}T^{a_L}+\sum_{a_R=1}^{3}A_M^{a_R}T^{a_R}+\sum_{\hat{a}=1}^{4}A_M^{\hat{a}}T^{\hat{a}},\tag{2.2}
$$

where $T^{a_L,a_R}(a_L,a_R=1,2,3)$ and $T^{\hat{a}}(\hat{a}=1,2,3,4)$ are the generators of $SO(4)\simeq SU(2)_L\times SU(2)_R$ and $SO(5)/SO(4)$, respectively. The quark-lepton multiplets Ψ_a are introduced in the vector representation of $SO(5)$, whereas n_F dark fermions Ψ_{F_i} in the spinor representation with $Q_X=\frac{1}{2}$. The dimensionless parameter c, which gives a bulk kink mass, plays an important role in controlling profiles of fermion wave functions. $\bar{\Psi}=i\Psi^\dagger\Gamma^0$.

The orbifold boundary conditions at $y_0=0$ and $y_1=L$ are given by

$$
\begin{aligned}
\begin{pmatrix}A_\mu\\A_y\end{pmatrix}(x,y_j-y)&=P_{\mathrm{vec}}\begin{pmatrix}A_\mu\\-A_y\end{pmatrix}(x,y_j+y)P_{\mathrm{vec}}^{-1},\\
\begin{pmatrix}B_\mu\\B_y\end{pmatrix}(x,y_j-y)&=\begin{pmatrix}B_\mu\\-B_y\end{pmatrix}(x,y_j+y),\\
\Psi_a(x,y_j-y)&=P_{\mathrm{vec}}\Gamma^5\Psi_a(x,y_j+y),\\
\Psi_{F_i}(x,y_j-y)&=\eta_{F_i}(-1)^jP_{\mathrm{sp}}\Gamma^5\Psi_{F_i}(x,y_j+y),\quad \eta_{F_i}=\pm1,\\
P_{\mathrm{vec}}&=\mathrm{diag}(-1,-1,-1,-1,+1),\\
P_{\mathrm{sp}}&=\mathrm{diag}(+1,+1,-1,-1),
\end{aligned}
\tag{2.3}
$$

which reduce the $SO(5)\times U(1)_X$ symmetry to $SO(4)\times U(1)_X\simeq SU(2)_L\times SU(2)_R\times U(1)_X$. $SO(4)\times U(1)_X$ symmetry is spontaneously broken to $SU(2)_L\times U(1)_Y$ by the brane scalar $\hat{\Phi}$.

The 4D Higgs field appears as a zero mode in the $SO(5)/SO(4)$ part of the fifth dimensional component of the vector potential $A_y^{\hat{a}}(x,y)$ with custodial symmetry. Without loss of generality one can set $\langle A_y^{\hat{a}}\rangle\propto\delta^{a4}$ when the electroweak symmetry is spontaneously broken. The 4D neutral Higgs field $H(x)$ is a fluctuation mode of the Wilson line phase θ_H which is an Aharonov-Bohm phase in the fifth dimension;

$$
\begin{aligned}
A_y^{\hat{4}}(x,y)&=\{\theta_H f_H+H(x)\}u_H(y)+\cdots,\\
\exp\left\{\frac{i}{2}\theta_H\cdot2\sqrt{2}T^{\hat{4}}\right\}&=\exp\left\{ig_A\int_0^L dy\langle A_y\rangle\right\},\\
f_H&=\frac{2}{g_A}\sqrt{\frac{k}{z_L^2-1}}=\frac{2}{g_w}\sqrt{\frac{k}{L(z_L^2-1)}}.
\end{aligned}
\tag{2.4}
$$

Here the wave function of the 4D Higgs boson is given by $u_H(y)=[2k/(z_L^2-1)]^{1/2}e^{2ky}$ for $0\le y\le L$ and $u_H(-y)=u_H(y)=u_H(y+2L)$. $g_w=g_A/\sqrt{L}$ is the dimensionless 4D $SU(2)_L$ coupling.

III. $H\to Z\gamma$

The Higgs decay processes $H\to\gamma\gamma$ and $H\to Z\gamma$ are absent at the tree level and occur at the one loop level. In the $SO(5)\times U(1)$ GHU not only the W boson, quarks and leptons in SM but also their KK modes and additional gauge bosons and dark fermions contribute to the processes. We show that these corrections are finite and small in the $SO(5)\times U(1)$ GHU, thanks to the cancellation among them.

A. $\Gamma(H\to\gamma\gamma)$

We shortly review the decay process $H\to\gamma\gamma$ in the $SO(5)\times U(1)$ GHU model. [23] We follow the notation of Ref. [6]. The decay rate in the SM is given by

$$\Gamma(H \to \gamma\gamma)_{\rm SM} = \frac{\alpha^2 g_w^2}{1024\pi^3}\frac{m_H^3}{m_W^2}\left|\sum_i N_{ci} e_i^2 F_i(\tau_i)\right|^2,$$
$$\tau_i = \frac{4m_i^2}{m_H^2}, \tag{3.1}$$

where N_{ci} is the number of the color degrees of freedom and e_i is the electromagnetic charge in units of e. Functions $F_1(\tau)$ and $F_{1/2}(\tau)$ are assigned for gauge bosons and fermions, respectively, and defined by

$$F_1(\tau) = 2 + 3\tau + 3\tau(2-\tau)f(\tau),$$
$$F_{1/2}(\tau) = -2\tau[1 + (1-\tau)f(\tau)],$$
$$f(\tau) = \begin{cases} [\sin^{-1}(\sqrt{1/\tau})]^2 & \text{for } \tau \geq 1, \\ -\frac{1}{4}\left[\ln\frac{1+\sqrt{1-\tau}}{1-\sqrt{1-\tau}} - i\pi\right]^2 & \text{for } \tau < 1. \end{cases} \tag{3.2}$$

In the large τ limit $F_{1/2} \to -\frac{4}{3}$ and $F_1 \to 7$.

In the $SO(5)\times U(1)$ GHU model, KK numbers are conserved by the electromagnetic interactions. The decay rate in the GHU becomes

$$\Gamma(H \to \gamma\gamma) = \frac{\alpha^2 g_w^2}{1024\pi^3}\frac{m_H^3}{m_W^2}\left|\mathcal{F}_W + \frac{4}{3}\mathcal{F}_t + n_F\mathcal{F}_F\right|^2, \tag{3.3}$$

where

$$\mathcal{F}_W = \sum_{n=0}^{\infty}\frac{g_{HW^{(n)}W^{(n)}}}{g_w m_W}\frac{m_W^2}{m_{W^{(n)}}^2}F_1(\tau_{W^{(n)}}) = \sum_{n=0}^{\infty} I_{W^{(n)}}\frac{m_W}{m_{W^{(n)}}}\cos\theta_H F_1(\tau_{W^{(n)}}),$$
$$\mathcal{F}_t = \sum_{n=0}^{\infty}\frac{y_{Ht^{(n)}t^{(n)}}}{y_t^{\rm SM}}\frac{m_t}{m_{t^{(n)}}}F_{1/2}(\tau_{t^{(n)}}) = \sum_{n=0}^{\infty} I_{t^{(n)}}\frac{m_t}{m_{t^{(n)}}}\cos\theta_H F_{1/2}(\tau_{t^{(n)}}),$$
$$\mathcal{F}_F = \sum_{n=1}^{\infty}\frac{y_{HF^{(n)}F^{(n)}}}{y_t^{\rm SM}}\frac{m_t}{m_{F^{(n)}}}F_{1/2}(\tau_{F^{(n)}}) = \sum_{n=1}^{\infty} I_{F^{(n)}}\frac{m_t}{m_{F^{(n)}}}\sin\frac{\theta_H}{2}F_{1/2}(\tau_{F^{(n)}}). \tag{3.4}$$

Here $I_{W^{(n)}}$, $I_{t^{(n)}}$, and $I_{F^{(n)}}$ are defined as $I_{W^{(n)}} = g_{HW^{(n)}W^{(n)}}/g_w m_{W^{(0)}}\cos\theta_H$, $I_{t^{(n)}} = y_{Ht^{(n)}t^{(n)}}/y_t^{\rm SM}\cos\theta_H$, and $I_{F^{(n)}} = y_{HF^{(n)}F^{(n)}}/y_t^{\rm SM}\sin\frac{\theta_H}{2}$. Contributions from light quarks and leptons and their KK modes are negligible.

In Fig. 1, the values of $I_{W^{(n)}}$, $I_{t^{(n)}}$, and $I_{F^{(n)}}$ by the numerical calculation in the $N_F = 4$ and $\theta_H = 0.1153$ case are shown. They approximately behave as

$$I_{W^{(n)}} \simeq (-1)^n\{0.0759 - 0.0065\ln n + 0.0022(\ln n)^2\},$$
$$I_{t^{(n)}} \simeq (-1)^n\{0.2304 - 0.0108\ln n + 0.0017(\ln n)^2\},$$
$$I_{F^{(n)}} \simeq (-1)^n\{1.0341 - 0.0457\ln n + 0.0108(\ln n)^2\} \tag{3.5}$$

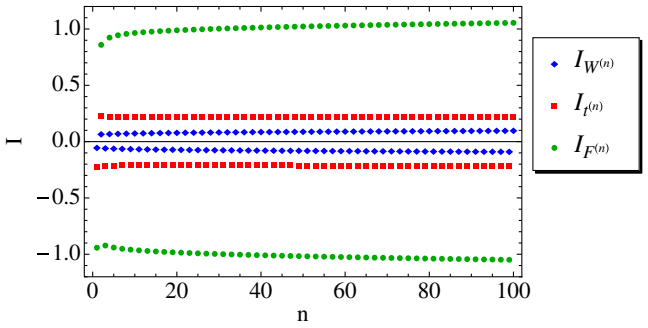

FIG. 1 (color online). Behaviors of $I_{W^{(n)}} = g_{HW^{(n)}W^{(n)}}/g_w m_{W^{(n)}}\cos\theta_H$, $I_{t^{(n)}} = y_{Ht^{(n)}t^{(n)}}/y_t^{\rm SM}\cos\theta_H$ and $I_{F^{(n)}} = y_{HF^{(n)}F^{(n)}}/y_t^{\rm SM}\sin\frac{\theta_H}{2}$ in the case of $n_F = 4$, $z_L = 10^5$ for which $\theta_H = 0.1153$.

for $50 \leq n \leq 200$. Note that the sign alternates in n. As the masses of the KK modes of the W boson, top quark and dark fermion are $m_n \simeq n \cdot m_{\rm KK}/2$, the sum in each $\mathcal{F}$ behaves as $\sum(-1)^n(\ln n)^\alpha/n$ ($\alpha = 0, 1, 2$) and converges. Moreover, the contributions from $n \geq 1$ are suppressed by the ratio of the electroweak scale to the KK scale. Hence the ratio of $\mathcal{F}$ to the zero-mode contribution becomes

$$\frac{\mathcal{F}_W}{\mathcal{F}_{W^{(0)}\rm only}} = 0.9997,$$
$$\frac{\mathcal{F}_t}{\mathcal{F}_{t^{(0)}\rm only}} = 0.9983,$$
$$\frac{\mathcal{F}_F}{\mathcal{F}_{t^{(0)}\rm only}} = -0.0032, \tag{3.6}$$

for $\theta_H = 0.114$ and $n_F = 4$. The ratio of the amplitude to that with only zero modes is

$$\frac{\mathcal{F}_W + \frac{4}{3}\mathcal{F}_t + 4\mathcal{F}_F}{\mathcal{F}_{W^{(0)}\rm only} + \frac{4}{3}\mathcal{F}_{t^{(0)}\rm only}} = 1.0027. \tag{3.7}$$

It is found that the contributions of the KK modes are less than 1% and negligible. The couplings of the zero modes are approximately given by $g_{HWW} \simeq g_{HWW}^{\rm SM}\cos\theta_H = g_w m_W\cos\theta_H$ and $y_t \simeq y_t^{\rm SM}\cos\theta_H$. Therefore the decay rate in the GHU is approximately $\cos^2\theta_H$ times that in the standard model. The deviation from the standard model amounts only 1% for $\theta_H \sim 0.1$.

B. Gauge boson loops

The decay process $H \to Z\gamma$ is more involved than $H \to \gamma\gamma$. The KK number need not be conserved at the Z and H vertices, and $W_R^{(n)}$ also participates. The gauge boson loop processes for $H \to Z\gamma$ are shown in Fig. 2. We note that $HW_R^{(m)}W_R^{(n)}$ couplings vanish. The amplitude of W boson loop Figs. 2(a)–(c) is given in the unitary gauge by

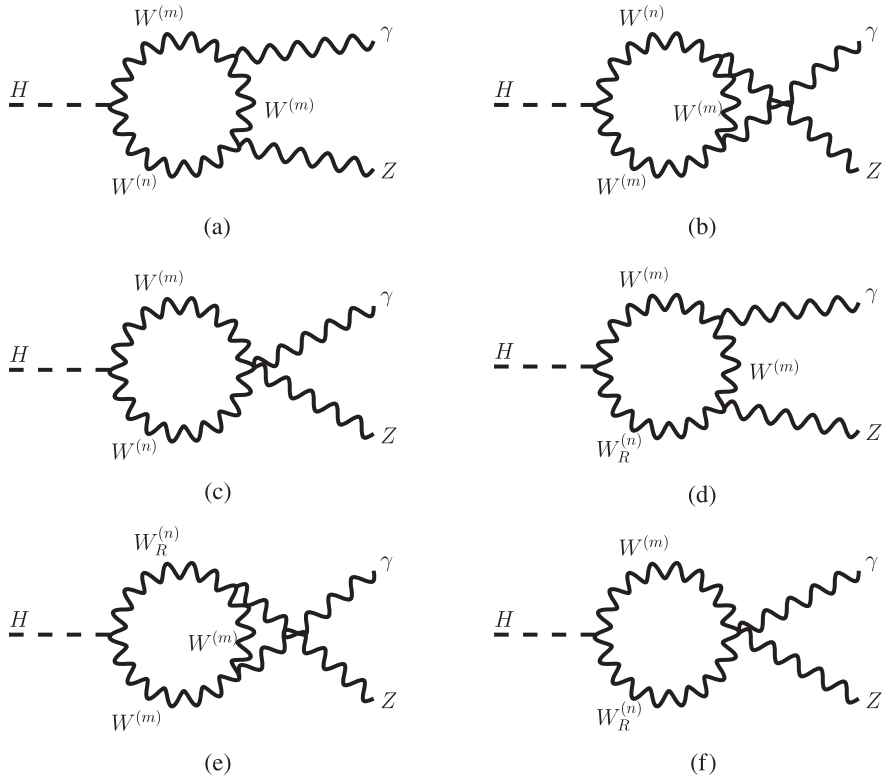

FIG. 2. The gauge boson loop processes for $H \to Z\gamma$ in the $SO(5) \times U(1)$ gauge-Higgs unification. W_R is the $SU(2)_R$ gauge boson and has no zero mode. Since $HW_R^{(m)}W_R^{(n)}$ couplings vanish, there are no diagrams involving two or more W_R' s.

$$
\begin{aligned}
i\mathcal{M}^{(a)}_{W^{(m)},W^{(n)}} + i\mathcal{M}^{(b)}_{W^{(m)},W^{(n)}} + i\mathcal{M}^{(c)}_{W^{(m)},W^{(n)}} &= e g_{HW^{(m)}W^{(n)}} g_{ZW^{(m)}W^{(n)}} \epsilon^*_\mu(k_1)\epsilon^*_\nu(k_2) \int \frac{d^4p}{(2\pi)^4} D_{\tau\alpha}(p, m_{W^{(m)}}) D_\sigma{}^\tau(p-k_1-k_2, m_{W^{(n)}}) \\
&\quad \times [2D_{\beta\rho}(p-k_1, m_{W^{(m)}})\{2\eta^{\alpha\beta}p^\mu - \eta^{\beta\mu}(p-2k_1)^\alpha - \eta^{\alpha\mu}(p+k_1)^\beta\} \\
&\quad \times \{2\eta^{\rho\sigma}(p-k_1)^\nu - \eta^{\sigma\nu}(p-k_1-2k_2)^\rho - \eta^{\rho\nu}(p-k_1+k_2)^\sigma\} \\
&\quad - (2\eta^{\mu\nu}\eta^{\alpha\sigma} - \eta^{\mu\alpha}\eta^{\nu\sigma} - \eta^{\mu\sigma}\eta^{\nu\alpha})], \\
D_{\mu\nu}(p,m) &= \left(\eta_{\mu\nu} - \frac{p_\mu p_\nu}{m^2}\right) \frac{1}{p^2 - m^2 + i\epsilon},
\end{aligned} \tag{3.8}
$$

where k_1 and k_2 are the photon and the Z boson momenta, respectively. The amplitude (3.8) itself is divergent. However, by adding the $m \leftrightarrow n$ diagrams and using $g_{HW^{(m)}W^{(n)}} = g_{HW^{(n)}W^{(m)}}$ and $g_{ZW^{(m)}W^{(n)}} = g_{ZW^{(n)}W^{(m)}}$, the amplitude becomes

$$
\begin{aligned}
&i\{\mathcal{M}^{(a)}_{W^{(m)},W^{(n)}} + \mathcal{M}^{(b)}_{W^{(m)},W^{(n)}} + \mathcal{M}^{(c)}_{W^{(m)},W^{(n)}} + (m \longleftrightarrow n)\} \\
&= e g_{HW^{(m)}W^{(n)}} g_{ZW^{(m)}W^{(n)}} \epsilon^*_\mu(k_1)\epsilon^*_\nu(k_2) \left(\eta^{\mu\nu} - \frac{k_2^\mu k_1^\nu}{k_1\cdot k_2}\right) \frac{i}{16\pi^2} \frac{1}{m^2_{W^{(m)}} m^2_{W^{(n)}}} \{(m^4_{W^{(m)}} + m^4_{W^{(n)}} + 10 m^2_{W^{(m)}} m^2_{W^{(n)}}) E_+(m_{W^{(m)}}, m_{W^{(n)}}) \\
&\quad + ((m^2_{W^{(m)}} + m^2_{W^{(n)}})(m_H^2 - m_Z^2) - m_H^2 m_Z^2) E_-(m_{W^{(m)}}, m_{W^{(n)}}) - (4 m^2_{W^{(m)}} m^2_{W^{(n)}}(m_H^2 - m_Z^2) + 2m_Z^4(m^2_{W^{(m)}} + m^2_{W^{(n)}})) \\
&\quad \times (C_0(m_{W^{(m)}}, m_{W^{(n)}}) + C_0(m_{W^{(n)}}, m_{W^{(m)}}))\}
\end{aligned} \tag{3.9}
$$

where

$$
\begin{aligned}
C_0(m_1^2, m_2^2) &\equiv C_0(0, m_H^2, m_Z^2, m_1^2, m_1^2, m_2^2), \\
E_\pm(m_1, m_2) &\equiv 1 + \frac{m_Z^2}{m_H^2 - m_Z^2}\{B_0(m_H^2, m_1^2, m_2^2) - B_0(m_Z^2, m_1^2, m_2^2)\} \pm \{m_1^2 C_0(m_1^2, m_2^2) + m_2^2 C_0(m_2^2, m_1^2)\},
\end{aligned} \tag{3.10}
$$

TABLE I. $J_{W^{(m)}W^{(n)}}$ defined in (3.12) is shown for $0 \le m, n \le 7$ and for $101 \le m, n \le 108$ in the $N_F = 4$, $z_L = 10^5$ case. Only the values larger than that of $O(10^{-4})$ are shown with three significant figures.

with the Passarino-Veltman functions [28,29] defined by

$$B_0(k^2, m_1^2, m_2^2) \equiv \frac{(2\pi)^{4-D}}{i\pi^2} \int d^D q \frac{1}{(q^2 - m_1^2)\{(q+k)^2 - m_2^2\}},$$
$$C_0(k_1^2, (k_1 - k_2)^2, k_2^2, m_1^2, m_2^2, m_3^2) \equiv \frac{1}{i\pi^2} \int d^D q \frac{1}{(q^2 - m_1^2)\{(q+k_1)^2 - m_2^2\}\{(q+k_2)^2 - m_3^2\}}. \tag{3.11}$$

For all C_0 and $E_\pm$, the $D \to 4$ limit has been safely taken, so that the amplitude (3.9) is finite.

To obtain the amplitude quantitatively, the numerical values of the couplings $g_{HW^{(m)}W^{(n)}}$ and $g_{ZW^{(m)}W^{(n)}}$ have to be evaluated. The details of evaluation and results are summarized in Appendix. It is convenient to define the dimensionless coupling $J_{W^{(m)}W^{(n)}}$ by

$$J_{W^{(m)}W^{(n)}} \equiv \frac{g_{HW^{(m)}W^{(n)}} g_{ZW^{(m)}W^{(n)}}}{g_w^2 \cos\theta_W \cos\theta_H \sqrt{m_{W^{(m)}} m_{W^{(n)}}}}. \tag{3.12}$$

The value of $J_{W^{(m)}W^{(n)}}$ is tabulated in Table I. It is seen that $J_{W^{(m)}W^{(n)}}$ with $|m-n| \ge 2$ is smaller than $J_{W^{(n)}W^{(n)}}$ by a factor 10^{-2}, whereas $J_{W^{(n\pm1)}W^{(n)}}$ and $J_{W^{(n)}W^{(n)}}$ are of the same order. $J_{W^{(n)}W^{(n)}}$ and $J_{W^{(n)}W^{(n+1)}}$ are plotted in Fig. 3 for $1 \le n \le 100$ in the $N_F = 4$, $z_L = 10^5$ case. $J_{W^{(n)}W^{(n+1)}}$ and $J_{W^{(n)}W^{(n)}}$ for $101 \le n \le 200$ are approximately given by

$$J_{W^{(n)}W^{(n)}} \simeq -0.0272 + 0.00320(\ln n) - 0.00083(\ln n)^2 + (-1)^{n-1}(-0.0563 + 0.00654(\ln n) - 0.00173(\ln n)^2),$$
$$J_{W^{(n)}W^{(n+1)}} \simeq 0.0135 - 0.00160(\ln n) + 0.00041(\ln n)^2 + (-1)^{n-1}(0.0567 - 0.00106(\ln n) + 0.00018(\ln n)^2). \tag{3.13}$$

Next we examine the asymptotic behavior of the amplitude for $m, n \gg 1$. The whole amplitude of the W boson loop is

$$i\mathcal{M}_W = \frac{i}{2} \sum_{m,n}^{\infty} \{\mathcal{M}^{(a)}_{W^{(m)},W^{(n)}} + \mathcal{M}^{(b)}_{W^{(m)},W^{(n)}} + \mathcal{M}^{(c)}_{W^{(m)},W^{(n)}} + (n \longleftrightarrow m)\}. \tag{3.14}$$

The diagonal part of the amplitude in (3.14) for $n \gg 1$ is rewritten as

$$
\begin{aligned}
&i\mathcal{M}^{(a)}_{W^{(n)},W^{(n)}} + i\mathcal{M}^{(b)}_{W^{(n)},W^{(n)}} + i\mathcal{M}^{(c)}_{W^{(n)},W^{(n)}} \\
&\quad = eg_w^2 \cos\theta_W \cos\theta_H \epsilon_\mu^*(k_1)\epsilon_\nu^*(k_2)\left(\eta^{\mu\nu} - \frac{k_2^\mu k_1^\nu}{k_1\cdot k_2}\right)\frac{i}{16\pi^2}\frac{J_{W^{(n)}W^{(n)}}}{2m^3_{W^{(n)}}} \\
&\qquad \times \left\{-\frac{m_H^2 - m_Z^2}{2m^2_{W^{(n)}}}(12m^4_{W^{(n)}} + 2m^2_{W^{(n)}}(m_H^2 - m_Z^2) - m_H^2 m_Z^2) I_1(\tau_{W^{(n)}}, \lambda_{W^{(n)}})\right. \\
&\qquad \left. + 4(4m^2_{W^{(n)}}(m_H^2 - m_Z^2) - m_H^2 m_Z^2 + m_Z^4) I_2(\tau_{W^{(n)}}, \lambda_{W^{(n)}})\right\},
\end{aligned} \tag{3.15}
$$

where

$$
\begin{aligned}
I_1(a,b) &= \frac{ab}{2(a-b)} + \frac{a^2b^2}{2(a-b)^2}[f(a) - f(b)] + \frac{a^2 b}{(a-b)^2}[g(a) - g(b)], \\
I_2(a,b) &= -\frac{ab}{2(a-b)}[f(a) - f(b)], \\
g(\tau) &= \begin{cases} \sqrt{\tau - 1}\sin^{-1}(\sqrt{1/\tau}) & \text{for } \tau \geq 1, \\ \frac{1}{2}\sqrt{1-\tau}\left[\ln\frac{1+\sqrt{1-\tau}}{1-\sqrt{1-\tau}} - i\pi\right] & \text{for } \tau < 1. \end{cases}
\end{aligned} \tag{3.16}
$$

and $\lambda_i \equiv 4m_i^2/m_Z^2$. τ_i and $f(a)$ are defined in (3.1) and (3.2). Here, we have used

$$
\begin{aligned}
&\frac{m_Z^2}{m_H^2 - m_Z^2}(B_0(m_H^2, m^2_{W^{(n)}}, m^2_{W^{(n)}}) - B_0(m_Z^2, m^2_{W^{(n)}}, m^2_{W^{(n)}})) = -1 - \frac{m_H^2 - m_Z^2}{2m^2_{W^{(n)}}} I_1(\tau_{W^{(n)}}, \lambda_{W^{(n)}}) + 2I_2(\tau_{W^{(n)}}, \lambda_{W^{(n)}}), \\
&C_0(0, m_H^2, m_Z^2, m^2_{W^{(n)}}, m^2_{W^{(n)}}, m^2_{W^{(n)}}) = -\frac{1}{m^2_{W^{(n)}}} I_2(\tau_{W^{(n)}}, \lambda_{W^{(n)}}).
\end{aligned} \tag{3.17}
$$

The functions I_1, I_2 in (3.17) approach constants for $m_{W^{(n)}} \to \infty$. Since $J_{W^{(m)}W^{(n)}}$ for $|m-n| \geq 2$ are negligible comparing to $J_{W^{(m)}W^{(n)}}$ for $|m-n| \leq 1$, only the amplitude for $|m-n| \leq 1$ need to be retained. For $n \gg 1$ $m_{W^{(n\pm1)}} \simeq m_{W^{(n)}}$ so that

$$
\begin{aligned}
&\frac{1}{2}\sum_m (i\mathcal{M}^{(a)}_{W^{(m)},W^{(n)}} + i\mathcal{M}^{(b)}_{W^{(m)},W^{(n)}} + i\mathcal{M}^{(c)}_{W^{(m)},W^{(n)}} + (n \longleftrightarrow m)) \\
&\quad \simeq eg_w^2 \cos\theta_W \cos\theta_H \epsilon_\mu^*(k_1)\epsilon_\nu^*(k_2)\left(\eta^{\mu\nu} - \frac{k_2^\mu k_1^\nu}{k_1\cdot k_2}\right)\frac{i}{16\pi^2}\frac{1}{2m^3_{W^{(n)}}}(J_{W^{(n)}W^{(n)}} + J_{W^{(n+1)}W^{(n)}} + J_{W^{(n-1)}W^{(n)}}) \\
&\qquad \times \left\{-\frac{m_H^2 - m_Z^2}{2m^2_{W^{(n)}}}(12m^4_{W^{(n)}} + 2m^2_{W^{(n)}}(m_H^2 - m_Z^2) - m_H^2 m_Z^2) I_1(\tau_{W^{(n)}}, \lambda_{W^{(n)}}) + 4(4m^2_{W^{(n)}}(m_H^2 - m_Z^2)\right. \\
&\qquad \left. - m_H^2 m_Z^2 + m_Z^4) I_2(\tau_{W^{(n)}}, \lambda_{W^{(n)}})\right\} \\
&\quad \approx \text{const} \times \frac{1}{n}(J_{W^{(n)}W^{(n)}} + J_{W^{(n+1)}W^{(n)}} + J_{W^{(n-1)}W^{(n)}}).
\end{aligned} \tag{3.18}
$$

Therefore the large n part of the sum in the whole amplitude of W boson loop is approximated as

$$
i\mathcal{M}_W \approx \sum_n^\infty \text{const} \times \frac{1}{n}(J_{W^{(n)}W^{(n)}} + J_{W^{(n+1)}W^{(n)}} + J_{W^{(n-1)}W^{(n)}}). \tag{3.19}
$$

Even though the sums $\sum J_{W^{(n)}W^{(n)}}/n$ and $\sum J_{W^{(n\pm1)}W^{(n)}}/n$ diverge individually, the combination $\sum (J_{W^{(n)}W^{(n)}} + J_{W^{(n+1)}W^{(n)}} + J_{W^{(n-1)}W^{(n)}})/n$ converges since

$$
J_{W^{(n)}W^{(n)}} + J_{W^{(n+1)}W^{(n)}} + J_{W^{(n-1)}W^{(n)}} \simeq (-1)^{n-1}\{-0.0563 + 0.00654(\ln n) - 0.00173(\ln n)^2\}. \tag{3.20}
$$

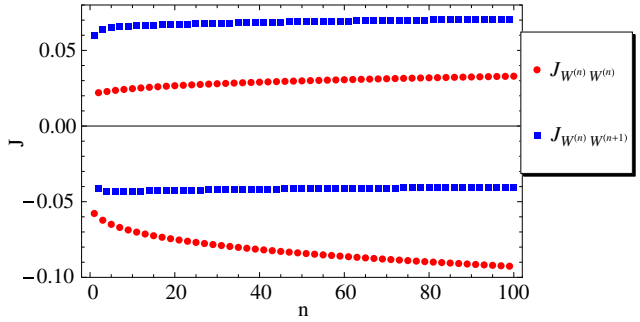

FIG. 3 (color online). $J_{W^{(n)}W^{(n)}}$ and $J_{W^{(n)}W^{(n+1)}}$ are plotted for $1 \le n \le 100$ in the $N_F = 4$, $z_L = 10^5$ case. The red circles and blue squares represent $J_{W^{(n)}W^{(n)}}$ and $J_{W^{(n)}W^{(n+1)}}$, respectively.

Next we consider the amplitudes which contain W_R in the loop. The amplitude $i\mathcal{M}^{(d)}_{W^{(m)},W_R^{(n)}} + i\mathcal{M}^{(e)}_{W^{(m)},W_R^{(n)}} + i\mathcal{M}^{(f)}_{W^{(m)},W_R^{(n)}}$ is obtained from (3.8) by replacing $W^{(n)}$ by $W_R^{(n)}$. The dimensionless coupling $J_{W^{(m)}W_R^{(n)}}$ is also defined as

$$J_{W^{(m)}W_R^{(n)}} \equiv \frac{g_{HW^{(m)}W_R^{(n)}} g_{ZW^{(m)}W_R^{(n)}}}{g_w^2 \cos\theta_W \cos\theta_H \sqrt{m_{W^{(m)}} m_{W_R^{(n)}}}}. \tag{3.21}$$

As is seen in the Table II, $J_{W^{(m)}W_R^{(n)}}$ is appreciable only when $m/2 - n = 0, 1, 2$. Note that $m_{W_R^{(n)}} \simeq n \cdot m_{\mathrm{KK}}$ while $m_{W^{(n)}} \simeq n \cdot m_{\mathrm{KK}}/2$. For $m/2 - n = 0,\ 1,\ 2$, $m_{W^{(m)}} \simeq m_{W^{(n)}} \simeq n \cdot m_{\mathrm{KK}}$ is satisfied. Hence the whole amplitude of the $W - W_R$ boson loop is

$$\begin{aligned} i\mathcal{M}_{W_R} &= \sum_{m,n}^{\infty} (i\mathcal{M}^{(d)}_{W^{(m)},W_R^{(n)}} + i\mathcal{M}^{(e)}_{W^{(m)},W_R^{(n)}} + i\mathcal{M}^{(f)}_{W^{(m)},W_R^{(n)}} \\ &\quad + i\mathcal{M}^{(d)}_{W_R^{(n)},W^{(m)}} + i\mathcal{M}^{(e)}_{W_R^{(n)},W^{(m)}} + i\mathcal{M}^{(f)}_{W_R^{(n)},W^{(m)}}) \\ &\approx \sum_{n}^{\infty} \mathrm{const} \times \frac{1}{n} (J_{W^{(n)}W_R^{(n/2)}} + J_{W^{(n)}W_R^{(n/2+1)}} \\ &\quad + J_{W^{(n)}W_R^{(n/2+2)}}). \end{aligned} \tag{3.22}$$

$J_{W^{(n)}W_R^{(n/2)}}$, $J_{W^{(n)}W_R^{(n/2+1)}}$ and $J_{W^{(n)}W_R^{(n/2+2)}}$ are plotted in Fig. 4 for $1 \le n \le 100$ in the $N_F = 4$, $z_L = 10^5$ case. $J_{W^{(n)}W_R^{(n/2)}}$, $J_{W^{(n)}W_R^{(n/2+1)}}$, $J_{W^{(n)}W_R^{(n/2+2)}}$ are approximated in this range by

$$\begin{aligned} J_{W^{(n)}W_R^{(n/2)}} &\simeq -0.0425 - 0.00268(\ln n) + 0.00023(\ln n)^2 \\ J_{W^{(n)}W_R^{(n/2+1)}} &\simeq 0.0411 + 0.00227(\ln n) - 0.00019(\ln n)^2 \\ J_{W^{(n)}W_R^{(n/2+2)}} &\simeq 0.0021 + 0.00017(\ln n) - 0.00001(\ln n)^2. \end{aligned} \tag{3.23}$$

$J_{W^{(n)}W_R^{(n/2)}} + J_{W^{(n)}W_R^{(n/2+1)}} + J_{W^{(n)}W_R^{(n/2+2)}}$ is small, and almost vanishes within numerical errors.

C. Fermion loops

Contributions of fermion loops to $\Gamma(H \to Z\gamma)$ are evaluated similarly. Top quark, charged dark fermions, and their KK excitations give substantial contributions as shown in Fig. 5, whereas contributions from other quarks and leptons are negligible.

The diagrams of fermion loops Fig. 5 (a, b) [or (c,d)], with generic fermions $f^{(m)}$, yield

TABLE II. $J_{W^{(m)}W_R^{(n)}}$ in (3.21) is shown for $0 \le m \le 7$, $1 \le n \le 4$ and for $101 \le m \le 108$, $51 \le n \le 55$ in the $N_F = 4$, $z_L = 10^5$ case. Only values larger than $O(10^{-4})$ are shown explicitly with three significant figures.

$$
\begin{aligned}
i\mathcal{M}^{(a)}_{f^{(m)},f^{(n)}} + i\mathcal{M}^{(b)}_{f^{(m)},f^{(n)}} = & -Q_f e\epsilon^*_\mu(k_1)\epsilon^*_\nu(k_2)\int\frac{d^4p}{(2\pi)^4}\frac{1}{p^2-m^2_{f^{(m)}}}\frac{1}{(p-k_1)^2-m^2_{f^{(m)}}}\frac{1}{(p-k_1-k_2)^2-m^2_{f^{(n)}}} \\
& \times \mathrm{Tr}[(y_{f^{(m)}f^{(n)}}+\hat{y}_{f^{(m)}f^{(n)}}\gamma^5)(\not{p}+m_{f^{(m)}})\gamma^\mu(\not{p}-\not{k}_1+m_{f^{(m)}})\gamma^\nu(g^V_{Zf^{(m)}f^{(n)}}+g^A_{Zf^{(m)}f^{(n)}}\gamma^5) \\
& \times(\not{p}-\not{k}_1-\not{k}_2+m_{f^{(n)}})+(y_{f^{(m)}f^{(n)}}+\hat{y}_{f^{(n)}f^{(m)}}\gamma^5)(-\not{p}+\not{k}_1+\not{k}_2+m_{f^{(n)}})\gamma^\nu \\
& \times(g^V_{Zf^{(m)}f^{(n)}}+g^A_{Zf^{(n)}f^{(m)}}\gamma^5)(-\not{p}+\not{k}_1+m_{f^{(m)}})\gamma^\mu(-\not{p}+m_{f^{(m)}})]. \qquad (3.24)
\end{aligned}
$$

The Yukawa couplings $y_{f^{(m)}f^{(n)}}$ and $\hat{y}_{f^{(m)}f^{(n)}}$ for $f^{(m)}=t^{(m)}$ and $F^{(m)}$ are given in (A25) and (A31), respectively. The amplitude (3.24) itself involves divergent integrals, but by adding the $m\leftrightarrow n$ diagrams and making use of $y_{f^{(m)}f^{(n)}}=y_{f^{(n)}f^{(m)}}$ and $\hat{y}_{f^{(m)}f^{(n)}}=-\hat{y}_{f^{(n)}f^{(m)}}$, one finds that

$$
\begin{aligned}
i\mathcal{M}^{(a)}_{f^{(m)},f^{(n)}} + i\mathcal{M}^{(b)}_{f^{(m)},f^{(n)}} + (m\leftrightarrow n) = & -\frac{iQ_f e}{4\pi^2}\epsilon^*_\mu(k_1)\epsilon^*_\nu(k_2)\left(\eta^{\mu\nu}-\frac{k_2^\mu k_1^\nu}{k_1\cdot k_2}\right)\{y_{f^{(m)}f^{(n)}}g^V_{Zf^{(m)}f^{(n)}}G_+(m_{f^{(m)}},m_{f^{(n)}}) \\
& -\hat{y}_{f^{(m)}f^{(n)}}g^A_{Zf^{(m)}f^{(n)}}G_-(m_{f^{(m)}},m_{f^{(n)}})\}, \\
G_\pm(m_1,m_2) = & \, 2(m_1\pm m_2)+\frac{2m_Z^2(m_1\pm m_2)}{m_H^2-m_Z^2}(B_0(m_H^2,m_1^2,m_2^2)-B_0(m_Z^2,m_1^2,m_2^2)) \\
& +m_1(2m_1^2\pm 2m_1m_2-m_H^2+m_Z^2)C_0(0,m_H^2,m_Z^2,m_1^2,m_1^2,m_2^2) \\
& \pm m_2(2m_2^2\pm 2m_1m_2-m_H^2+m_Z^2)C_0(0,m_H^2,m_Z^2,m_2^2,m_2^2,m_1^2). \qquad (3.25)
\end{aligned}
$$

In this form the amplitude is finite.

We define $J_{t^{(m)}t^{(n)}}$ and $J_{F^{+(m)}F^{+(n)}}$ by

$$
J_{t^{(m)}t^{(n)}} \equiv \frac{g^V_{Zt^{(m)}t^{(n)}}y_{t^{(m)}t^{(n)}}\cos\theta_W}{g_w y_t\cos\theta_H}, \qquad (3.26)
$$

$$
J_{F^{+(m)}F^{+(n)}} \equiv \frac{g^V_{ZF^{+(m)}F^{+(n)}}y_{F^{(m)}F^{(n)}}\cos\theta_W}{g_w y_t\sin\frac{\theta_H}{2}}. \qquad (3.27)
$$

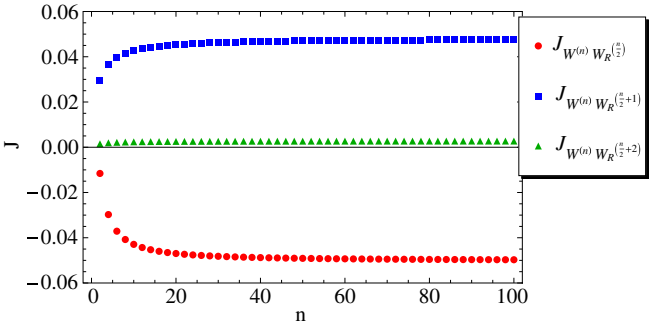

FIG. 4 (color online). $J_{W^{(n)}W_R^{(n/2)}}$, $J_{W^{(n)}W_R^{(n/2+1)}}$ and $J_{W^{(n)}W_R^{(n/2+2)}}$ are plotted for $1\le n\le 100$ in the $N_F=4$, $z_L=10^5$ case. The red circles, blue squares, green triangles represent $J_{W^{(n)}W_R^{(n/2)}}$, $J_{W^{(n)}W_R^{(n/2+1)}}$ and $J_{W^{(n)}W_R^{(n/2+2)}}$, respectively.

In the Tables III and IV, $J_{t^{(m)}t^{(n)}}$ and $J_{F^{+(m)}F^{+(n)}}$ by the numerical evaluation are shown. As in the case of $J_{W^{(n)}W^{(n)}}$, $J_{t^{(m)}t^{(n)}}$ and $J_{F^{+(m)}F^{+(n)}}$ for $|m-n|\ge 2$ become negligible for $m,\ n>100$. In addition, the terms proportional to

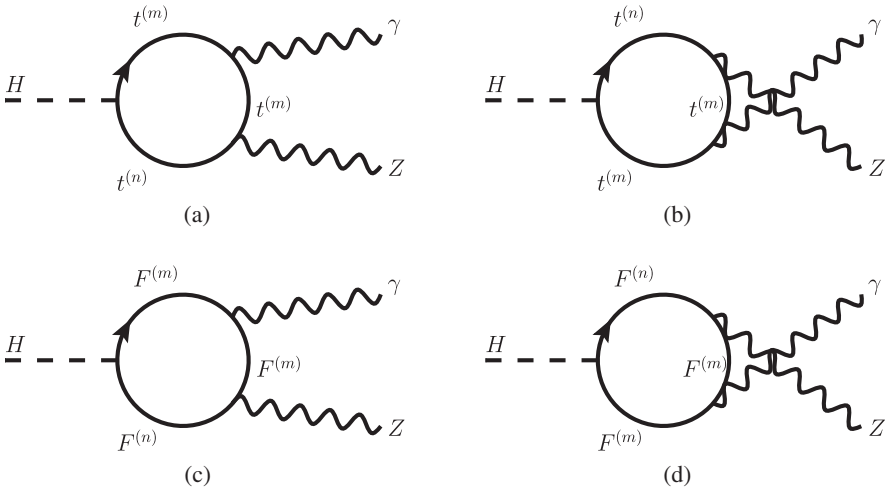

FIG. 5. The fermion loop processes of $H\to Z\gamma$ decay in the $SO(5)\times U(1)$ gauge-Higgs unification. F^+ is the charged dark fermion which does not have a zero mode.

TABLE III. $J_{t^{(m)}t^{(n)}}$ is shown for $0 \le m, n \le 7$ and for $101 \le m, n \le 108$ in the $N_F = 4$, $z_L = 10^5$ case. Only the values larger than $O(10^{-4})$ are shown with three significant figures.

$\hat{y}_{f^{(m)}f^{(n)}} g^A_{Zf^{(m)}f^{(n)}}$ are negligible around $m, n = 100$. The ratio $(\hat{y}_{f^{(m)}f^{(n)}}/y_{f^{(m)}f^{(n)}}) \cdot (g^A_{Zf^{(m)}f^{(n)}}/g^V_{Zf^{(m)}f^{(n)}})$ is smaller than 10^{-4}, and the $\hat{y}_{f^{(m)}f^{(n)}} g^A_{Zf^{(m)}f^{(n)}}$ term in (3.25) may be dropped.

For the asymptotic behavior of the amplitude for m, $n \gg 1$ only the $|m-n| \le 1$ terms are relevant. For $|m-n| \le 1$, $m_{f^{(n\pm1)}} \simeq m_{f^{(n)}}$ and the amplitudes are evaluated as

TABLE IV. $J_{F^{+(m)}F^{+(n)}}$ is shown for $0 \le m, n \le 7$ and for $101 \le m, n \le 108$ in the $N_F = 4$, $z_L = 10^5$ case. Only the values larger than $O(10^{-4})$ are shown with three significant figures.

$$
\begin{aligned}
i\mathcal{M}_{\text{fermion}} &\equiv \frac{1}{2}\sum_{m,n}^{\infty}\{i\mathcal{M}^{(a)}_{t^{(m)},t^{(n)}} + i\mathcal{M}^{(b)}_{t^{(m)},t^{(n)}} + i\mathcal{M}^{(c)}_{F^{+(m)},F^{+(n)}} + i\mathcal{M}^{(d)}_{F^{+(m)},F^{+(n)}} + (m \leftrightarrow n)\} \\
&\approx \sum_{n}^{\infty}\frac{i}{4\pi^2}\epsilon^{*}_{\mu}(k_1)\epsilon^{*}_{\nu}(k_2)\left(\eta^{\mu\nu} - \frac{k_2^{\mu}k_1^{\nu}}{k_1\cdot k_2}\right)\frac{e g_w y_t \cos\theta_H}{\cos\theta_W}(m_H^2 - m_Z^2) \\
&\quad\times\left\{\frac{2}{3m_{t^{(n)}}}(J_{t^{(n)}t^{(n)}} + J_{t^{(n+1)}t^{(n)}} + J_{t^{(n-1)}t^{(n)}})[I_1(\tau_{t^{(n)}},\lambda_{t^{(n)}}) - I_2(\tau_{t^{(n)}},\lambda_{t^{(n)}})]\right. \\
&\quad\left.+\frac{1}{m_{F^{+(n)}}}(J_{F^{+(n)}F^{+(n)}} + J_{F^{+(n+1)}F^{+(n)}} + J_{F^{+(n-1)}F^{+(n)}})[I_1(\tau_{F^{+(n)}},\lambda_{F^{+(n)}}) - I_2(\tau_{F^{+(n)}},\lambda_{F^{+(n)}})]\right\}. \qquad (3.28)
\end{aligned}
$$

$J_{t^{(n)}t^{(m)}}$ and $J_{F^{+(n)}F^{+(m)}}$ $(m = n, n+1)$ are plotted in Figs. 6 and 7. They are approximately given, for $101 \le n \le 200$, by

$$
\begin{aligned}
J_{t^{(n)}t^{(n)}} &\simeq -0.0597 + 0.00323(\ln n) - 0.00047(\ln n)^2 + (-1)^{n-1}\{-0.0230 + 0.00122(\ln n) - 0.00018(\ln n)^2\}, \\
J_{t^{(n)}t^{(n+1)}} &\simeq 0.0296 - 0.00162(\ln n) + 0.00024(\ln n)^2 + (-1)^{n-1}\{0.0362 - 0.00143(\ln n) + 0.00020(\ln n)^2\}, \qquad (3.29)
\end{aligned}
$$

$$
\begin{aligned}
J_{F^{+(n)}F^{+(n)}} &\simeq 0.280 - 0.0172(\ln n) + 0.00331(\ln n)^2 + (-1)^{n-1}\{-0.0212 + 0.00131(\ln n) - 0.00026(\ln n)^2\}, \\
J_{F^{+(n)}F^{+(n+1)}} &\simeq -0.138 + 0.0084(\ln n) - 0.00163(\ln n)^2 + (-1)^{n-1}\{-0.2218 + 0.00558(\ln n) - 0.00107(\ln n)^2\}. \qquad (3.30)
\end{aligned}
$$

Adding them, one finds, within numerical errors, that

$$
\begin{aligned}
J_{t^{(n)}t^{(n)}} + J_{t^{(n+1)}t^{(n)}} + J_{t^{(n-1)}t^{(n)}} &\approx (-1)^{n-1}\{-0.0230 + 0.00122(\ln n) - 0.00018(\ln n)^2\}, \\
J_{F^{+(n)}F^{+(n)}} + J_{F^{+(n+1)}F^{+(n)}} + J_{F^{+(n-1)}F^{+(n)}} &\approx (-1)^{n-1}\{-0.0212 + 0.00131(\ln n) - 0.00026(\ln n)^2\}. \qquad (3.31)
\end{aligned}
$$

Since $i\mathcal{M}_f \propto \sum_n (J_{f^{(n)}f^{(n)}} + J_{f^{(n+1)}f^{(n)}} + J_{f^{(n-1)}f^{(n)}})/n$ for large n, the sum converges as in the case of the gauge boson loops.

D. Total amplitude

The ratio of the sum of the all boson contributions to the W boson contribution and that of all the fermion contributions to the top quark contribution are given by

$$
\frac{\mathcal{M}_{\text{boson}}}{\mathcal{M}_{W^{(0)}\text{only}}} = 0.9994, \qquad \frac{\mathcal{M}_{\text{fermion}}}{\mathcal{M}_{t^{(0)}\text{only}}} = 1.0023, \qquad (3.32)
$$

for $z_L = 10^5$, $n_F = 4$, and $\theta_H = 0.1153$, respectively where $\mathcal{M}_{\text{boson}} \equiv \mathcal{M}_W + \mathcal{M}_{W_R}$. The ratio of the whole amplitude to the W boson and top quark contributions is

$$
\frac{\mathcal{M}_{\text{boson}} + \mathcal{M}_{\text{fermion}}}{\mathcal{M}_{W^{(0)}\text{only}} + \mathcal{M}_{t^{(0)}\text{only}}} = 0.9993. \qquad (3.33)
$$

One finds that the KK mode contributions are negligible. As $g_{HW^{(0)}W^{(0)}} \simeq g_w \cos\theta_H$ and $y_{t^{(0)}} \simeq y_{t\text{SM}} \cos\theta_H$, the decay width is approximated by

$$
\Gamma(H \to Z\gamma)_{\text{GHU}} \simeq \Gamma(H \to Z\gamma)_{\text{SM}} \times \cos^2\theta_H. \qquad (3.34)
$$

In the gauge-Higgs unification, the decay width of $H \to WW$, $H \to ZZ$, $H \to bb$ and $H \to \tau\tau$ are suppressed

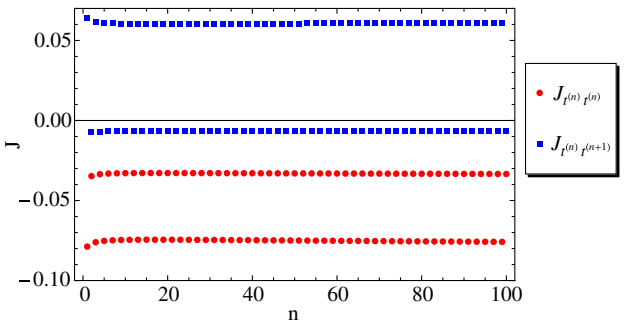

FIG. 6 (color online). $J_{t^{(n)}t^{(n)}}$ and $J_{t^{(n)}t^{(n+1)}}$ are plotted for $1 \le n \le 100$ in the $N_F = 4$, $z_L = 10^5$ case. The red circles and blue squares express $J_{t^{(n)}t^{(n)}}$ and $J_{t^{(n)}t^{(n+1)}}$, respectively.

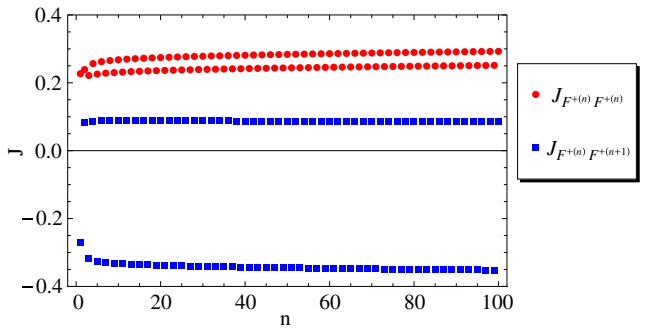

FIG. 7 (color online). $J_{F^{+(n)}F^{+(n)}}$ and $J_{F^{+(n)}F^{+(n+1)}}$ are plotted for $1 \le n \le 100$ in the $N_F = 4$, $z_L = 10^5$ case. The red circles and blue squares express $J_{F^{+(n)}F^{+(n)}}$ and $J_{F^{+(n)}F^{+(n+1)}}$, respectively.

by $\cos^2\theta_H$ at the tree level. The decay width of the $H \to \gamma\gamma$ and $H \to Z\gamma$ are also suppressed by $\cos^2\theta_H$. Therefore the branching ratios of the Higgs decay modes in this model are almost the same as in the SM. The dominant process in the Higgs boson production is $gg \to H$, and the production cross section is also suppressed by $\cos^2\theta_H$. Therefore the signal strength, $\sigma(gg\to H)B(H\to Z\gamma)/[\sigma(gg\to H)B(H\to Z\gamma)]_{\rm SM}$, is approximately $\cos^2\theta_H$ as in the other decay modes. For $\theta_H \sim 0.1$, the deviation from the SM amounts only 1%.

We stress the finiteness of $\Gamma(H \to Z\gamma)$ in the gauge-Higgs unification which results from nontrivial cancellation among contributions of the KK modes. One might wonder why such cancellation takes place and what underlies the finiteness of the amplitude $\mathcal{M}(H \to Z\gamma)$ in the gauge-Higgs unification. We argue that it is guaranteed by the gauge invariance and by the fact that the 4D Higgs field H is the fluctuation mode of the AB phase θ_H. In the effective action the 4D Higgs field $H(x)$ and AB phase θ_H appear in the combination of $\theta_H + H(x)/f_H$ so that $\mathcal{M}(H \to Z\gamma)$ is related to $(\partial/\partial\theta_H)\Pi_{Z\gamma}(\theta_H)$ where $\Pi_{Z\gamma}(\theta_H)$ is the $Z\gamma$ vacuum polarization. The 5D gauge invariance guarantees that $\Pi_{Z\gamma}(\theta_H)$ is periodic in θ_H, and can be expanded in a Fourier series $\Pi_{Z\gamma}(\theta_H) = \sum_n \alpha_n e^{in\theta_H}$. The θ_H-dependence of the Z couplings of the fields running the inside loops is known to be very weak. At the one loop level the dominant θ_H-dependence of $\Pi_{Z\gamma}(\theta_H)$ comes from the propagators inside the loop. Hence the divergence degree is lowered by differentiating $\Pi_{Z\gamma}(\theta_H)$ with respect to θ_H. There should exist a positive integer q such that $\partial^q\Pi_{Z\gamma}/\partial\theta_H^q = \sum_{n\neq 0}(in)^q\alpha_n e^{in\theta_H}$ is finite. This in turn implies that $\Pi_{Z\gamma}(\theta_H) - \alpha_0$ is finite, from which the finiteness of $\mathcal{M}(H \to Z\gamma)$ at the one loop level follows. A similar argument has been employed to prove the finiteness of the effective potential $V_{\rm eff}(\theta_H)$ at the one loop level [30].

IV. CONCLUSION AND DISCUSSIONS

In this paper we have evaluated the decay rate $\Gamma(H \to Z\gamma)$ in the $SO(5) \times U(1)$ gauge-Higgs unification. The processes $H \to \gamma\gamma$ and $H \to Z\gamma$ do not occur at the tree level. They do proceed at the one loop level, where an infinite number of the KK modes of gauge bosons and fermions give loop corrections. Contrary to the naive expectation that the sum of an infinite number of the KK mode contributions may yield substantial corrections to the decay rates in the SM, it has been known that the correction to $\Gamma(H \to \gamma\gamma)$ coming from KK modes turns out very tiny, thanks to the cancellation among the KK mode corrections.

We have examined the process $H \to Z\gamma$ in detail, for which the KK number need not be conserved inside the loop. We have shown, by direct evaluation, that there appears miraculous cancellation among the loop diagrams in which the KK number is conserved in the loop and those in which the KK number is not conserved. As a result the amplitude for $H \to Z\gamma$ becomes finite. We also showed that the correction due to various KK modes is very small. $\Gamma(H \to Z\gamma)$ in the gauge-Higgs unification is approximately $\cos^2\theta_H$ times that in the SM. The deviation from the SM is very small for $\theta_H < 0.1$.

The result is very promising. The $SO(5) \times U(1)$ gauge-Higgs unification yields almost the same phenomenology as the SM at low energies. At higher energy scale it predicts KK excitation modes as Z' and W' events and a dark matter candidate, which awaits confirmation at 14 TeV LHC and by DM direct-detection experiments. Small deviations of HWW and HZZ couplings from the SM will be checked in future colliders [31]. In addition to deriving more predictions for collider experiments, the scenario of the gauge-Higgs unification has to be refined. The scenario of the gauge-Higgs grand unification has been proposed [32]. An attempt has been made to dynamically determine orbifold boundary conditions [33]. The Hosotani mechanism, essential for the electroweak gauge symmetry breaking in the gauge-Higgs unification, has been investigated nonperturbatively on the lattice [34]. The gauge-Higgs unification is one of the keys to investigate the extra dimension.

APPENDIX: COUPLINGS OF KK MODES TO Z AND H

We summarize the Z and H couplings of the KK modes relevant for $H \to Z\gamma$.

1. Base functions

Mode functions for KK towers of various fields in the RS spacetime are expressed in terms of Bessel functions. For gauge fields we define

$$\begin{aligned} C(z;\lambda) &= \frac{\pi}{2}\lambda z z_L F_{1,0}(\lambda z, \lambda z_L), \\ C'(z;\lambda) &= \frac{\pi}{2}\lambda^2 z z_L F_{0,0}(\lambda z, \lambda z_L), \\ S(z;\lambda) &= -\frac{\pi}{2}\lambda z F_{1,1}(\lambda z, \lambda z_L), \\ S'(z;\lambda) &= -\frac{\pi}{2}\lambda^2 z F_{0,1}(\lambda z, \lambda z_L), \\ \hat{S}(z;\lambda) &= \frac{C(1;\lambda)}{S(1;\lambda)} S(z;\lambda), \end{aligned} \tag{A1}$$

where $F_{\alpha,\beta}(u,v) = J_\alpha(u)Y_\beta(v) - Y_\alpha(u)J_\beta(v)$. They satisfy

$$\begin{aligned} &C(z_L;\lambda) = z_L, \qquad C'(z_L;\lambda) = 0, \qquad S(z_L;\lambda) = 0, \\ &S'(z_L;\lambda) = \lambda, \qquad CS' - SC' = \lambda z. \end{aligned} \tag{A2}$$

For fermions with a bulk mass parameter c we define

$$\begin{pmatrix} C_L \\ S_L \end{pmatrix}(z;\lambda,c) = \pm\frac{\pi}{2}\lambda\sqrt{zz_L}F_{c+\frac{1}{2},c\mp\frac{1}{2}}(\lambda z,\lambda z_L),$$
$$\begin{pmatrix} C_R \\ S_R \end{pmatrix}(z;\lambda,c) = \mp\frac{\pi}{2}\lambda\sqrt{zz_L}F_{c-\frac{1}{2},c\pm\frac{1}{2}}(\lambda z,\lambda z_L). \quad \text{(A3)}$$

They satisfy

$$D_+(c)\begin{pmatrix} C_L \\ S_L \end{pmatrix} = \lambda\begin{pmatrix} S_R \\ C_R \end{pmatrix}, \qquad D_-(c)\begin{pmatrix} C_R \\ S_R \end{pmatrix} = \lambda\begin{pmatrix} S_L \\ C_L \end{pmatrix},$$
$$D_\pm(c) = \pm\frac{d}{dz} + \frac{c}{z},$$
$$C_R = C_L = 1, \qquad S_R = S_L = 0, \quad \text{at } z = z_L,$$
$$C_L C_R - S_L S_R = 1. \quad \text{(A4)}$$

In the following we evaluate various couplings by inserting the formulas for the KK expansions. Basic formulas for the KK expansions of gauge fields and quark fields are summarized in Ref. [24], whereas those for dark fermions are given in Ref. [25]. We adopt the same notation as in those references. The numerical values for the various couplings are given for the parameter set

$$z_L = 10^5, \qquad \theta_H = 0.1153,$$
$$m_{\rm KK} = 7.405\ \text{TeV}, \qquad k = 2.357\times 10^8\ \text{GeV},$$
$$c_t = 0.2270, \qquad c_F = 0.3321. \quad \text{(A5)}$$

2. $ZW^{(m)}W^{(n)}$ coupling

The $ZW^{(m)}W^{(n)}$ coupling is contained in

$$\int_1^{z_L}\frac{dz}{kz}\left(-\frac{1}{4}\right)\mathrm{Tr}[F_{\mu\nu}F_{\rho\sigma}]\eta^{\mu\rho}\eta^{\nu\sigma} \supset ig_A\int_1^{z_L}\frac{dz}{kz}\mathrm{Tr}[(\partial_\mu\hat{Z}_\nu - \partial_\nu\hat{Z}_\mu)[\hat{W}^+_\rho,\hat{W}^-_\sigma]$$
$$+ (\partial_\mu\hat{W}^-_\nu - \partial_\nu\hat{W}^-_\mu)[\hat{Z}_\rho,\hat{W}^+_\sigma] + (\partial_\mu\hat{W}^+_\nu - \partial_\nu\hat{W}^+_\mu)[\hat{Z}_\rho,\hat{W}^-_\sigma]]\eta^{\mu\rho}\eta^{\nu\sigma}$$
$$\supset i\sum_{m,n} g_{ZW^{(m)}W^{(n)}}\eta^{\mu\rho}\eta^{\nu\sigma}\{(\partial_\mu Z_\nu - \partial_\nu Z_\mu)W^{+(m)}_\rho W^{-(n)}_\sigma$$
$$- (\partial_\mu W^{+(m)}_\nu - \partial_\nu W^{+(m)}_\mu)Z_\rho W^{-(n)}_\sigma + (\partial_\mu W^{-(n)}_\nu - \partial_\nu W^{-(n)}_\mu)Z_\rho W^{+(m)}_\sigma\} \quad \text{(A6)}$$

so that one finds that

$$g_{ZW^{(m)}W^{(n)}} = g_w\sqrt{L}\int_1^{z_L}\frac{dz}{kz}\left\{h^L_Z\left(h^L_{W^{(m)}}h^L_{W^{(n)}} + \frac{\hat{h}_{W^{(m)}}\hat{h}_{W^{(n)}}}{2}\right) + h^R_Z\left(h^R_{W^{(m)}}h^R_{W^{(n)}} + \frac{\hat{h}_{W^{(m)}}\hat{h}_{W^{(n)}}}{2}\right)\right.$$
$$\left. + \hat{h}_Z\left(\frac{h^L_{W^{(m)}}\hat{h}_{W^{(n)}} + h^R_{W^{(m)}}\hat{h}_{W^{(n)}} + \hat{h}_{W^{(m)}}h^L_{W^{(n)}} + \hat{h}_{W^{(m)}}h^R_{W^{(n)}}}{2}\right)\right\}$$
$$= g_w\cos\theta_W\frac{\sqrt{L}}{\sqrt{r_Z r_{W^{(m)}} r_{W^{(n)}}}}\int_1^{z_L}\frac{dz}{kz}\frac{1}{\sqrt{2}}\left[2C_Z((1+\cos^2\theta_H)C_{W^{(m)}}C_{W^{(n)}} + \sin^2\theta_H\hat{S}_{W^{(m)}}\hat{S}_{W^{(n)}})\right.$$
$$\left. + \frac{\sin^2\theta_H}{\cos^2\theta_W}\{-C_Z(C_{W^{(m)}}C_{W^{(n)}} + \hat{S}_{W^{(m)}}\hat{S}_{W^{(n)}}) + \hat{S}_Z(C_{W^{(m)}}\hat{S}_{W^{(n)}} + \hat{S}_{W^{(m)}}C_{W^{(n)}})\}\right]. \quad \text{(A7)}$$

Here $C_{W^{(m)}} = C(z;\lambda_{W^{(m)}})$ etc. Numerical values of $g_{ZW^{(m)}W^{(n)}}$ are given in Table V.

TABLE V. $g_{ZW^{(m)}W^{(n)}}/g_w\cos\theta_W$. Only the values larger than $O(10^{-3})$ are shown and written by three significant figures.

	0	1	2	3	4	5	6	7
0	1.	$O(10^{-4})$	$O(10^{-7})$	$O(10^{-5})$	$O(10^{-7})$	$O(10^{-6})$	$O(10^{-8})$	$O(10^{-6})$

2	$O(10^{-7})$	0.032	0.350	−0.022	$O(10^{-7})$	$O(10^{-4})$	$O(10^{-6})$	$O(10^{-4})$
3	$O(10^{-5})$	$O(10^{-5})$	−0.022	0.996	0.032	$O(10^{-5})$	$O(10^{-4})$	$O(10^{-6})$
4	$O(10^{-7})$	$O(10^{-4})$	$O(10^{-7})$	0.032	0.350	−0.023	$O(10^{-5})$	$O(10^{-4})$
5	$O(10^{-6})$	$O(10^{-6})$	$O(10^{-4})$	$O(10^{-5})$	−0.023	0.996	0.032	$O(10^{-5})$
6	$O(10^{-8})$	$O(10^{-5})$	$O(10^{-6})$	$O(10^{-4})$	$O(10^{-5})$	0.032	0.350	−0.023
7	$O(10^{-6})$	$O(10^{-6})$	$O(10^{-4})$	$O(10^{-6})$	$O(10^{-4})$	$O(10^{-5})$	−0.023	0.996

3. $\gamma Z W^{(m)} W^{(n)}$ coupling

Similarly $\gamma Z W^{(m)} W^{(n)}$ coupling is contained in

$$(g_A)^2 \int_1^{z_L} \frac{dz}{kz} \mathrm{Tr}[[\hat{A}_\mu^{\gamma(A)}, \hat{W}_\nu^+]([\hat{Z}_\rho, \hat{W}_\sigma^-] - [\hat{Z}_\sigma, \hat{W}_\rho^-]) + [\hat{A}_\mu^{\gamma(A)}, \hat{W}_\nu^-]([\hat{Z}_\rho, \hat{W}_\sigma^+] - [\hat{Z}_\sigma, \hat{W}_\rho^+])]\eta^{\mu\rho}\eta^{\nu\sigma}$$
$$\supset \sum_{m,n} g_{\gamma Z W^{(m)} W^{(n)}} \eta^{\mu\rho}\eta^{\nu\sigma}\{A_\mu^\gamma W_\nu^{+(m)}(Z_\rho W_\sigma^{-(n)} - Z_\sigma W_\rho^{-(n)}) + A_\mu^\gamma W_\nu^{-(n)}(Z_\rho W_\sigma^{+(m)} - Z_\sigma W_\rho^{+(m)})\} \tag{A8}$$

so that

$$g_{\gamma Z W^{(m)} W^{(n)}} = -g_w^2 L \int_1^{z_L} \frac{dz}{kz} \left\{ h_\gamma^L h_{W^{(m)}}^L \left(h_Z^L h_{W^{(n)}}^L + \frac{\hat{h}_Z \hat{h}_{W^{(n)}}}{2} \right) + h_\gamma^R h_{W^{(m)}}^R \left(h_Z^R h_{W^{(n)}}^R + \frac{\hat{h}_Z \hat{h}_{W^{(n)}}}{2} \right) \right.$$
$$\left. + \frac{h_\gamma^L + h_\gamma^R}{2} \hat{h}_{W^{(m)}} \left(\frac{h_Z^L \hat{h}_{W^{(n)}} + h_Z^R \hat{h}_{W^{(n)}} + \hat{h}_Z h_{W^{(n)}}^L + \hat{h}_Z h_{W^{(n)}}^R}{2} \right) \right\}$$
$$= -e g_{Z W^{(m)} W^{(n)}}. \tag{A9}$$

The relation $g_{\gamma Z W^{(m)} W^{(n)}} = -e g_{Z W^{(m)} W^{(n)}}$ follows from the gauge invariance as well.

4. $H W^{(m)} W^{(n)}$ coupling

The Higgs coupling $H W^{(m)} W^{(n)}$ is contained in the $\mathrm{Tr} F_{\mu z} F^{\mu z}$ term

$$-i g_A k^2 \int_1^{z_L} \frac{dz}{kz} \mathrm{Tr}(\partial_z \hat{W}_\mu^- [\hat{W}_\nu^+, \hat{H}] + \partial_z \hat{W}_\mu^+ [\hat{W}_\nu^-, \hat{H}]) \eta^{\mu\nu} \supset -\sum_{m,n} g_{H W^{(m)} W^{(n)}} H W_\mu^{+(m)} W_\nu^{-(n)} \eta^{\mu\nu} \tag{A10}$$

so that

$$g_{H W^{(m)} W^{(n)}} = i g_A k^2 \int_1^{z_L} \frac{dz}{kz} \frac{i}{2} u_H(z) [-(\partial_z \hat{h}_{W^{(m)}})(h_{W^{(n)}}^L - h_{W^{(n)}}^R) + \partial_z (h_{W^{(m)}}^L - h_{W^{(m)}}^R) \hat{h}_{W^{(n)}} + (m \longleftrightarrow n)]$$
$$= -g_w \sqrt{\frac{kL}{z_L^2 - 1}} \frac{1}{\sqrt{r_{W^{(m)}} r_{W^{(n)}}}} \sin\theta_H \cos\theta_H \int_1^{z_L} dz \{(\partial_z \hat{S}_{W^{(m)}}) C_{W^{(n)}} - (\partial_z C_{W^{(m)}}) \hat{S}_{W^{(n)}} + (m \longleftrightarrow n)\}. \tag{A11}$$

Numerical values of $g_{H W^{(m)} W^{(n)}}$ are given in Table VI.

TABLE VI. $g_{H W^{(m)} W^{(n)}} / g_w \cos\theta_H$ in the unit of GeV written by three significant figures. The values smaller than $O(10)$ are abbreviated.

	0	1	2	3	4	5	6	7

5. $ZW^{(m)}W_R^{(n)}$ coupling

The $ZW^{(m)}W_R^{(n)}$ coupling in

$$i\sum_{m,n} g_{ZW^{(m)}W_R^{(n)}}\eta^{\mu\rho}\eta^{\nu\sigma}\{(\partial_\mu Z_\nu-\partial_\nu Z_\mu)(W_\rho^{+(m)}W_{R\sigma}^{-(n)}+W_\rho^{-(m)}W_{R\sigma}^{+(n)})+(\partial_\mu W_\nu^{-(m)}-\partial_\nu W_\mu^{-(m)})Z_\rho W_{R\sigma}^{+(n)}$$
$$-(\partial_\mu W_\nu^{+(m)}-\partial_\nu W_\mu^{+(m)})Z_\rho W_{R\sigma}^{-(n)}+(\partial_\mu W_{R\nu}^{-(n)}-\partial_\nu W_{R\mu}^{-(n)})Z_\rho W_\sigma^{+(m)}-(\partial_\mu W_{R\nu}^{+(n)}-\partial_\nu W_{R\mu}^{+(n)})Z_\rho W_\sigma^{-(m)}\} \tag{A12}$$

is given by

$$g_{ZW^{(m)}W_R^{(n)}}=g_w\sqrt{L}\int_1^{z_L}\frac{dz}{kz}\left\{h_Z^L h_{W^{(m)}}^L h_{W_R^{(n)}}^L+h_Z^R h_{W^{(m)}}^R h_{W_R^{(n)}}^R+\hat{h}_Z\hat{h}_{W^{(m)}}\frac{h_{W_R^{(n)}}^L+h_{W_R^{(n)}}^R}{2}\right\}$$
$$=g_w\cos\theta_W\frac{\sqrt{L}}{\sqrt{r_Z r_{W^{(m)}} r_{W_R^{(n)}}}}\int_1^{z_L}\frac{dz}{kz}\frac{1}{\sqrt{2}}\frac{\sin^2\theta_H}{\cos^2\theta_W}\frac{\cos\theta_H}{\sqrt{1+\cos^2\theta_H}}\{C_Z C_{W^{(m)}} C_{W_R^{(n)}}-\hat{S}_Z\hat{S}_{W^{(m)}}C_{W_R^{(n)}}\}. \tag{A13}$$

Numerical values of $g_{ZW^{(m)}W_R^{(n)}}$ are given in Table VII.

6. $\gamma ZW^{(m)}W_R^{(n)}$ coupling

Similarly $\gamma ZW^{(m)}W_R^{(n)}$ coupling is contained in

$$(g_A)^2\int_1^{z_L}\frac{dz}{kz}\eta^{\mu\rho}\eta^{\nu\sigma}\mathrm{Tr}[[\hat{A}_\mu^{\gamma(A)},\hat{W}_\nu^+]([\hat{Z}_\rho,\hat{W}_{R\sigma}^-]-[\hat{Z}_\sigma,\hat{W}_{R\rho}^-])+[\hat{A}_\mu^{\gamma(A)},\hat{W}_\nu^-]([\hat{Z}_\rho,\hat{W}_{R\sigma}^+]-[\hat{Z}_\sigma,\hat{W}_{R\rho}^+])$$
$$\times[\hat{A}_\mu^{\gamma(A)},\hat{W}_{R\nu}^-]([\hat{Z}_\rho,\hat{W}_{R\sigma}^+]-[\hat{Z}_\sigma,\hat{W}_\rho^+])+[\hat{A}_\mu^{\gamma(A)},\hat{W}_{R\nu}^-]([\hat{Z}_\rho,\hat{W}_{R\sigma}^+]-[\hat{Z}_\sigma,\hat{W}_\rho^+])]$$
$$\supset\sum_{m,n}g_{\gamma ZW^{(m)}W_R^{(n)}}\eta^{\mu\rho}\eta^{\nu\sigma}\{A_\mu^\gamma W_\nu^{+(m)}(Z_\rho W_{R\sigma}^{-(n)}-Z_\sigma W_{R\rho}^{-(n)})+A_\mu^\gamma W_\nu^{-(n)}(Z_\rho W_{R\sigma}^{+(m)}-Z_\sigma W_{R\rho}^{+(m)})$$
$$+A_\mu^\gamma W_{R\nu}^{+(m)}(Z_\rho W_\sigma^{-(n)}-Z_\sigma W_\rho^{-(n)})+A_\mu^\gamma W_{R\nu}^{-(n)}(Z_\rho W_\sigma^{+(m)}-Z_\sigma W_\rho^{+(m)})\} \tag{A14}$$

so that

$$g_{\gamma ZW^{(m)}W_R^{(n)}}=-g_w^2\sqrt{L}\int_1^{z_L}\frac{dz}{kz}\left\{h_{\gamma^{(0)}}^L h_{W^{(m)}}^L h_Z^L h_{W_R^{(n)}}^L+h_{\gamma^{(0)}}^R h_{W^{(m)}}^R h_Z^R h_{W_R^{(n)}}^R+\frac{1}{2}(h_{\gamma^{(0)}}^L+h_{\gamma^{(0)}}^R)\hat{h}_{W^{(m)}}\frac{1}{2}\hat{h}_Z(h_{W_R^{(n)}}^L+h_{W_R^{(n)}}^R)\right\}$$
$$=-eg_w g_{ZW^{(m)}W_R^{(n)}}. \tag{A15}$$

The relation $g_{\gamma ZW^{(m)}W_R^{(n)}}=-eg_{ZW^{(m)}W_R^{(n)}}$ follows from the gauge invariance as well.

7. $HW^{(m)}W_R^{(n)}$ and $HW_R^{(m)}W_R^{(n)}$ coupling

Similarly the $HW^{(m)}W_R^{(n)}$ coupling contained in

$$-ig_A k^2\int_1^{z_L}\frac{dz}{kz}\mathrm{Tr}(\partial_z\hat{W}_{R\mu}^-[\hat{W}_\nu^+,\hat{H}]+\partial_z\hat{W}_\mu^+[\hat{W}_{R\nu}^-,\hat{H}])\eta^{\mu\nu}\supset-\sum_{m,n}g_{HW^{(m)}W_R^{(n)}}HW_\mu^{+(m)}W_{R\nu}^{-(n)}\eta^{\mu\nu} \tag{A16}$$

TABLE VIII. $g_{HW^{(m)}W_R^{(n)}}/g_w \cos\theta_H$ in the unit of GeV written by three significant figures. The values smaller than $O(10)$ are abbreviated.

		m							
		0	1	2	3	4	5	6	7
	1	112	−60.7	3.47×10^3	$O(1)$	−55.8	$O(1)$	161	$O(1)$
n	2	80.9	−118	1.72×10^4	−278	1.62×10^4	−70.2	391	$O(1)$
	3	$O(1)$	$O(1)$	4.83×10^3	−260	3.32×10^4	−527	2.93×10^4	−140
	4	30.4	−19.4	1.13×10^3	−17.3	7.96×10^3	−412	4.94×10^4	−789

is given by

$$g_{HW^{(m)}W_R^{(n)}} = ig_A k^2 \int_1^{z_L} \frac{dz}{kz}\frac{i}{2} u_H(z)[\partial_z(h^L_{W_R^{(n)}} - h^R_{W_R^{(n)}})\hat{h}_{W^{(m)}} - (\partial_z \hat{h}_{W^{(m)}})(h^L_{W_R^{(n)}} - h^R_{W_R^{(n)}})]$$
$$= -g_w\sqrt{\frac{kL}{z_L^2-1}}\frac{1}{\sqrt{r_{W^{(m)}} r_{W_R^{(n)}}}}(-\sin\theta_H\cos\theta_H)\int_1^{z_L} dz[(\partial_z C_{W_R^{(n)}})\hat{S}_{W^{(m)}} - (\partial_z \hat{S}_{W^{(m)}})C_{W_R^{(n)}}]. \quad \text{(A17)}$$

Numerical values of $g_{HW^{(m)}W_R^{(n)}}$ are given in Table VIII. The $HW_R^{(m)}W_R^{(n)}$ couplings vanish for all m, n as a result of the Lie algebra.

8. $Zt^{(m)}t^{(n)}$ coupling

The Z couplings of the top quark tower are found from

$$\sum_{a=1}^{2}\int_1^{z_L} dz\sqrt{G}\bar{\Psi}_a(-ig_A A_\mu - ig_B Q_{X_a}B_\mu)z\gamma^\mu\Psi_a \supset -ig_w Z_\mu\sqrt{L}\int_1^{z_L}\frac{dz}{k}$$
$$\times\left\{\frac{h_Z^L}{2}(\bar{\tilde{U}}\gamma^\mu\tilde{U} - \bar{\tilde{B}}\gamma^\mu\tilde{B} + \bar{\tilde{t}}\gamma^\mu\tilde{t}) + \frac{h_Z^R}{2}(\bar{\tilde{U}}\gamma^\mu\tilde{U} + \bar{\tilde{B}}\gamma^\mu\tilde{B} - \bar{\tilde{t}}\gamma^\mu\tilde{t}) + \frac{\hat{h}_Z}{2}(\bar{\tilde{B}}\gamma^\mu\tilde{t'} + \bar{\tilde{t}}\gamma^\mu\tilde{t'} + \bar{\tilde{t'}}\gamma^\mu\tilde{B} + \bar{\tilde{t'}}\gamma^\mu\tilde{t})\right.$$
$$\left. + Q_{X_1}t_\phi h_Z^B(\bar{\tilde{B}}\gamma^\mu\tilde{B} + \bar{\tilde{t}}\gamma^\mu\tilde{t} + \bar{\tilde{t}'}\gamma^\mu\tilde{t'}) + Q_{X_2}t_\phi h_Z^B\bar{\tilde{U}}\gamma^\mu\tilde{U}\right\}. \quad \text{(A18)}$$

The $Zt^{(m)}t^{(n)}$ couplings are found to be

$$-i\frac{g_w}{\cos\theta_W}\sum_{m,n}Z_\mu(-i)\bar{t}_L^{(m)}\gamma^\mu t_L^{(n)}\frac{\sqrt{L}}{\sqrt{2r_Z}}\int_1^{z_L}dz\left\{C_Z f^{(m)}_{U_L}f^{(n)}_{U_L} + \cos\theta_H C_Z(-f^{(m)}_{B_L}f^{(n)}_{B_L} + f^{(m)}_{t_L}f^{(n)}_{t_L})\right.$$
$$+\frac{-\sqrt{2}\sin\theta_H}{2}\hat{S}_Z(f^{(m)}_{B_L}f^{(n)}_{t'_L} + f^{(m)}_{t_L}f^{(n)}_{t'_L} + f^{(m)}_{t'_L}f^{(n)}_{B_L} + f^{(m)}_{t'_L}f^{(n)}_{t_L})$$
$$\left. - 2\sin^2\theta_W C_Z Q_{X_1}(f^{(m)}_{U_L}f^{(n)}_{U_L} + f^{(m)}_{B_L}f^{(n)}_{B_L} + f^{(m)}_{t_L}f^{(n)}_{t_L} + f^{(m)}_{t'_L}f^{(n)}_{t'_L})\right\} \quad \text{(A19)}$$

for the left-handed component $t_L^{(n)}$ and a similar expression for $t_R^{(n)}$. Noting that $Q_{X_1} = \frac{2}{3}$ and $Q_{X_2} = -\frac{1}{3}$, one finds that

$$Z_\mu\sum_{m,n}\{g_{Zt_L^{(m)}t_L^{(n)}}\bar{t}_L^{(m)}\gamma^\mu t_L^{(n)} + g_{Zt_R^{(m)}t_R^{(n)}}\bar{t}_R^{(m)}\gamma^\mu t_R^{(n)}\} \quad \text{(A20)}$$

TABLE IX. $g^V_{Zt^{(m)}t^{(n)}} = \frac{1}{2}\{g_{Zt_L^{(m)}t_L^{(n)}} + g_{Zt_R^{(m)}t_R^{(n)}}\}$ in the unit of $g/\cos\theta_W$. The values larger than $O(10^{-3})$ are shown. $g^A_{Zt^{(m)}t^{(n)}} = \frac{1}{2}\{g_{Zt_L^{(m)}t_L^{(n)}} - g_{Zt_R^{(m)}t_R^{(n)}}\}$ in the unit of $g/\cos\theta_W$ is smaller than $O(10^{-3})$ in the range of $m, n \le 10$, except for $g^A_{Zt^{(0)}t^{(0)}} = -0.2501$.

	0	1	2	3	4	5	6	7
0	0.095	−0.008	0.001	$O(10^{-4})$	$O(10^{-5})$	$O(10^{-4})$	$O(10^{-5})$	$O(10^{-5})$

2	0.001	0.059	−0.149	−0.010	$O(10^{-5})$	$O(10^{-4})$	$O(10^{-5})$	$O(10^{-4})$
3	$O(10^{-4})$	$O(10^{-4})$	−0.010	0.338	0.056	$O(10^{-5})$	0.002	$O(10^{-6})$
4	$O(10^{-5})$	0.002	$O(10^{-5})$	0.056	−0.149	−0.010	$O(10^{-5})$	$O(10^{-4})$
5	$O(10^{-4})$	$O(10^{-5})$	$O(10^{-4})$	$O(10^{-5})$	−0.010	0.338	0.056	$O(10^{-4})$
6	$O(10^{-5})$	$O(10^{-6})$	$O(10^{-5})$	0.002	$O(10^{-5})$	0.056	−0.150	−0.010
7	$O(10^{-5})$	$O(10^{-6})$	$O(10^{-4})$	$O(10^{-6})$	$O(10^{-4})$	$O(10^{-4})$	−0.010	0.338

where

$$g_{Zt_L^{(m)}t_L^{(n)}} = \frac{g_w}{\cos\theta_W}\frac{\sqrt{2L}}{\sqrt{r_Z r_{t^{(m)}} r_{t^{(n)}}}}\int_1^{z_L} dz\left[\left(\frac{\tilde{\mu}^2}{\mu_2^2}+c_H^2\right)C_L^{(m)}C_L^{(n)}C_Z + \frac{s_H^2}{2}\left(C_L^{(m)}\frac{C_L^{(n)}(1)}{S_L^{(n)}(1)}S_L^{(n)} + \frac{C_L^{(m)}(1)}{S_L^{(m)}(1)}S_L^{(m)}C_L^{(m)}\right)\hat{S}_Z\right.$$
$$\left. -\frac{2}{3}\sin^2\theta_W\left\{\left(2\frac{\tilde{\mu}^2}{\mu_2{}^2}+c_H^2+1\right)C_L^{(m)}C_L^{(n)} + s_H^2\frac{C_L^{(m)}(1)}{S_L^{(m)}(1)}S_L^{(m)}\frac{C_L^{(n)}(1)}{S_L^{(n)}(1)}S_L^{(n)}\right\}C_Z\right],$$
$$g_{Zt_R^{(m)}t_R^{(n)}} = \frac{g_w}{\cos\theta_W}\frac{\sqrt{2}\sqrt{L}}{\sqrt{r_Z r_{t^{(m)}} r_{t^{(n)}}}}\int_1^{z_L} dz\left[\left(\frac{\tilde{\mu}^2}{\mu_2^2}+c_H^2\right)S_R^{(m)}S_R^{(n)}C_Z + \frac{s_H^2}{2}\left(S_R^{(m)}\frac{C_L^{(n)}(1)}{S_L^{(n)}(1)}C_R^{(n)} + \frac{C_L^{(m)}(1)}{S_L^{(m)}(1)}C_R^{(m)}S_R^{(m)}\right)\hat{S}_Z\right.$$
$$\left. -\frac{2}{3}\sin^2\theta_W\left\{\left(2\frac{\tilde{\mu}^2}{\mu_2{}^2}+c_H^2+1\right)S_R^{(m)}S_R^{(n)} + s_H^2\frac{C_L^{(m)}(1)}{S_L^{(m)}(1)}C_R^{(m)}\frac{C_L^{(n)}(1)}{S_L^{(n)}(1)}C_R^{(n)}\right\}C_Z\right]. \tag{A21}$$

Therefore the vector and axial vector coupling are written by

$$g^V_{Zt^{(m)}t^{(n)}} = \frac{g_{Zt_L^{(m)}t_L^{(n)}} + g_{Zt_R^{(m)}t_R^{(n)}}}{2}, \qquad g^A_{Zt^{(m)}t^{(n)}} = \frac{g_{Zt_L^{(m)}t_L^{(n)}} - g_{Zt_R^{(m)}t_R^{(n)}}}{2} \tag{A22}$$

Numerical values of $g^V_{Zt^{(m)}t^{(n)}}$ are given in Table IX.

9. $Ht^{(m)}t^{(n)}$ coupling

The Higgs couplings of the top quark tower are contained in

$$\int_1^{z_L} dz\sqrt{G}\bar{\Psi}_1(-ig_A k z A_z)\gamma^5\Psi_1 \supset -ig_w\sqrt{L}H\int_1^{z_L} dz u_H(z)\frac{i}{2}(\bar{B}\gamma^5 t' - \bar{t}\gamma^5 t' - \bar{t}'\gamma^5 B + \bar{t}'\gamma^5 t)$$
$$= \frac{g_w k\sqrt{L}}{2}\sum_{m,n} H i t_L^{(m)\dagger}t_R^{(n)}\int_1^{\infty} z_L dz u_H(z)(f_{B_L}^{(m)}f_{t'_R}^{(n)} - f_{t_L}^{(m)}f_{t'_R}^{(n)} - f_{t'_L}^{(m)}f_{B_R}^{(n)} + f_{t'_L}^{(m)}f_{t_R}^{(n)}) + (L\leftrightarrow R)$$
$$= i\sum_{m,n} H(g_{Ht_L^{(m)\dagger}t_R^{(n)}}t_L^{(m)\dagger}t_R^{(n)} - g_{Ht_R^{(m)\dagger}t_L^{(n)}}t_R^{(m)\dagger}t_L^{(n)}). \tag{A23}$$

One finds that

$$g_{Ht_R^{(m)\dagger}t_L^{(n)}} = g_{Ht_L^{(n)\dagger}t_R^{(m)}} = -\frac{g_w k\sqrt{L}}{2}\int_1^{z_L} dz u_H(z)(f_{B_R}^{(m)}f_{t'_L}^{(n)} - f_{t_R}^{(m)}f_{t'_L}^{(n)} - f_{t'_R}^{(m)}f_{B_L}^{(n)} + f_{t'_R}^{(m)}f_{t_L}^{(n)})$$
$$= -\frac{g_w\sqrt{kL}}{2}\frac{\sqrt{2}}{\sqrt{(z_L^2-1)r_{t^{(m)}}r_{t^{(n)}}}}\int_1^{z_L} dz z\left\{-\sqrt{2}c_H S_R^{(m)}s_H\frac{C_L^{(n)}(1)}{S_L^{(n)}(1)}S_L^{(n)} + \sqrt{2}s_H\frac{C_L^{(m)}(1)}{S_L^{(m)}(1)}C_R^{(m)}c_H C_L^{(n)}\right\}. \tag{A24}$$

We denote

$$y_{t^{(m)}t^{(n)}} = \frac{g_{Ht_L^{(m)\dagger}t_R^{(n)}} + g_{Ht_R^{(m)\dagger}t_L^{(n)}}}{2}, \qquad \hat{y}_{t^{(m)}t^{(n)}} = \frac{-g_{Ht_L^{(m)\dagger}t_R^{(n)}} + g_{Ht_R^{(m)\dagger}t_L^{(n)}}}{2}. \tag{A25}$$

For $m = n$

$$y_{t^{(m)}t^{(m)}} = -\frac{g_w k\sqrt{kL}}{2}\frac{\sqrt{z_L^2-1}}{r_{t^{(n)}}} s_H c_H \frac{C_L^{(m)}(1)}{S_L^{(m)}(1)}, \qquad \hat{y}_{t^{(m)}t^{(m)}} = 0. \tag{A26}$$

Numerical values of $y_{t^{(m)}t^{(n)}}$ and $\hat{y}_{t^{(m)}t^{(n)}}$ are given in Tables X and XI, respectively.

10. $ZF^{(m)}F^{(n)}$ coupling

The Z couplings of the dark fermion tower are given by

$$\begin{aligned}
&\int_1^{z_L} dz\sqrt{G}\bar{\Psi}_F(-ig_A A_\mu - ig_B Q_{X_F} B_\mu) z\gamma^\mu \Psi_F \\
&= -iZ_\mu \frac{g_w}{\cos\theta_W}\frac{\sqrt{L}}{\sqrt{2}\sqrt{r_Z}}\int_1^{z_L} dz \sum_{m,n}[\{(1+\cos\theta_H)C(z) f_{lL}^{*(m)} f_{lL}^{(n)} + (1-\cos\theta_H)C(z) f_{rL}^{*(m)} f_{rL}^{(n)} \\
&\quad - \sin\theta_H \hat{S}(z)(i f_{lL}^{*(m)} f_{rL}^{(n)} - i f_{rL}^{*(m)} f_{lL}^{(n)})\}\bar{F}_L^{(m)}\gamma^\mu I_3 F_L^{(n)} - 2\sin^2\theta_W (f_{lL}^{*(m)} f_{lL}^{(n)} + f_{rL}^{*(m)} f_{rL}^{(n)}) \\
&\quad \times \bar{F}_L^{(m)}\gamma^\mu (I_3 + Q_{X_F}) F_L^{(n)} + (L \to R)] \\
&= -iZ_\mu \sum_{m,n}\{g_{ZF_L^{+(m)}F_L^{+(n)}}\bar{F}_L^{+(m)}\gamma^\mu F_L^{+(n)} + g_{ZF_R^{+(m)}F_R^{+(n)}}\bar{F}_R^{+(m)}\gamma^\mu F_R^{+(n)} + g_{ZF_L^{0(m)}F_L^{0(n)}}\bar{F}_L^{0(m)}\gamma^\mu F_L^{0(n)} \\
&\quad + g_{ZF_R^{0(m)}F_R^{0(n)}}\bar{F}_R^{0(m)}\gamma^\mu F_R^{0(n)}\},
\end{aligned} \tag{A27}$$

where $F_L^{(n)}$ is a abbreviation of the doublet $(F_L^{+(n)}, F_L^{0(n)})^T$ and I_3 is a isospin operator. For $Q_{X_F} = 1/2$ one finds that

TABLE X. $y_{t^{(m)}t^{(n)}}$ in the unit of $y_t \cos\theta_H$. Only the values larger than $O(10^{-3})$ are shown and written by three significant figures.

(Received 14 April 2014; published 21 May 2014)

Signatures of the SO(5) × U(1) gauge-Higgs unification at LHC and future colliders are explored. The Kaluza-Klein (KK) mass spectra of γ, Z, Z_R and the Higgs self-couplings obey universality relations with the Aharonov-Bohm phase θ_H in the fifth dimension. The current data at low energies and at LHC indicate $\theta_H < 0.2$. Couplings of quarks and leptons to KK gauge bosons are determined. Three neutral gauge bosons, the first KK modes $Z_R^{(1)}$, $Z^{(1)}$, and $\gamma^{(1)}$, appear as Z' bosons in dilepton events at LHC. For $\theta_H = 0.114$, the mass and decay width of $Z_R^{(1)}$, $Z^{(1)}$, and $\gamma^{(1)}$ are (5.73, 482), (6.07, 342), and (6.08 TeV, 886 GeV), respectively. For $\theta_H = 0.073$ their masses are $8.00 \sim 8.61$ TeV. An excess of events in the dilepton invariant mass should be observed in the Z' search at the upgraded LHC at 14 TeV.

I. INTRODUCTION

The discovery of the Higgs boson of a mass around 126 GeV [1,2] supports the scenario of unification of forces and symmetry breaking envisioned in the standard model (SM) of electroweak interactions. Experimental data so far are consistent with what the SM describes, but more data are necessary to pin down whether or not the discovered boson is definitively the Higgs boson in the SM. Other scenarios such as supersymmetric models [3,4], little Higgs models [5–8], composite Higgs models [9–16], warped extra-dimension models [17–19], and UED models [20–26] have been proposed in anticipation of physics beyond the SM. It is urgent to derive and predict new phenomena which can be observed and checked in the experiments at the upgraded 14 TeV LHC.

The gauge-Higgs unification is formulated in higher-dimensional gauge theory [27–32]. The four-dimensional Higgs boson appears as a part of the extra-dimensional component of gauge fields, being unified with four-dimensional gauge fields such as W, Z, and γ. Dynamics of the Higgs boson are governed by the gauge principle. Most viable is the $SO(5) \times U(1)$ gauge-Higgs unification in the Randall-Sundrum warped space [9,33–37]. At low energies it yields almost the same physics as the SM, being consistent with LHC data and others. Higgs couplings to gauge bosons, quarks, and leptons at the tree level are suppressed by a common factor $\cos\theta_H$, where θ_H is the Aharonov-Bohm phase in the extra dimension [38]. All of the precision measurements [9,39], the tree-unitary constraint [40], and the Z' search [41–43] indicate $\theta_H < 0.2$. Branching fractions of various decay modes of the Higgs boson remain nearly the same as in the SM, and the signal strengths of the Higgs decay modes relative to the SM are $\sim \cos^2\theta_H$ [37]. We note that though the gauge-Higgs unification model has similarity to the composite Higgs models, it is more restrictive and has more predictive power.

To distinguish the gauge-Higgs unification from the SM we examine the prediction of new particles. It has been pointed out that the first Kaluza-Klein (KK) modes of Z and γ, denoted as $Z^{(1)}$ and $\gamma^{(1)}$, must appear around 6 TeV for $\theta_H \sim 0.1$. In this paper we give detailed analysis of production of $Z_R^{(1)}$, $Z^{(1)}$ and $\gamma^{(1)}$ at the upgraded LHC. Here Z_R is the gauge boson associated with $SU(2)_R$, which does not have a zero mode. It will be shown that $Z_R^{(1)}$, $Z^{(1)}$ and $\gamma^{(1)}$ have large widths and can be seen as e^+e^- or $\mu^+\mu^-$ signals. Once their masses are determined, the value of θ_H is fixed from the universality relations, which leads to further prediction of the Higgs self-couplings, etc. Many other signals of gauge-Higgs unification have been discussed in the literature [44–67].

In Sec. II the action of the model is given. In addition to quark-lepton multiplets in the vector representation of $SO(5)$, fermion multiplets in the spinor representation of $SO(5)$ are introduced to realize the observed unstable Higgs boson. In Sec. III the effective potential $V_{\rm eff}(\theta_H)$ is evaluated and relevant parameters of the model are determined. It is shown that there appear universality relations among θ_H, the KK mass scale $m_{\rm KK}$, $m_{Z_R^{(1)}}$, $m_{Z^{(1)}}$, $m_{\gamma^{(1)}}$, and Higgs cubic and quartic couplings. In Sec. IV dilepton ($e^+e^-, \mu^+\mu^-$) signals at LHC in the so-called Z' search are examined. In the SO(5) × U(1) gauge-Higgs unification $Z_R^{(1)}$, $Z^{(1)}$ and $\gamma^{(1)}$ appear as Z' bosons. Their masses are around 6 TeV (8 TeV) for $\theta_H = 0.114$ (0.073), and they have large decay widths. We show that they must be found in the upgraded LHC at 14 TeV. Section V is devoted to conclusions. In the Appendixes we summarize KK mass spectra, wave functions and gauge couplings of gauge fields, quark-leptons, and $SO(5)$-spinor fermions.

II. MODEL

The model is defined in the Randall-Sundrum warped spacetime [17] with the metric

$$ds^2 = G_{MN}dx^M dx^N = e^{-2\sigma(y)}\eta_{\mu\nu}dx^\mu dx^\nu + dy^2, \quad (2.1)$$

where $\eta_{\mu\nu} = \mathrm{diag}(-1,1,1,1)$, $\sigma(-y) = \sigma(y)$, $\sigma(y+2L) = \sigma(y)$ and $\sigma(y) = k|y|$ for $|y| \le L$. The Planck brane and TeV brane are located at $y = 0$ and $y = L$, respectively. In the bulk region, $0 < y < L$, the cosmological constant is given by $\Lambda = -6k^2$. The warp factor $z_L = e^{kL}$ is large; $z_L \gg 1$. The KK mass scale is given by $m_{\mathrm{KK}} = \pi k/(z_L - 1) \sim \pi k z_L^{-1}$. In the fundamental region $0 \le y \le L$ the metric can be written, in terms of the conformal coordinate $z = e^{ky}$, as

$$ds^2 = \frac{1}{z^2}\left(\eta_{\mu\nu}dx^\mu dx^\nu + \frac{dz^2}{k^2}\right). \quad (2.2)$$

The gauge symmetry in the bulk region is given by $SO(5)\times U(1)_X \times SU(3)_C$ with the corresponding gauge fields A_M, B_M and G_M and gauge couplings g_A, g_B and g_C. Quark-lepton multiplets Ψ_a are introduced in the vector representation **5** of $SO(5)$, whereas additional fermions Ψ_{F_i} are introduced in the spinor representation **4** of $SO(5)$ [34,36,37]. The $SO(5)$ gauge symmetry is partially broken to $SO(4) \simeq SU(2)_L \times SU(2)_R$ by orbifold boundary conditions. On the Planck brane at $y = 0$ ($z = 1$) there live right-handed brane fermions $\hat{\chi}_{\alpha R}$ and brane scalar $\hat{\Phi}$, which are $(\mathbf{2},\mathbf{1})$ and $(\mathbf{1},\mathbf{2})$ representation of $SU(2)_L \times SU(2)_R$, respectively. The brane interactions are manifestly gauge-invariant under $SO(4)\times U(1)_X \times SU(3)_C$. The brane scalar $\hat{\Phi}$ spontaneously breaks $SU(2)_R \times U(1)_X$ to $U(1)_Y$ by $\langle\hat{\Phi}\rangle \gg m_{\mathrm{KK}}$, which, in turn, induces mixing among Ψ_a and $\hat{\chi}_{\alpha R}$ and makes all exotic fermions acquire masses of $O(m_{\mathrm{KK}})$. The resultant theory at low energies (< 1 TeV) has the SM gauge symmetry $SU(2)_L \times U(1)_Y \times SU(3)_C$ with the SM matter content. All $SO(4)\times U(1)_X$ anomalies are cancelled. Finally the $SU(2)_L \times U(1)_Y$ gauge symmetry is dynamically broken to $U(1)_{\mathrm{EM}}$ by the Hosotani mechanism.

The bulk part of the action is given by

$$\begin{aligned} S_{\mathrm{bulk}} = \int d^5x\sqrt{-G}\Bigg[& -\mathrm{tr}\left(\frac{1}{4}F^{(A)MN}F^{(A)}_{MN} + \frac{1}{2\xi_A}(f^{(A)}_{\mathrm{gf}})^2 + \mathcal{L}^{(A)}_{\mathrm{gh}}\right) \\ & - \left(\frac{1}{4}F^{(B)MN}F^{(B)}_{MN} + \frac{1}{2\xi_B}(f^{(B)}_{\mathrm{gf}})^2 + \mathcal{L}^{(B)}_{\mathrm{gh}}\right) \\ & - \mathrm{tr}\left(\frac{1}{2}F^{(G)MN}F^{(G)}_{MN} + \frac{1}{\xi_C}(f^{(G)}_{\mathrm{gf}})^2 + \mathcal{L}^{(G)}_{\mathrm{gh}}\right) \\ & + \sum_a \bar{\Psi}_a \mathcal{D}(c_a)\Psi_a + \sum_{i=1}^{n_F}\bar{\Psi}_{F_i}\mathcal{D}(c_{F_i})\Psi_{F_i}\Bigg], \\ \mathcal{D}(c) = \Gamma^A e_A{}^M \Bigg(& \partial_M + \frac{1}{8}\omega_{MBC}[\Gamma^B,\Gamma^C] \\ & - ig_A A_M - ig_B Q_X B_M - ig_C Q^{\mathrm{color}} G_M\Bigg) - c\sigma'(y). \end{aligned} \quad (2.3)$$

The gauge fixing and ghost terms are denoted as functionals with subscripts gf and gh, respectively. $F^{(A)}_{MN} = \partial_M A_N - \partial_N A_M - ig_A[A_M, A_N]$, $F^{(B)}_{MN} = \partial_M B_N - \partial_N B_M$, and $F^{(G)}_{MN} = \partial_M G_N - \partial_N G_M - ig_C[G_M, G_N]$. The gauge fixing function is taken as $f^{(A)}_{\mathrm{gf}} = z^2\{\eta^{\mu\nu}\mathcal{D}_\mu A_\nu + \xi_A k^2 z \mathcal{D}^c_z(A^q_z/z)\}$ with a background field A^c_z ($A_z = A^c_z + A^q_z$), $B^c_z = G^c_z = 0$. $Q^{\mathrm{color}} = 1$ for quark-multiplets and $Q^{\mathrm{color}} = 0$ otherwise. The $SO(5)$ gauge fields A_M are decomposed as

$$A_M = \sum_{a_L=1}^{3} A^{a_L}_M T^{a_L} + \sum_{a_R=1}^{3} A^{a_R}_M T^{a_R} + \sum_{\hat{a}=1}^{4} A^{\hat{a}}_M T^{\hat{a}}, \quad (2.4)$$

where $T^{a_L,a_R}(a_L, a_R = 1,2,3)$ and $T^{\hat{a}}(\hat{a} = 1,2,3,4)$ are the generators of $SO(4) \simeq SU(2)_L \times SU(2)_R$ and $SO(5)/SO(4)$, respectively. The electric charge is given by

$$Q_{\mathrm{EM}} = T^{3_L} + T^{3_R} + Q_X. \quad (2.5)$$

In the fermion part $\bar{\Psi} = i\Psi^\dagger\Gamma^0$ and Γ^M matrices are given by

$$\begin{aligned} \Gamma^\mu &= \begin{pmatrix} & \sigma^\mu \\ \bar{\sigma}^\mu & \end{pmatrix}, \qquad \Gamma^5 = \begin{pmatrix} 1 & \\ & -1 \end{pmatrix}, \\ \sigma^\mu &= (1,\vec{\sigma}), \qquad \bar{\sigma}^\mu = (-1,\vec{\sigma}). \end{aligned} \quad (2.6)$$

The $c\sigma'(y)$ term in the action (2.3) gives a bulk kink mass. The dimensionless parameter c plays an important role in controlling profiles of fermion wave functions.

The orbifold boundary conditions at $y_0 = 0$ and $y_1 = L$ are given by

$$\begin{aligned} \begin{pmatrix} A_\mu \\ A_y \end{pmatrix}(x, y_j - y) &= P_{\mathrm{vec}}\begin{pmatrix} A_\mu \\ -A_y \end{pmatrix}(x, y_j + y)P^{-1}_{\mathrm{vec}}, \\ \begin{pmatrix} B_\mu \\ B_y \end{pmatrix}(x, y_j - y) &= \begin{pmatrix} B_\mu \\ -B_y \end{pmatrix}(x, y_j + y), \\ \begin{pmatrix} G_\mu \\ G_y \end{pmatrix}(x, y_j - y) &= \begin{pmatrix} G_\mu \\ -G_y \end{pmatrix}(x, y_j + y), \\ \Psi_a(x, y_j - y) &= P_{\mathrm{vec}}\Gamma^5\Psi_a(x, y_j + y), \\ \Psi_{F_i}(x, y_j - y) &= (-1)^j P_{\mathrm{sp}}\Gamma^5\Psi_{F_i}(x, y_j + y), \\ P_{\mathrm{vec}} &= \mathrm{diag}(-1,-1,-1,-1,+1), \\ P_{\mathrm{sp}} &= \mathrm{diag}(+1,+1,-1,-1). \end{aligned} \quad (2.7)$$

The $SO(5)$ symmetry is reduced to $SO(4) \simeq SU(2)_L \times SU(2)_R$ by the orbifold boundary conditions. At this stage the four-dimensional components of the five-dimensional gauge fields have zero modes in $SO(4)\times U(1)_X \times SU(3)_C$, whereas the extra-dimensional components have zero modes in $SO(5)/SO(4)$, $A^{\hat{a}}_y$ or $A^{\hat{a}}_z$ ($a = 1,\ldots,4$). The latter contains the four-dimensional Higgs field, which is a

doublet both in $SU(2)_L$ and in $SU(2)_R$. Without loss of generality one can set $\langle A_y^{\hat{a}}\rangle \propto \delta^{a4}$ when the EW symmetry is spontaneously broken by the Hosotani mechanism. The zero modes of $A_y^{\hat{a}}$ ($a = 1, 2, 3$) are absorbed by W and Z bosons. The four-dimensional neutral Higgs field $H(x)$ is a fluctuation mode of the Wilson line phase θ_H,

$$A_y^{\hat{4}}(x,y) = \{\theta_H f_H + H(x)\}\tilde{u}_H(y) + \cdots,$$
$$\exp\left\{\frac{i}{2}\theta_H \cdot 2\sqrt{2}T^{\hat{4}}\right\} = \exp\left\{ig_A\int_0^L dy\langle A_y\rangle\right\},$$
$$f_H = \frac{2}{g_A}\sqrt{\frac{k}{z_L^2-1}} = \frac{2}{g_w}\sqrt{\frac{k}{L(z_L^2-1)}}. \tag{2.8}$$

Here the wave function of the four-dimensional Higgs boson is given by $\tilde{u}_H(y) = [2k/(z_L^2-1)]^{1/2}e^{2ky}$ for $0 \le y \le L$ and $\tilde{u}_H(-y) = \tilde{u}_H(y) = \tilde{u}_H(y+2L)$. $g_w = g_A/\sqrt{L}$ is the dimensionless four-dimensional $SU(2)_L$ coupling.

Quark-lepton multiplets Ψ_a are in the vector representation of $SO(5)$. They are decomposed into $SO(4)$ vectors and singlets. One $SO(4)$ vector multiplet contains two $SU(2)_L$ doublets. In each generation

$$\Psi_1 = \left[\begin{pmatrix}T\\B\end{pmatrix}, \begin{pmatrix}t\\b\end{pmatrix}, t'\right]_{2/3},$$
$$\Psi_2 = \left[\begin{pmatrix}U\\D\end{pmatrix}, \begin{pmatrix}X\\Y\end{pmatrix}, b'\right]_{-1/3},$$
$$\Psi_3 = \left[\begin{pmatrix}\nu_\tau\\\tau\end{pmatrix}, \begin{pmatrix}L_{1X}\\L_{1Y}\end{pmatrix}, \tau'\right]_{-1},$$
$$\Psi_4 = \left[\begin{pmatrix}L_{2X}\\L_{2Y}\end{pmatrix}, \begin{pmatrix}L_{3X}\\L_{3Y}\end{pmatrix}, \nu'_\tau\right]_{0}, \tag{2.9}$$

where the subscripts denote Q_X. We choose the bulk mass parameters such that $c_1 = c_2$ and $c_3 = c_4$ in each generation. With the boundary condition in (2.7), zero modes appear in

$$\left[Q_{1L} = \begin{pmatrix}T_L\\B_L\end{pmatrix}, q_L = \begin{pmatrix}t_L\\b_L\end{pmatrix}, t'_R\right],$$
$$\left[Q_{2L} = \begin{pmatrix}U_L\\D_L\end{pmatrix}, Q_{3L} = \begin{pmatrix}X_L\\Y_L\end{pmatrix}, b'_R\right],$$
$$\left[\ell_L = \begin{pmatrix}\nu_{\tau L}\\\tau_L\end{pmatrix}, L_{1L} = \begin{pmatrix}L_{1XL}\\L_{1YL}\end{pmatrix}, \tau'_R\right],$$
$$\left[L_{2L} = \begin{pmatrix}L_{2XL}\\L_{2YL}\end{pmatrix}, L_{3L} = \begin{pmatrix}L_{3XL}\\L_{3YL}\end{pmatrix}, \nu'_{\tau R}\right]. \tag{2.10}$$

On the Planck brane there exist the brane scalar $\hat{\Phi}$ in $(\mathbf{1},\mathbf{2})$ representation of $SU(2)_L \times SU(2)_R$ with $Q_X = \frac{1}{2}$ and the brane fermions in $(\mathbf{2},\mathbf{1})$ representation of $SU(2)_L \times SU(2)_R$.

$$\hat{\chi}^q_{1R} = \begin{pmatrix}\hat{T}_R\\\hat{B}_R\end{pmatrix}_{7/6}, \qquad \hat{\chi}^q_{2R} = \begin{pmatrix}\hat{U}_R\\\hat{D}_R\end{pmatrix}_{1/6},$$
$$\hat{\chi}^q_{3R} = \begin{pmatrix}\hat{X}_R\\\hat{Y}_R\end{pmatrix}_{-5/6}, \qquad \hat{\chi}^l_{1R} = \begin{pmatrix}\hat{L}_{1XR}\\\hat{L}_{1YR}\end{pmatrix}_{-3/2},$$
$$\hat{\chi}^l_{2R} = \begin{pmatrix}\hat{L}_{2XR}\\\hat{L}_{2YR}\end{pmatrix}_{1/2}, \qquad \hat{\chi}^l_{3R} = \begin{pmatrix}\hat{L}_{3XR}\\\hat{L}_{3YR}\end{pmatrix}_{-1/2}, \tag{2.11}$$

where the subscripts denote Q_X. $\hat{\chi}^q_{aR}$'s are $SU(3)_C$ triplets. With these brane fermions all four-dimensional anomalies in $SO(4) \times U(1)_X$ are cancelled [36].

The brane part of the action is given by

$$\begin{aligned}S_{\text{brane}} = \int d^5x\sqrt{-G}\delta(y)\Big\{&-(D_\mu\hat{\Phi})^\dagger D^\mu\hat{\Phi} - \lambda_{\hat{\Phi}}(\hat{\Phi}^\dagger\hat{\Phi} - w^2)^2\\ &+\sum_{\alpha=1}^{3}(\hat{\chi}^{q\dagger}_{\alpha R}i\bar{\sigma}^\mu D_\mu\hat{\chi}^q_{\alpha R} + \hat{\chi}^{l\dagger}_{\alpha R}i\bar{\sigma}^\mu D_\mu\hat{\chi}^l_{\alpha R})\\ &- i[\kappa^q_1\hat{\chi}^{q\dagger}_{1R}\check{\Psi}_{1L}\tilde{\hat{\Phi}} + \tilde{\kappa}^q\hat{\chi}^{q\dagger}_{2R}\check{\Psi}_{1L}\hat{\Phi} + \kappa^q_2\hat{\chi}^{q\dagger}_{2R}\check{\Psi}_{2L}\tilde{\hat{\Phi}}\\ &+\kappa^q_3\hat{\chi}^{q\dagger}_{3R}\check{\Psi}_{2L}\hat{\Phi} - (\text{H.c.})]\\ &- i[\tilde{\kappa}^l\hat{\chi}^{l\dagger}_{3R}\check{\Psi}_{3L}\tilde{\hat{\Phi}} + \kappa^l_1\hat{\chi}^{l\dagger}_{1R}\check{\Psi}_{3L}\hat{\Phi} + \kappa^l_2\hat{\chi}^{l\dagger}_{2R}\check{\Psi}_{4L}\tilde{\hat{\Phi}}\\ &+\kappa^l_3\hat{\chi}^{l\dagger}_{3R}\check{\Psi}_{4L}\hat{\Phi} - (\text{H.c.})]\Big\},\end{aligned}$$
$$D_\mu\hat{\Phi} = \left(\partial_\mu - ig_A\sum_{a_R=1}^{3}A^{a_R}_\mu T^{a_R} - iQ_X g_B B_\mu\right)\hat{\Phi},$$
$$\begin{aligned}D_\mu\hat{\chi}_{\alpha R} = \Big(&\partial_\mu - ig_A\sum_{a_L=1}^{3}A^{a_L}_\mu T^{a_L}\\ &- iQ_X g_B B_\mu - ig_C Q^{\text{color}}G_\mu\Big)\hat{\chi}_{\alpha R},\end{aligned}$$
$$\check{\Psi}_{1L} = \begin{pmatrix}T_L & t_L\\B_L & b_L\end{pmatrix}\text{etc.}, \qquad \tilde{\hat{\Phi}} = i\sigma_2\hat{\Phi}^*. \tag{2.12}$$

$\langle\hat{\Phi}\rangle = (0,w)^t \neq 0$ breaks $SU(2)_R \times U(1)_X$ to $U(1)_Y$. It also induces mass mixing on the brane,

$$\begin{aligned}S^{\text{mass}}_{\text{brane}} = \int d^5x\sqrt{-G}\delta(y)\Big\{&-\sum_{\alpha=1}^{3}i\mu^q_\alpha(\hat{\chi}^{q\dagger}_{\alpha R}Q_{\alpha L} - Q^\dagger_{\alpha L}\hat{\chi}^q_{\alpha R})\\ &- i\tilde{\mu}^q(\hat{\chi}^{q\dagger}_{2R}q_L - q^\dagger_L\hat{\chi}^q_{2R})\\ &-\sum_{\alpha=1}^{3}i\mu^l_\alpha(\hat{\chi}^{l\dagger}_{\alpha R}L_{\alpha L} - L^\dagger_{\alpha L}\hat{\chi}^l_{\alpha R})\\ &- i\tilde{\mu}^l(\hat{\chi}^{l\dagger}_{3R}\ell_L - \ell^\dagger_L\hat{\chi}^l_{3R})\Big\},\end{aligned}$$
$$\frac{\mu^q_\alpha}{\kappa^q_\alpha} = \frac{\tilde{\mu}^l}{\tilde{\kappa}^q} = \frac{\mu^l_\alpha}{\kappa^l_\alpha} = \frac{\tilde{\mu}^l}{\tilde{\kappa}^l} = w, \tag{2.13}$$

where $\mu_\alpha, \tilde{\mu}$ define brane mass parameters. In the present paper we assume that the brane interactions are diagonal in

the generation of quarks and leptons. In this case all of $\mu_\alpha, \tilde{\mu}$ and w can be taken to be real and positive without loss of generality. As far as $\mu_\alpha, \tilde{\mu} \gg m_{\rm KK}$, only $\tilde{\mu}^q/\mu_2^q$ and $\tilde{\mu}^l/\mu_3^l$ become relevant at low energies.

As shown in Sec. III, the effective potential $V_{\rm eff}(\theta_H)$ is minimized at $\theta_H \neq 0$, thereby the electroweak symmetry breaking taking place. The gauge fields are expanded in KK towers. In particular, four-dimensional components of the $SO(5) \times U(1)_X$ gauge fields are expanded, in the twisted gauge, as

$$A_\mu(x,z) + \frac{g_B}{g_A} B_\mu(x,z) T_B = \hat{W}^-_\mu + \hat{W}^+_\mu + \hat{Z}_\mu + \hat{A}^\gamma_\mu + \hat{W}^-_{R\mu} + \hat{W}^+_{R\mu} + \hat{Z}_{R\mu} + \hat{A}^{\hat{4}}_\mu. \tag{2.14}$$

Here we have introduced T_B such that ${\rm Tr}{T_B}^2 = 1$, ${\rm Tr}T_B T^\alpha = 0$ and ${\rm Tr}T^\alpha T^\beta = \delta^{\alpha\beta}$ where T^α's are generators of $SO(5)$ in the tensorial representation. The $\hat{W}^\pm, \hat{Z}$ and $\hat{A}^\gamma$ towers contain $W^\pm, Z$ and γ. The other towers do not contain light modes. Each of the $\hat{W}^+, \hat{W}^-, \hat{Z}$ towers splits into two KK towers at $\theta_H = 0$. In all, (2.14) contains 11 KK towers. Details of wave functions of each KK tower are tabulated in Appendix B.

The fermion Ψ_{F_i} are introduced in the spinor representation of $SO(5)$ unlike other fields in the bulk which are in the vector or adjoint representations [37]. As explained in the next section, the existence of Ψ_{F_i} in addition to the other bulk fields leads to nontrivial dependence of the effective potential $V_{\rm eff}(\theta_H)$ on θ_H and to the instability of the four-dimensional Higgs boson. The boundary condition $\Psi_{F_i}(x, y_j - y) = (-1)^j P_{\rm sp} \Gamma^5 \Psi_{F_i}(x, y_j + y)$ in (2.7) implies that there is no zero mode for $\theta_H = 0$ and that the lowest KK modes of $\Psi_{F_i}(x,z)$ dominantly couple to the $SU(2)_R$ gauge bosons. If the boundary condition $\Psi_{F_i}(x, y_j - y) = (-1)^{j+1} P_{\rm sp} \Gamma^5 \Psi_{F_i}(x, y_j + y)$ were taken, then the lowest KK modes of $\Psi_{F_i}(x,z)$ would dominantly couple to the $SU(2)_L$ gauge bosons. The lowest, neutral component of Ψ_{F_i} turns out stable and becomes the dark matter of the Universe, as will be explained in a separate paper [67]. For this reason the $SO(5)$-spinor fermion Ψ_{F_i} is called a dark fermion.

III. HIGGS BOSON AND THE UNIVERSALITY

As explained in (2.8), the extra-dimensional component $A_z = (kz)^{-1} A_y$ contains the four-dimensional Higgs field,

$$A^{\hat{4}}_z(x,z) = \{\theta_H f_H + H(x)\} u_H(z) + \cdots,$$
$$u_H(z) = \sqrt{\frac{2}{k(z_L^2 - 1)}}\, z \quad \text{for } 1 \le z \le z_L. \tag{3.1}$$

The value of θ_H is determined by the location of the global minimum of the effective potential $V_{\rm eff}(\theta_H)$. The Higgs boson mass is given by

$$m_H^2 = \frac{1}{f_H^2} \frac{d^2 V_{\rm eff}}{d\theta_H^2}\bigg|_{\rm min}. \tag{3.2}$$

In this section we explain how the parameters of the model are determined, and show that universality relations appear among θ_H, the KK mass $m_{\rm KK}$, the masses of $Z^{(1)}$ and $\gamma^{(1)}$, and the Higgs self-couplings [37].

A. $V_{\rm eff}(\theta_H)$

Let us first consider the case in which all $SO(5)$-spinor fermions (dark fermions) Ψ_{F_i} are degenerate at the tree level, i.e., $c_{F_i} = c_F$ $(i = 1, \ldots, n_F)$. At the one-loop level only the KK towers whose mass spectra depend on θ_H contribute to the effective potential $V_{\rm eff}(\theta_H)$. Those spectra are given by (B6) for the W tower, (B8) for the Z tower, (B22) for the D tower, (C4) for the top quark tower, (C7) for the bottom quark tower, and (C9) for the F tower or the dark fermions. Contributions of other quarks and leptons turn out exponentially suppressed and negligible.

The relevant parameters of the model are $k, z_L, g_A, g_B, c_t, \tilde{\mu}/\mu_2, c_F$ and n_F, from which $V_{\rm eff}(\theta_H)$ is determined. Other brane mass parameters are irrelevant so long as $\mu_\alpha, \tilde{\mu}, w \gg m_{\rm KK}$. These eight parameters are chosen such that m_Z, α_w, $\sin^2\theta_W$, m_t, m_b, and m_H take the observed values [68]. (To be precise, $\sin^2\theta_W$ is determined by global fit.) This procedure leaves two parameters, say z_L and n_F, free. The procedure is highly involved as everything must be determined at the global minimum of $V_{\rm eff}(\theta_H)$, which, however, is to be found after all parameters are specified. In other words, all parameters must be determined self-consistently.

First we note that with those given parameters, the one-loop effective potential is given by

$$V_{\rm eff}(\theta_H, c_t, r_t, c_F, n_F, k, z_L, \theta_W; \xi) = 2(3-\xi^2) I[Q_W] + (3-\xi^2) I[Q_Z] + 3\xi^2 I[Q_D] - 12\{I[Q_{\rm top}] + I[Q_{\rm bottom}]\} - 8 n_F I[Q_F],$$
$$I[Q(q;\theta_H)] = \frac{(k z_L^{-1})^4}{(4\pi)^2} \int_0^\infty dq q^3 \ln\{1 + Q(q;\theta_H)\},$$
$$Q_W = \cos^2\theta_W Q_Z = \frac{1}{2} Q_D = \frac{1}{2} Q_0\left[q; \frac{1}{2}\right] \sin^2\theta_H,$$
$$Q_{\rm top} = \frac{Q_{\rm bottom}}{r_t} = \frac{Q_0[q; c_t]}{2(1+r_t)} \sin^2\theta_H,$$
$$Q_F = Q_0[q; c_F] \cos^2\frac{1}{2}\theta_H,$$
$$Q_0[q;c] = \frac{z_L}{q^2 \hat{F}_{c-\frac{1}{2}, c-\frac{1}{2}}(q z_L^{-1}, q) \hat{F}_{c+\frac{1}{2}, c+\frac{1}{2}}(q z_L^{-1}, q)},$$
$$\hat{F}_{\alpha,\beta}(u,v) = I_\alpha(u) K_\beta(v) - e^{-i(\alpha-\beta)\pi} K_\alpha(u) I_\beta(v), \tag{3.3}$$

where $r_t = (\tilde{\mu}/\mu_2)^2$ and K_α and I_α are modified Bessel functions. In the following we take the 't Hooft–Feynman gauge $\xi = 1$.

TABLE I. Parameters and masses in the case of degenerate dark fermions with $n_F = 5$. All masses and k are given in units of TeV.

z_L	θ_H	$m_{\rm KK}$	k	c_t	c_F	$m_{F^{(1)}}$	$m_{Z_R^{(1)}}$	$m_{Z^{(1)}}$	$m_{\gamma^{(1)}}$
10^9	0.473	2.50	7.97×10^8	0.376	0.459	0.353	1.92	1.97	1.98
10^8	0.351	3.13	9.97×10^7	0.357	0.445	0.502	2.40	2.48	2.48
10^7	0.251	4.06	1.29×10^7	0.330	0.430	0.735	3.11	3.24	3.24
10^6	0.172	5.45	1.74×10^6	0.292	0.410	1.11	4.17	4.37	4.38
10^5	0.114	7.49	2.38×10^5	0.227	0.382	1.75	5.73	6.07	6.08
10^4	0.0730	10.5	3.33×10^4	0.0366	0.333	2.91	8.00	8.61	8.61

We adopt the following algorithm to find consistent solutions. We fix the two parameters z_L and n_F.

(1) Suppose that the minimum of $V_{\rm eff}$ is located at $\theta_H = \theta_1$. Equation (B8) and $\sin^2\theta_W$ determine $\lambda_{Z^{(0)}}$, which fixes k by the Z boson mass $m_Z = \lambda_{Z^{(0)}} k$.
(2) c_t and r_t are determined from (C4) and (C7) such that the observed masses of the top and bottom quarks are reproduced.
(3) Now $V_{\rm eff}(\theta_H)$ in (3.3) is evaluated with c_F being a parameter. c_F is determined by the condition

$$\left.\frac{dV_{\rm eff}}{d\theta_H}\right|_{\theta_1} = 0, \tag{3.4}$$

which assures that the minimum of $V_{\rm eff}(\theta_H)$ is located at θ_1.
(4) With these parameters the Higgs boson mass m_H is evaluated from (3.2). This gives $m_H(\theta_1)$, which, in general, differs from the observed value $m_H = 126$ GeV.
(5) We vary the value θ_1 and repeat the procedure from step 1 until we get $m_H(\theta_1) = 126$ GeV.

In this manner the value $\theta_H = \theta_1$ at the minimum is determined as $\theta_H(z_L, n_F)$. All other quantities such as the mass specta of all KK towers, gauge couplings of all particles, and Yukawa couplings of all fermions are determined as functions of z_L, n_F. Determined values for θ_H, $m_{\rm KK}$, $m_{Z^{(1)}}$, etc. are tabulated in Table I in the case of $n_F = 5$.

TABLE II. Parameters and masses in the case of nondegenerate dark fermions with $(n_F^h, n_F^l) = (3, 2)$ and $c_F^l - c_F^h = 0.03$. Masses are given in units of TeV. The values of $m_{\rm KK}$, k, c_t, $m_{Z^{(1)}}$, $m_{Z_R^{(1)}}$, and $m_{\gamma^{(1)}}$ are the same in three digits as those in Table I in the degenerate case.

Smaller c_t and c_F correspond to heavier masses of the top quark and dark fermions $F^{+(1)}$ and $F^{0(1)}$ and give larger contributions to $V_{\rm eff}(\theta_H)$. As n_F gets larger, c_F ($m_{F^{(1)}}$) becomes larger (smaller) with fixed m_H, as the contribution from each dark fermion to $V_{\rm eff}$ becomes small. Given n_F, only a limited region for z_L is allowed. For $n_F = 1, 2, 3$ one cannot reproduce the Higgs mass 126 GeV when z_L becomes too small. When $n_F \geq 4$, one cannot reproduce the top quark mass for $z_L < 10^4$.

Dark fermions may not be degenerate. Suppose that n_F^h multiplets have the bulk mass $c_{F_i} = c_F^h$, and n_F^l multiplets have $c_{F_i} = c_F^l$. Small difference between c_F^h and c_F^l can yield a substantial difference in masses, whereas $V_{\rm eff}(\theta_H)$ is almost unaffected. For instance, when $n_F = n_F^h + n_F^l = 5$, a difference $c_F^l - c_F^h = 0.01(0.03)$ leads to $m_{F_h} - m_{F_l} =$ 30 to 80 GeV (80 to 240 GeV). The dark fermion masses $m_{F_h^{(1)}}$ and $m_{F_l^{(1)}}$ in the case of $(n_F^h, n_F^l) = (3, 2)$ and $c_F^l - c_F^h = 0.03$ are tabulated in Table II. It is found that the numerical values of $m_{\rm KK}$, k, c_t, $m_{Z^{(1)}}$, $m_{Z_R^{(1)}}$, and $m_{\gamma^{(1)}}$ are the same as those in Table I to the accuracy of three digits.

B. The universality

As described above, various quantities such as θ_H, $m_{\rm KK}$, the mass spectra, Higgs cubic and quartic self-couplings λ_3, λ_4, and Yukawa couplings are determined as functions of z_L and n_F in the case of degenerate dark fermions. In other words they depend not only on z_L, but also on how dark fermions are introduced, which could spoil the predictability of the model. Surprisingly it has been found

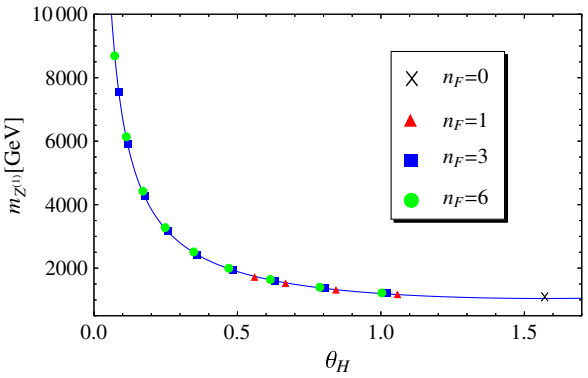

FIG. 1 (color online). θ_H vs $m_{Z^{(1)}}$ for $m_H = 126$ GeV with n_F degenerate dark fermions.

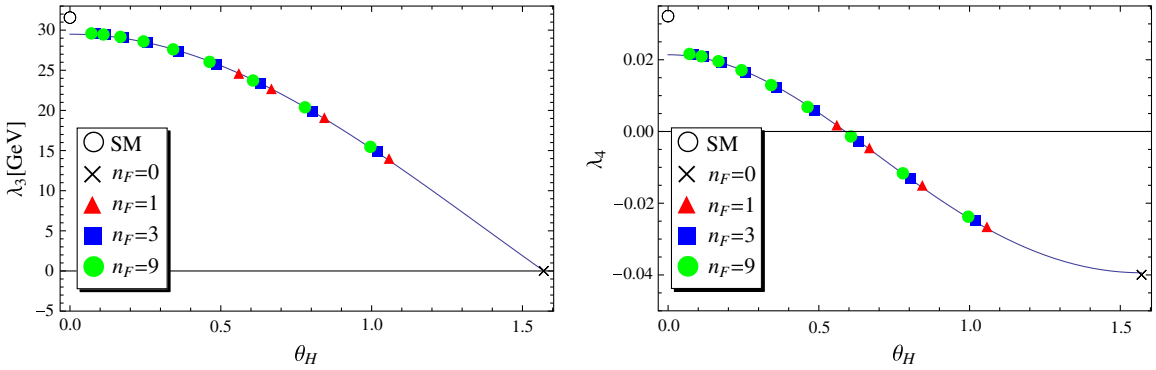

FIG. 2 (color online). θ_H vs λ_3^H and λ_4^H for $m_H = 126$ GeV with n_F degenerate dark fermions. In the SM $\lambda_3^{\rm SM} = 31.5$ GeV and $\lambda_4^{\rm SM} = 0.0320$. The fitting curves are given by (3.6).

in Ref. [37] that universal relations are held among θ_H, $m_{\rm KK}$, $m_{Z_R^{(1)}}$, $m_{Z^{(1)}}$, $m_{\gamma^{(1)}}$, λ_3, and λ_4 irrespective of n_F. This property is called the universality. It implies that once one of these quantities is determined from experiments, then other quantities are predicted, irrespective of the details of the dark fermion sector. The mass spectrum of dark fermions, $m_{F^{(1)}}$, on the other hand, sensitively depends on n_F.

It is most enlightening to express these universal relations as functions of θ_H. The masses $m_{\rm KK}$, $m_{Z_R^{(1)}}$, $m_{Z^{(1)}}$, $m_{\gamma^{(1)}}$ are expressed in the form of

$$m_{\rm KK} \sim \frac{1352\ {\rm GeV}}{(\sin\theta_H)^{0.786}}, \qquad m_{Z_R^{(1)}} \sim \frac{1038\ {\rm GeV}}{(\sin\theta_H)^{0.784}},$$
$$m_{Z^{(1)}} \sim \frac{1044\ {\rm GeV}}{(\sin\theta_H)^{0.808}}, \qquad m_{\gamma^{(1)}} \sim \frac{1056\ {\rm GeV}}{(\sin\theta_H)^{0.804}}. \tag{3.5}$$

The relation between θ_H and $m_{Z^{(1)}}$ is plotted in Fig. 1 for $n_F = 0, 1, 3, 6$. One can see that the curve is universal, independent of n_F. (The case of $n_F = 0$ corresponds to $\theta_H = \frac{1}{2}\pi$ and the stable Higgs boson.)

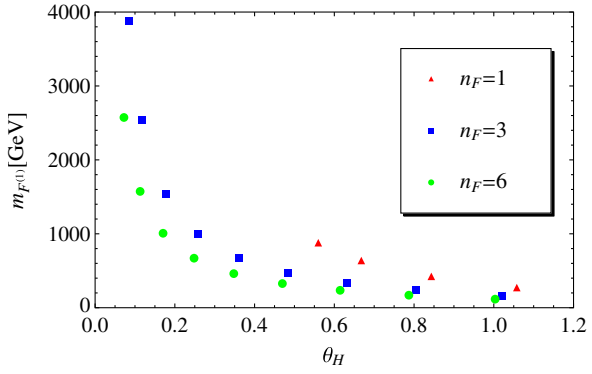

FIG. 3 (color online). θ_H vs m_F for $m_H = 126$ GeV with n_F degenerate dark fermions.

Similarly the Higgs cubic and quartic self-couplings, λ_3 and λ_4 are plotted against θ_H for $n_F = 0, 1, 3, 9$ in Fig. 2. The fitting curves are given by

$$\lambda_3/{\rm GeV} = 26.7\cos\theta_H + 1.42(1+\cos 2\theta_H),$$
$$\lambda_4 = -0.0106 + 0.0304\cos 2\theta_H + 0.00159\cos 4\theta_H. \tag{3.6}$$

These numbers should be compared with $\lambda_3^{\rm SM} = 31.5$ GeV and $\lambda_4^{\rm SM} = 0.0320$ in the SM. We note that the effective potential $V_{\rm eff}(\theta_H)$ is bounded from below so that the negative λ_4 for $\theta_H > 0.6$ does not cause the instability. In the gauge-Higgs unification there is no instability problem in the Higgs couplings.

It should be noted that no universality is found in the mass spectrum of the dark fermions. The mass $m_{F^{(1)}}$ is plotted in Fig. 3 for various n_F.

The universality relations are determined with the fixed Higgs boson mass m_H. If m_H were smaller or larger than the observed value, the universality relations would slightly change. The KK mass scale $m_{\rm KK}$ increases as m_H. The fitting curve is parmetrized as $m_{\rm KK} = \alpha/|\sin\theta_H|^\beta$ with given m_H. The values of α and β for various m_H are tabulated in Table III. We plotted $m_{\rm KK}(\theta_H)$ for $m_H = 110$, 126, 140 GeV in Fig. 4.

We stress that the universality leads to powerful predictions. Once the value of θ_H is determined from, say, $m_{Z^{(1)}}$, many other quantities are predicted for experimental confirmation. The gauge-Higgs unification scenario is very predictive.

TABLE III. Universality relation $m_{\rm KK} = \alpha/|\sin\theta_H|^\beta$ with various value of m_H.

m_H(GeV)	α(TeV)	β
110	1.20	0.733
120	1.30	0.766
126	1.35	0.786

IV. e^+e^-, $\mu^+\mu^-$ EVENTS IN THE Z' SEARCH

One of the distinctive predictions of the $SO(5) \times U(1)$ gauge-Higgs unification is the existence of the KK excited modes of Z and γ. Independent of the details of the dark fermion sector the universality predicts that $m_{Z^{(1)}}, m_{\gamma^{(1)}} \sim 6$ TeV (3 TeV) for $\theta_H = 0.1$ (0.2) as depicted in Fig. 1. $Z^{(1)}$ and $\gamma^{(1)}$ partially decay to e^+e^- or $\mu^+\mu^-$, which should appear as clear signals in the Z' search at LHC [69–74]. We evaluate the production and decay rates of those particles.

In our model there are four kinds of neutral gauge bosons at the TeV scale. [See Eq. (2.14)]. They are the first KK mode of Z boson, $Z^{(1)}$, the first KK mode of photon, $\gamma^{(1)}$, the $Z_R^{(1)}$ boson and the $A^{\hat{4}}$ boson. Among them the $A^{\hat{4}}$ boson does not couple to SM particles so that it escapes from detection in the Z' search. $Z^{(1)}$, $\gamma^{(1)}$, and $Z_R^{(1)}$ are the candidates for Z' bosons.

A. Couplings and decay widths

To evaluate the production and decay rates of Z' bosons we need to know the four-dimensional Z' couplings of quarks and leptons. They are obtained from the five-dimensional gauge interaction terms by inserting wave functions of gauge bosons and quarks or leptons and integrating over the fifth-dimensional coordinate. The couplings of the photon, Z boson and $Z_R^{(1)}$ boson towers can be written as

$$\begin{aligned}
\mathcal{L} \supset & \sum_{n,i} A_\mu^{\gamma(n)} [g_{u^iL}^{\gamma(n)} \bar{u}^i{}_L^i \gamma^\mu u_L^i + g_{u^iR}^{\gamma(n)} \bar{u}_R^i \gamma^\mu u_R^i + g_{d^iL}^{\gamma(n)} \bar{d}_L^i \gamma^\mu d_L^i + g_{d^iR}^{\gamma(n)} \bar{d}_R^i \gamma^\mu d_R^i + g_{e^iL}^{\gamma(n)} \bar{e}_L^i \gamma^\mu e_L^i + g_{e^iR}^{\gamma(n)} \bar{e}_R^i \gamma^\mu e_R^i] \\
& + \sum_{n,i} Z_\mu^{(n)} [g_{u^iL}^{Z(n)} \bar{u}_L^i \gamma^\mu u_L^i + g_{u^iR}^{Z(n)} \bar{u}_R^i \gamma^\mu u_R^i + g_{d^iL}^{Z(n)} \bar{d}_L^i \gamma^\mu d_L^i + g_{d^iR}^{Z(n)} \bar{d}_R^i \gamma^\mu d_R^i + g_{\nu^iL}^{Z(n)} \bar{\nu}_L^i \gamma^\mu \nu_L^i + g_{\nu^iR}^{Z(n)} \bar{\nu}_R^i \gamma^\mu \nu_R^i \\
& + g_{e^iL}^{Z(n)} \bar{e}_L^i \gamma^\mu e_L^i + g_{e^iR}^{Z(n)} \bar{e}_R^i \gamma^\mu e_R^i] + \sum_{n,i} Z_{R\mu}^{(n)} [g_{u^iL}^{Z_R^{(n)}} \bar{u}_L^i \gamma^\mu u_L^i + g_{u^iR}^{Z_R^{(n)}} \bar{u}_R^i \gamma^\mu u_R^i + g_{d^iL}^{Z_R^{(n)}} \bar{d}_L^i \gamma^\mu d_L^i \\
& + g_{d^iR}^{Z_R^{(n)}} \bar{d}_R^i \gamma^\mu d_R^i + g_{\nu^iL}^{Z_R^{(n)}} \bar{\nu}_L^i \gamma^\mu \nu_L^i + g_{\nu^iR}^{Z_R^{(n)}} \bar{\nu}_R^i \gamma^\mu \nu_R^i + g_{e^iL}^{Z_R^{(n)}} \bar{e}_L^i \gamma^\mu e_L^i + g_{e^iR}^{Z_R^{(n)}} \bar{e}_R^i \gamma^\mu e_R^i],
\end{aligned} \tag{4.1}$$

where the superscript i denotes the generation, i.e., $(u^1, u^2, u^3) = (u, c, t)$, etc. Explicit formulas for the gauge couplings are given in Appendix D. The relevant couplings of the Z' bosons are tabulated in Table IV and Table V.

The decay width of the Z' boson is given by

$$\Gamma_{Z'} = \sum_i \frac{m_{Z'}}{12\pi} \left(\frac{(g_{iL}^{Z'})^2 + (g_{iR}^{Z'})^2}{2} + 2 g_{iL}^{Z'} g_{iR}^{Z'} \frac{m_i^2}{m_{Z'}^2} \right) \sqrt{1 - \frac{4m_i^2}{m_{Z'}^2}}. \tag{4.2}$$

Here i runs over all fermions including SM fermions and dark fermions. The contribution of its decay to W^+W^- is very small and can be neglected [59]. The evaluated $\Gamma_{Z'}$ for $\theta_H = 0.114$ is summarized in Table IV. It is seen that all of $Z_R^{(1)}$, $Z^{(1)}$, and $\gamma^{(1)}$ have large decay widths ($300 \sim 900$ GeV) in quite contrast to the narrow width of the Z boson. It is mainly due to the large couplings of right-handed quarks and leptons.

B. Production at LHC

In our study, we calculate the dilepton production cross sections through the Z' boson exchange together with the SM processes mediated by the Z boson and photon. The

dependence of the cross section on the final state dilepton invariant mass $M_{\ell\ell}$ is described as

$$\frac{d\sigma(pp \to \ell^+\ell^- X)}{dM_{\ell\ell}} = \sum_q \int_{-1}^{1} d\cos\theta \int_{\frac{M^2_{\ell\ell}}{E^2_{\rm CMS}}}^{1} dx_1 \frac{2M_{\ell\ell}}{x_1 E^2_{\rm CMS}} \times f_q(x_1, M^2_{\ell\ell}) f_{\bar q}\left(\frac{M^2_{\ell\ell}}{x_1 E^2_{\rm CMS}}, M^2_{\ell\ell}\right) \frac{d\sigma(\bar q q \to \ell^+\ell^-)}{d\cos\theta}, \tag{4.3}$$

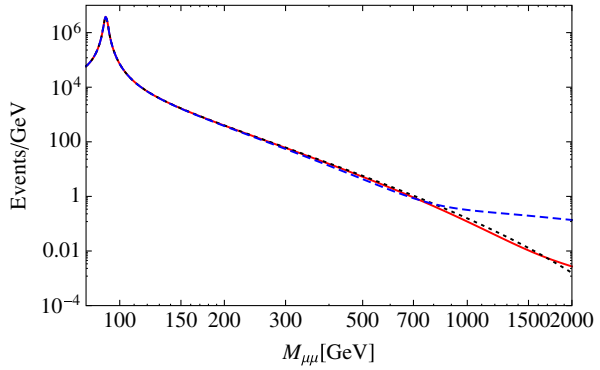

FIG. 5 (color online). The differential cross section multiplied by an integrated luminosity of 20.6 fb^{-1} for $pp \to \mu^+\mu^- X$ at the 8 TeV LHC for $\theta_H = 0.114$ (red solid curve) and for $\theta_H = 0.251$ (blue dashed curve). The black dashed line represents the SM background.

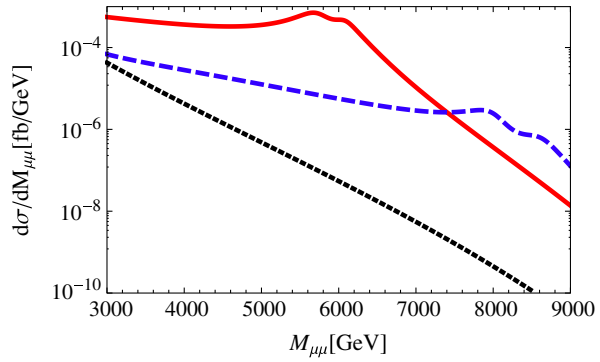

FIG. 6 (color online). The differential cross section for $pp \to \mu^+\mu^- X$ at the 14 TeV LHC for $\theta_H = 0.114$ (red solid curve) and for $\theta_H = 0.073$ (blue dashed curve) . The nearly straight line represents the SM background.

where $E_{\rm CMS}$ is the center-of-mass energy of the LHC and f_q's are the parton distribution functions(PDFs) for q quark. In our numerical analysis, we employ CTEQ5M [75] for the PDFs. Formulas to calculate $d\sigma(\bar q q \to \ell^+\ell^-)/d\cos\theta$ are listed in Appendix E.

Figure 5 shows the differential cross section for $pp \to \mu^+\mu^-$ together with the SM cross section mediated by the Z boson and photon for $\theta_H = 0.114$ ($n_F = 5$, $z_L = 10^5$). The deviation from the SM is very small below 3 TeV because the couplings of the Z boson or photon to SM fermions are almost the same as in the SM. For this reason it is difficult to see the signals of the gauge-Higgs unification at 8 TeV LHC experiments. In the case of $\theta_H = 0.251$ ($n_F = 5$, $z_L = 10^7$), the deviation from the SM is large. The Z' masses are around 3 TeV (See Table 1.) and the decay widths of $Z^{(1)}_R$,$Z^{(1)}$ and $\gamma^{(1)}$ are 341, 221 and 629 GeV. The masses of Z' bosons are heavier than the plot range of Fig. 5. However the decay widths of Z' bosons are very wide and the deviation from the SM is large. Therefore the $\theta_H = 0.251$ case is excluded by the 8 TeV LHC experiments.

On the other hand, at 14 TeV LHC experiments, we expect the signals. Figure 6 shows the differential cross section $d\sigma/dM_{\mu\mu}$ in the range 3 TeV $< M_{\mu\mu} <$ 9 TeV for $\theta_H = 0.114$ and 0.073. The contributions from $Z^{(2)}$ boson and higher KK modes are negligible because the couplings are very small and the widths are very narrow (see Table IV). One sees a very large deviation from the SM, which can be detected at the upgraded LHC.

V. CONCLUSIONS

In the present paper we have explored LHC signals of the $SO(5) \times U(1)$ gauge-Higgs unification, particularly dilepton events associated with the production and decay of the Z' bosons at 14 TeV LHC. In the $SO(5) \times U(1)$ gauge-Higgs unification the four-dimensional Higgs boson appears as a part of the extra-dimensional component of the $SO(5)$ gauge fields, and the quark or lepton multiplets are introduced in the vector representation of $SO(5)$. In addition, dark fermions are introduced in the spinor representation of $SO(5)$, which are vital to realize the observed unstable Higgs boson.

The four-dimensional Higgs boson is the fluctuation mode of the Aharonov-Bohm phase θ_H in the fifth dimension. The phase θ_H, determined by the location of the global minimum of the effective potential $V_{\rm eff}(\theta_H)$,

plays an important role in determining the couplings among gauge boson, quarks and leptons, and the Higgs boson. It has been known that the value $\theta_H < 0.2$ is consistent with the data at low energies.

The shape of $V_{\rm eff}(\theta_H)$, and therefore the location of global minimum θ_H, sensitively depends on the details of the dark fermion sector, which could spoil the predictability of the gauge-Higgs unification scenario. On the contrary, we have shown that there holds the universality in the relations among $m_{\rm KK}$, $m_{Z^{(1)}}$, $m_{\gamma^{(1)}}$, $m_{Z_R^{(1)}}$, λ_3, λ_4 and θ_H, irrespective of the details of the dark fermion sector. For instance, one finds that $m_{Z^{(1)}}(\theta_H) \sim 1044\text{GeV}/(\sin\theta_H)^{0.804}$. The universality implies that once the value of, say, $m_{Z^{(1)}}$ is determined from experiments, then other quantities such as λ_3 and λ_4 are predicted to be tested.

In the $SO(5) \times U(1)$ gauge-Higgs unification the three gauge bosons, $Z_R^{(1)}$, $Z^{(1)}$, and $\gamma^{(1)}$, appear as Z' bosons in dilepton events at LHC. It is interesting that the masses of these bosons turn out around 6 (8 TeV) for $\theta_H = 0.114$ (0.073), which is exactly in the region explored at the 14 TeV LHC. As right-handed quarks and leptons have large couplings to those Z' bosons, the widths of those bosons become large; the decay widths of $Z_R^{(1)}$, $Z^{(1)}$ and $\gamma^{(1)}$ are 482, 342 and 886 GeV (553, 494 GeV and 1.04 TeV) for $\theta_H = 0.114$ (0.073). Notice the relatively large ratio of width/mass $= 0.06 \sim 0.15$ in contrast to that of the Z boson. As the difference in masses of $Z^{(1)}$ and $\gamma^{(1)}$ is small, there should appear two peaks in dilepton events. Due to the large widths the excess of events over those expected in the SM should be seen in much wider range of energies. For $\theta_H = 0.114$, for instance, an excess due to the broad widths of the Z' resonances should be observed above 3 TeV in the dilepton invariant mass. The discovery of the Z' bosons in the 3–9 TeV range would give strong support for the gauge-Higgs unification, signaling the existence of extra dimensions.

In the present paper we have focused on the LHC signals classified in the universality class, specifically on the Z' events. There are other collider signals [76–81] such as the forward-backward asymmetry (at Tevatron) and the charge asymmetry (at LHC) in $t\bar{t}$ pair production and QCD parity violation at LHC [82–86]. We hope to report on these issues in the near future.

APPENDIX A: BASE FUNCTIONS

Mode functions for KK towers are expressed in terms of Bessel functions. For gauge fields we define

$$C(z;\lambda) = \frac{\pi}{2}\lambda z z_L F_{1,0}(\lambda z, \lambda z_L), \qquad C'(z;\lambda) = \frac{\pi}{2}\lambda^2 z z_L F_{0,0}(\lambda z, \lambda z_L), \qquad S(z;\lambda) = -\frac{\pi}{2}\lambda z F_{1,1}(\lambda z, \lambda z_L),$$
$$S'(z;\lambda) = -\frac{\pi}{2}\lambda^2 z F_{0,1}(\lambda z, \lambda z_L), \qquad \hat{S}(z;\lambda) = \frac{C(1;\lambda)}{S(1;\lambda)} S(z;\lambda), \qquad F_{\alpha,\beta}(u,v) = J_\alpha(u) Y_\beta(v) - Y_\alpha(u) J_\beta(v). \tag{A1}$$

These functions satisfy

$$C(z_L;\lambda) = z_L, \qquad C'(z_L;\lambda) = 0, \qquad S(z_L;\lambda) = 0, \qquad S'(z_L;\lambda) = \lambda, \qquad CS' - SC' = \lambda z. \tag{A2}$$

For fermions with a bulk mass parameter c, we define

$$\begin{pmatrix} C_L \\ S_L \end{pmatrix}(z;\lambda,c) = \pm\frac{\pi}{2}\lambda\sqrt{z z_L} F_{c+\frac{1}{2}, c\mp\frac{1}{2}}(\lambda z, \lambda z_L), \qquad \begin{pmatrix} C_R \\ S_R \end{pmatrix}(z;\lambda,c) = \mp\frac{\pi}{2}\lambda\sqrt{z z_L} F_{c-\frac{1}{2}, c\pm\frac{1}{2}}(\lambda z, \lambda z_L). \tag{A3}$$

They satisfy

$$D_+(c)\begin{pmatrix} C_L \\ S_L \end{pmatrix} = \lambda\begin{pmatrix} S_R \\ C_R \end{pmatrix}, \qquad D_-(c)\begin{pmatrix} C_R \\ S_R \end{pmatrix} = \lambda\begin{pmatrix} S_L \\ C_L \end{pmatrix}, \qquad D_\pm(c) = \pm\frac{d}{dz} + \frac{c}{z}, \tag{A4}$$

and

$$C_R = C_L = 1, \qquad S_R = S_L = 0 \quad \text{for } z = z_L, \qquad C_L C_R - S_L S_R = 1, \qquad S_L(z;\lambda,-c) = -S_R(z;\lambda,c). \tag{A5}$$

APPENDIX B: KK TOWERS OF BOSONIC FIELDS

1. Twisted gauge

To find the spectrum and wave function of each KK mode for $\theta_H \neq 0$, it is convenient to move to the twisted gauge in which $\langle \tilde{A}_z \rangle = 0$. This is achieved by a gauge transformation $\tilde{A}_M = \Omega A_M \Omega^{-1} + 1/g_A \Omega \partial_M \Omega^{-1}$ with $\partial_z \Omega = -i g_A \Omega \langle A_z \rangle$;

$$\Omega = \exp\left\{ i g_A \theta_H f_H T^{\hat{4}} \int_y^L dy u_H(y) \right\} = \exp\left\{ i \theta_H \frac{z_L^2 - z^2}{z_L^2 - 1} \sqrt{2} T^{\hat{4}} \right\} \quad \text{for } 1 \le z \le z_L. \tag{B1}$$

The orbifold boundary condition matrices P_j at $y = y_j$ $[(y_0, y_1) = (0, L)]$ change from P_j to $\tilde{P}_j = \Omega(y_j - y) P_0 \Omega(y_j + y)^{-1}$. Ω in (B1) has been chosen such that $\Omega|_{y=L} = 1$ and the orbifold boundary condition at the TeV brane remains unchanged. On the other hand, the orbifold boundary condition matrix P_0 changes to $\tilde{P}_0 = \Omega(-y) P_0 \Omega(y)^{-1}$,

$$\tilde{P}_0^{\rm vec} = \begin{pmatrix} -1 & & & & \\ & -1 & & & \\ & & -1 & & \\ & & & -\cos 2\theta_H & \sin 2\theta_H \\ & & & \sin 2\theta_H & \cos 2\theta_H \end{pmatrix},$$
$$\tilde{P}_0^{\rm sp} = \begin{pmatrix} \cos\theta_H & -i \sin\theta_H \\ i \sin\theta_H & -\cos\theta_H \end{pmatrix} \otimes I_2. \tag{B2}$$

In the twisted gauge the fields satisfy free equations at the tree level, but obey the θ_H-dependent boundary condition specified by (B2). Wave functions of the four-dimensional components of the gauge fields are expressed in terms of either $C(z;\lambda)$ or $S(z;\lambda)$ in (A1), depending on the boundary condition (Neumann or Dirichelet) at the TeV brane. Wave functions of the fifth-dimensional components of the gauge fields, on the other hand, are expressed in terms of either $C'(z;\lambda)$ or $S'(z;\lambda)$. The boundary condition at the Planck brane at $z = 1$ mixes fields through (B2) and determines eigenvalues $\{\lambda_n\}$ in each KK tower.

2. KK towers of A_μ and B_μ

$A_\mu(x,z)$ and $B_\mu^X(x,z)$ are expanded in KK towers.

$$\tilde{A}_\mu(x,z) + \frac{g_B}{g_A} B_\mu(x,z) T_B = \hat{W}_\mu^- + \hat{W}_\mu^+ + \hat{Z}_\mu + \hat{A}_\mu^\gamma + \hat{W}_{R\mu}^- + \hat{W}_{R\mu}^+ + \hat{Z}_{R\mu} + \hat{A}_\mu^{\hat{4}}, \tag{B3}$$

where

$$\hat{W}_\mu^\mp = \sum_n W_\mu^{(n)\mp}(x) \left\{ h^L_{W^{(n)}} \frac{T^{1_L} \mp i T^{2_L}}{\sqrt{2}} + h^R_{W^{(n)}} \frac{T^{1_R} \mp i T^{2_R}}{\sqrt{2}} + \hat{h}_{W^{(n)}} \frac{T^{\hat{1}} \mp i T^{\hat{2}}}{\sqrt{2}} \right\},$$
$$\hat{Z}_\mu = \sum_n Z_\mu^{(n)}(x) \left\{ h^L_{Z^{(n)}} T^{3_L} + h^R_{Z^{(n)}} T^{3_R} + \hat{h}_{Z^{(n)}} T^{\hat{3}} + \frac{g_B}{g_A} h^B_{Z^{(n)}} T_B \right\},$$
$$\hat{A}_\mu^\gamma = \sum_n A_\mu^{\gamma(n)}(x) \left\{ h^L_{\gamma^{(n)}} T^{3_L} + h^R_{\gamma^{(n)}} T^{3_R} + \frac{g_B}{g_A} h^B_{\gamma^{(n)}} T_B \right\},$$
$$\hat{W}_{R\mu}^\mp = \sum_n W_{R\mu}^{(n)\mp}(x) \left\{ h^L_{W_R^{(n)}} \frac{T^{1_L} \mp i T^{2_L}}{\sqrt{2}} + h^R_{W_R^{(n)}} \frac{T^{1_R} \mp i T^{2_R}}{\sqrt{2}} \right\},$$
$$\hat{Z}_{R\mu} = \sum_n Z_{R\mu}^{(n)}(x) \left\{ h^L_{Z_R^{(n)}} T^{3_L} + h^R_{Z_R^{(n)}} T^{3_R} + \frac{g_B}{g_A} h^B_{Z_R^{(n)}} T_B \right\}, \quad \hat{A}_\mu^{\hat{4}} = \sum_n A_\mu^{\hat{4}(n)}(x) \hat{h}_{A^{\hat{4}(n)}} T^{\hat{4}},$$
$$\hat{W}^\pm = \frac{\hat{W}^1 \mp i \hat{W}^2}{\sqrt{2}}, \qquad \hat{W}_R^\pm = \frac{\hat{W}_R^1 \mp i \hat{W}_R^2}{\sqrt{2}}. \tag{B4}$$

The two gauge coupling constants are related to the weak mixing angle θ_W by

$$c_\phi = \frac{g_A}{\sqrt{g_A^2 + g_B^2}}, \qquad s_\phi = \frac{g_B}{\sqrt{g_A^2 + g_B^2}}, \qquad \cos\theta_W = \frac{1}{\sqrt{1 + s_\phi^2}}. \tag{B5}$$

The KK spectrum and corresponding wave functions for each tower are summarized as follows.

a. W tower

The spectrum of the W tower is given by

$$2S(1;\lambda_{W^{(n)}})C'(1;\lambda_{W^{(n)}}) + \lambda_{W^{(n)}}\sin^2\theta_H = 0, \quad \text{(B6)}$$

which includes the W boson as the lowest mode $W = W^{(0)}$. The mode functions are

$$\begin{pmatrix} h^L_{W^{(n)}}(z) \\ h^R_{W^{(n)}}(z) \\ \hat{h}_{W^{(n)}}(z) \end{pmatrix} = \frac{1}{\sqrt{2r_{W^{(n)}}}} \begin{pmatrix} (1+\cos\theta_H)C(z;\lambda_{W^{(n)}}) \\ (1-\cos\theta_H)C(z;\lambda_{W^{(n)}}) \\ -\sqrt{2}\sin\theta_H \hat{S}(z;\lambda_{W^{(n)}}) \end{pmatrix},$$

$$r_{W^{(n)}} = \int_1^{z_L} \frac{dz}{kz}\{(1+\cos^2\theta_H)C(z;\lambda_{W^{(n)}})^2 + \sin^2\theta_H \hat{S}(z;\lambda_{W^{(n)}})^2\}. \quad \text{(B7)}$$

b. Z tower

KK spectrum of the Z tower is given by

$$2S(1;\lambda_{Z^{(n)}})C'(1;\lambda_{Z^{(n)}}) + (1+s_\phi^2)\lambda_{Z^{(n)}}\sin^2\theta_H = 0, \quad \text{(B8)}$$

which includes the Z boson $Z = Z^{(0)}$. The mode functions of the Z tower are

$$\begin{pmatrix} h^L_{Z^{(n)}}(z) \\ h^R_{Z^{(n)}}(z) \\ \hat{h}_{Z^{(n)}}(z) \\ h^B_{Z^{(n)}} \end{pmatrix} = \frac{1}{\sqrt{1+s_\phi^2}} \frac{1}{\sqrt{2r_{Z^{(n)}}}} \times \begin{pmatrix} \{(1+s_\phi^2)(1+\cos\theta_H) - 2s_\phi^2\}C(z;\lambda_{Z^{(n)}}) \\ \{(1+s_\phi^2)(1-\cos\theta_H) - 2s_\phi^2\}C(z;\lambda_{Z^{(n)}}) \\ -\sqrt{2}(1+s_\phi^2)\sin\theta_H \hat{S}(z;\lambda_{Z^{(n)}}) \\ -2s_\phi c_\phi C(z;\lambda_{Z^{(n)}}) \end{pmatrix},$$

$$r_{Z^{(n)}} = \int_1^{z_L} \frac{dz}{kz}\{c_\phi^2 C(z;\lambda_{Z^{(n)}})^2 + (1+s_\phi^2)[\cos^2\theta_H C(z;\lambda_{Z^{(n)}})^2 + \sin^2\theta_H \hat{S}(z;\lambda_{Z^{(n)}})^2\}. \quad \text{(B9)}$$

c. Photon tower

The spectrum of the photon tower is given by

$$C'(1;\lambda_{\gamma^{(n)}}) = 0, \quad \text{(B10)}$$

which includes a massless photon $\lambda_{\gamma^{(0)}} = 0$. The mode functions are

$$\begin{pmatrix} h^L_{\gamma^{(n)}}(z) \\ h^R_{\gamma^{(n)}}(z) \\ h^B_{\gamma^{(n)}} \end{pmatrix} = \frac{1}{\sqrt{1+s_\phi^2}} \frac{1}{\sqrt{r_{\gamma^{(n)}}}} \begin{pmatrix} s_\phi C(z;\lambda_{\gamma^{(n)}}) \\ s_\phi C(z;\lambda_{\gamma^{(n)}}) \\ c_\phi \end{pmatrix} C(z;\lambda_{\gamma^{(n)}}),$$

$$r_{\gamma^{(n)}} = \int_1^{z_L} \frac{dz}{kz} C(z;\lambda_{\gamma^{(n)}})^2. \quad \text{(B11)}$$

In particular for the photon $\gamma = \gamma^{(0)}$,

$$\begin{pmatrix} h^L_\gamma(z) \\ h^R_\gamma(z) \\ h^B_\gamma \end{pmatrix} = \frac{1}{\sqrt{(1+s_\phi^2)L}} \begin{pmatrix} s_\phi \\ s_\phi \\ c_\phi \end{pmatrix}. \quad \text{(B12)}$$

d. W_R tower

The spectrum of the W_R tower is given by

$$C(1;\lambda_{W_R^{(n)}}) = 0. \quad \text{(B13)}$$

The corresponding mode functions are

$$\begin{pmatrix} h^L_{W_R^{(n)}}(z) \\ h^R_{W_R^{(n)}}(z) \end{pmatrix} = \frac{1}{\sqrt{2r_{W_R^{(n)}}}} \begin{pmatrix} +1-\cos\theta_H \\ -1-\cos\theta_H \end{pmatrix} C(z;\lambda_{W_R^{(n)}}),$$

$$r_{W_R^{(n)}} = \int_1^{z_L} \frac{dz}{kz} C(z;\lambda_{W_R^{(n)}})^2. \quad \text{(B14)}$$

e. Z_R tower

The spectrum of the Z_R tower is given by

$$C(1;\lambda_{Z_R^{(n)}}) = 0, \quad \text{(B15)}$$

turning out identical to the W_R tower spectrum, $\lambda_{Z_R^{(n)}} = \lambda_{W_R^{(n)}}$. The corresponding mode functions are

$$\begin{pmatrix} h^L_{Z_R^{(n)}}(z) \\ h^R_{Z_R^{(n)}}(z) \\ h^B_{Z_R^{(n)}} \end{pmatrix} = \frac{1}{\sqrt{1+(1+2t_\phi^2)\cos^2\theta_H}\sqrt{2r_{Z_R^{(n)}}}} \times \begin{pmatrix} -\cos\theta_H - 1 \\ -\cos\theta_H + 1 \\ 2t_\phi\cos\theta_H \end{pmatrix} C(z;\lambda_{Z_R^{(n)}}),$$

$$r_{Z_R^{(n)}} = \int_1^{z_L} \frac{dz}{kz} C(z;\lambda_{Z_R^{(n)}})^2 = r_{W_R^{(n)}}, \qquad t_\phi \equiv \frac{s_\phi}{c_\phi}. \quad \text{(B16)}$$

f. $A^{\hat{4}}$ tower

The spectrum and wave functions of $A^{\hat{4}}$ tower are

$$S(1;\lambda_{A^{\hat{4}(n)}}) = 0, \tag{B17}$$

$$h_{A^{\hat{4}(n)}}(z) = \frac{1}{\sqrt{r_{A^{\hat{4}(n)}}}} S(z;\lambda_{A^{\hat{4}(n)}}),$$
$$r_{A^{\hat{4}(n)}} = \int_1^{z_L} \frac{dz}{kz} S(z;\lambda_{A^{\hat{4}(n)}})^2. \tag{B18}$$

3. KK towers of A_z and B_z

$A_z(x,z)$ and $B_z(x,z)$ are expanded in KK towers as

$$\tilde{A}_z(x,z) = \sum_{a=1}^{3} \hat{G}^a + \sum_{a=1}^{3} \hat{D}^a + \hat{H},$$
$$\hat{G}^a = \sum_n G^{a(n)}(x)\{u^L_{G^{(n)}} T^{a_L} + u^R_{G^{(n)}} T^{a_R}\},$$
$$\hat{D}^a = \sum_n D^{a(n)}(x)\{u^L_{D^{(n)}} T^{a_L} + u^R_{D^{(n)}} T^{a_R} + \hat{u}_{D^{(n)}} T^{\hat{a}}\},$$
$$\hat{H} = \sum_n H^{(n)}(x) u_{H^{(n)}} T^{\hat{4}},$$
$$B_z(x,z) = \sum_n B^{(n)}(x) u_{B^{(n)}} T_B. \tag{B19}$$

a. G tower

The G tower spectrum and corresponding mode functions are given by

$$C'(1;\lambda_{G^{(n)}}) = 0, \qquad \lambda_{G^{(n)}} \neq 0. \tag{B20}$$

$$u^L_{G^{(n)}} = u^R_{G^{(n)}} = \frac{1}{\sqrt{2}} \frac{1}{\sqrt{r_{G^{(n)}}}} C'(z;\lambda_{G^{(n)}}),$$
$$r_{G^{(n)}} = \int_1^{z_L} \frac{kdz}{z} C'(z;\lambda_{G^{(n)}})^2. \tag{B21}$$

b. D tower

The spectrum of the D tower is given by

$$S(1;\lambda_{D^{(n)}})C'(1;\lambda_{D^{(n)}}) + \lambda_{D^{(n)}}\sin^2\theta_H$$
$$= C(1;\lambda_{D^{(n)}})S'(1;\lambda_{D^{(n)}}) - \lambda_{D^{(n)}}\cos^2\theta_H = 0. \tag{B22}$$

Corresponding mode functions are given by

$$\begin{pmatrix} h^L_{D^{(n)}}(z) \\ h^R_{D^{(n)}}(z) \\ \hat{h}_{D^{(n)}}(z) \end{pmatrix} = \frac{1}{\sqrt{2r_{D^{(n)}}}} \begin{pmatrix} \cos\theta_H C'(z;\lambda_{D^{(n)}}) \\ -\cos\theta_H C'(z;\lambda_{D^{(n)}}) \\ -\sqrt{2}\sin\theta_H \hat{S}'(z;\lambda_{D^{(n)}}) \end{pmatrix},$$
$$\hat{S}'(z;\lambda) = \frac{C(1;\lambda)}{S(1;\lambda)} S'(z;\lambda),$$
$$r_{D^{(n)}} = \int_1^{z_L} \frac{kdz}{z} \{\cos^2\theta_H C'(z;\lambda_{D^{(n)}})^2 + \sin^2\theta_H \hat{S}'(z;\lambda_{D^{(n)}})^2\}. \tag{B23}$$

c. Higgs (H) tower

The spectrum of the Higgs tower is determined by

$$\lambda_{H^{(n)}} S(1;\lambda_{H^{(n)}}) = 0, \tag{B24}$$

which includes the zero mode $\lambda_{H^{(0)}} = 0$ for the four-dimensional Higgs boson $H = H^{(0)}$. The mode functions are

$$u_{H^{(0)}}(z) = u_H(z) = \sqrt{\frac{2}{k(z_L^2 - 1)}} z, \tag{B25}$$

for the four-dimensional Higgs boson, and

$$u_{H^{(n)}}(z) = \frac{1}{\sqrt{r_{H^{(n)}}}} S'(z;\lambda_{H^{(n)}}),$$
$$r_{H^{(n)}} = \int_1^{z_L} \frac{kdz}{z} S'(z;\lambda_{H^{(n)}})^2 \tag{B26}$$

for KK-excited states ($n \geq 1$).

d. B tower

The B tower spectrum and corresponding mode functions are given by

$$C'(1;\lambda_{B^{(n)}}) = 0, \qquad \lambda_{B^{(n)}} \neq 0. \tag{B27}$$

$$u_{B^{(n)}} = \frac{1}{\sqrt{r_{B^{(n)}}}} C'(z;\lambda_{B^{(n)}}),$$
$$r_{B^{(n)}} = \int_1^{z_L} \frac{kdz}{z} C'(z;\lambda_{B^{(n)}})^2. \tag{B28}$$

APPENDIX C: WAVE FUNCTIONS OF FERMIONS

Wave functions of KK towers of fermions are expressed in terms of $C_L(z;\lambda,c)$ and $S_L(z;\lambda,c)$ in (A3) for left-handed components and $C_R(z;\lambda,c)$ and $S_R(z;\lambda,c)$ for right-handed components.

1. Quark-lepton towers

Wave functions for the KK tower of an up-type quark t (top) are given by

$$\begin{pmatrix} U_L(x,z) \\ B_L(x,z) \\ t_L(x,z) \\ t'_L(x,z) \end{pmatrix} \supset \frac{\sqrt{k}z^2}{\sqrt{r_{t^{(n)}}}} \begin{pmatrix} a_U^{(n)} C_L^{(2)}(z,\lambda_{t^{(n)}}) \\ a_B^{(n)} C_L^{(1)}(z,\lambda_{t^{(n)}}) \\ a_t^{(n)} C_L^{(1)}(z,\lambda_{t^{(n)}}) \\ a_{t'}^{(n)} S_L^{(1)}(z,\lambda_{t^{(n)}}) \end{pmatrix} t_L^{(n)}(x) \equiv \sqrt{k}z^2 \begin{pmatrix} f_{U_L}^{(n)}(z) \\ f_{B_L}^{(n)}(z) \\ f_{t_L}^{(n)}(z) \\ f_{t'_L}^{(n)}(z) \end{pmatrix} t_L^{(n)}(x),$$

$$\begin{pmatrix} U_R(x,z) \\ B_R(x,z) \\ t_R(x,z) \\ t'_R(x,z) \end{pmatrix} \supset \frac{\sqrt{k}z^2}{\sqrt{r_{t^{(n)}}}} \begin{pmatrix} a_U^{(n)} S_R^{(2)}(z,\lambda_{t^{(n)}}) \\ a_B^{(n)} S_R^{(1)}(z,\lambda_{t^{(n)}}) \\ a_t^{(n)} S_R^{(1)}(z,\lambda_{t^{(n)}}) \\ a_{t'}^{(n)} C_R^{(1)}(z,\lambda_{t^{(n)}}) \end{pmatrix} t_R^{(n)}(x) \equiv \sqrt{k}z^2 \begin{pmatrix} f_{U_R}^{(n)}(z) \\ f_{B_R}^{(n)}(z) \\ f_{t_R}^{(n)}(z) \\ f_{t'_R}^{(n)}(z) \end{pmatrix} t_R^{(n)}(x),$$

$$\begin{aligned} r_{t^{(n)}} &= \int_1^{z_L} dz \{ a_U^{(n)2} C_L^{(2)}(z,\lambda_{t^{(n)}})^2 + (a_B^{(n)2} + a_t^{(n)2}) C_L^{(1)}(z,\lambda_{t^{(n)}})^2 + a_{t'}^{(n)2} S_L^{(1)}(z,\lambda_{t^{(n)}})^2 \} \\ &= \int_1^{z_L} dz \{ a_U^{(n)2} S_R^{(2)}(z,\lambda_{t^{(n)}})^2 + (a_B^{(n)2} + a_t^{(n)2}) S_R^{(1)}(z,\lambda_{t^{(n)}})^2 + a_{t'}^{(n)2} C_R^{(1)}(z,\lambda_{t^{(n)}})^2 \}. \end{aligned} \tag{C1}$$

Here $C_L^{(i)}(z,\lambda_{t^{(n)}}) = C_L(z;\lambda_{t^{(n)}},c_i)$, $S_R^{(i)}(z,\lambda_{b^{(n)}}) = S_R(z;\lambda_{b^{(n)}},c_i)$, etc., and other towers of $Q_{\rm EM} = \frac{2}{3}e$ fermions have been suppressed. The common factors are given by

$$\begin{pmatrix} a_U^{(n)} \\ a_B^{(n)} \\ a_t^{(n)} \\ a_{t'}^{(n)} \end{pmatrix} = \begin{pmatrix} -\sqrt{2}\tilde{\mu}^q C_L^{(1)}/\mu_2^q C_L^{(2)} \\ (1-\cos\theta_H)/\sqrt{2} \\ (1+\cos\theta_H)/\sqrt{2} \\ -\sin\theta_H C_L^{(1)}/S_L^{(1)} \end{pmatrix}, \quad C_L^{(i)} \equiv C_L(1;\lambda_{t^{(n)}},c_i), \qquad S_L^{(i)} \equiv S_L(1;\lambda_{t^{(n)}},c_i), \tag{C2}$$

where $\lambda_{t^{(n)}}$ satisfies

$$(\mu_2^q)^2 C_L(1;\lambda_{t^{(n)}},c_2) \left\{ S_R(1;\lambda_{t^{(n)}},c_1) + \frac{\sin^2\theta_H}{2S_L(1;\lambda_{t^{(n)}},c_1)} \right\} + (\tilde{\mu}^q)^2 C_L(1;\lambda_{t^{(n)}},c_1) S_R(1;\lambda_{t^{(n)}},c_2) = 0, \tag{C3}$$

or for $c_1 = c_2 \equiv c_t$

$$2\left\{ 1 + \left(\frac{\mu_2^q}{\tilde{\mu}^q} \right)^2 \right\} S_L(1;\lambda_{t^{(n)}},c_t) S_R(1;\lambda_{t^{(n)}},c_t) + \left(\frac{\mu_2^q}{\tilde{\mu}^q} \right)^2 \sin^2\theta_H = 0. \tag{C4}$$

For a down-type quark b (bottom), we have

$$\begin{pmatrix} b_L(x,z) \\ X_L(x,z) \\ D_L(x,z) \\ b'_L(x,z) \end{pmatrix} \supset \frac{\sqrt{k}z^2}{\sqrt{r_{b^{(n)}}}} \begin{pmatrix} a_b^{(n)} C_L^{(1)}(z,\lambda_{b^{(n)}}) \\ a_X^{(n)} C_L^{(2)}(z,\lambda_{b^{(n)}}) \\ a_D^{(n)} C_L^{(2)}(z,\lambda_{b^{(n)}}) \\ a_{b'}^{(n)} S_L^{(2)}(z,\lambda_{b^{(n)}}) \end{pmatrix} b_L^{(n)}(x) \equiv \sqrt{k}z^2 \begin{pmatrix} f_{b_L}^{(n)}(z) \\ f_{X_L}^{(n)}(z) \\ f_{D_L}^{(n)}(z) \\ f_{b'_L}^{(n)}(z) \end{pmatrix} b_L^{(n)}(x),$$

$$\begin{pmatrix} b_R(x,z) \\ X_R(x,z) \\ D_R(x,z) \\ b'_R(x,z) \end{pmatrix} \supset \frac{\sqrt{k}z^2}{\sqrt{r_{b^{(n)}}}} \begin{pmatrix} a_b^{(n)} S_R^{(1)}(z,\lambda_{b^{(n)}}) \\ a_X^{(n)} S_R^{(2)}(z,\lambda_{b^{(n)}}) \\ a_D^{(n)} S_R^{(2)}(z,\lambda_{b^{(n)}}) \\ a_{b'}^{(n)} C_R^{(2)}(z,\lambda_{b^{(n)}}) \end{pmatrix} b_R^{(n)}(x) \equiv \sqrt{k}z^2 \begin{pmatrix} f_{b_R}^{(n)}(z) \\ f_{X_R}^{(n)}(z) \\ f_{D_R}^{(n)}(z) \\ f_{b'_R}^{(n)}(z) \end{pmatrix} b_R^{(n)}(x),$$

$$\begin{pmatrix} a_b^{(n)} \\ a_X^{(n)} \\ a_D^{(n)} \\ a_{b'}^{(n)} \end{pmatrix} = \begin{pmatrix} -\sqrt{2}\mu_2^q C_L^{(2)}/\tilde{\mu}^q C_L^{(1)} \\ (1-\cos\theta_H)/\sqrt{2} \\ (1+\cos\theta_H)/\sqrt{2} \\ \sin\theta_H C_L^{(2)}/S_L^{(2)} \end{pmatrix}, \quad C_L^{(i)} \equiv C_L(1;\lambda_{b^{(n)}},c_i), \qquad S_L^{(i)} \equiv S_L(1;\lambda_{b^{(n)}},c_i),$$

$$\begin{aligned} r_{b^{(n)}} &= \int_1^{z_L} dz \{ a_b^{(n)2} C_L^{(1)}(z,\lambda_{b^{(n)}})^2 + (a_X^{(n)2} + a_D^{(n)2}) C_L^{(2)}(z,\lambda_{b^{(n)}})^2 + a_{b'}^{(n)2} S_L^{(2)}(z,\lambda_{b^{(n)}})^2 \} \\ &= \int_1^{z_L} dz \{ a_b^{(n)2} S_R^{(1)}(z,\lambda_{b^{(n)}})^2 + (a_X^{(n)2} + a_D^{(n)2}) S_R^{(2)}(z,\lambda_{b^{(n)}})^2 + a_{b'}^{(n)2} C_R^{(2)}(z,\lambda_{b^{(n)}})^2 \}. \end{aligned} \tag{C5}$$

The spectrum is determined by

$$(\tilde{\mu}^q)^2 C_L(1;\lambda_{b^{(n)}},c_1) \left[S_R(1;\lambda_{b^{(n)}},c_2) + \frac{\sin^2\theta_H}{2S_L(1;\lambda_{b^{(n)}},c_2)} \right] + (\mu_2^q)^2 C_L(1;\lambda_{b^{(n)}},c_2) S_R(1;\lambda_{b^{(n)}},c_1) = 0, \tag{C6}$$

or for $c_1 = c_2 = c_t$

$$2\left\{ 1 + \left(\frac{\mu_2^q}{\tilde{\mu}^q} \right)^2 \right\} S_L(1;\lambda_{b^{(n)}},c_t) S_R(1;\lambda_{b^{(n)}},c_t) + \sin^2\theta_H = 0. \tag{C7}$$

For a lepton mupltiplet (ν_τ, τ), the wave functions are given by the following replacement rules:

$$\begin{pmatrix} U \\ B \\ t \\ t' \end{pmatrix} \to \begin{pmatrix} \nu_\tau \\ L_{2Y} \\ L_{3X} \\ \nu'_\tau \end{pmatrix}, \qquad \begin{pmatrix} b \\ D \\ X \\ b' \end{pmatrix} \to \begin{pmatrix} L_{3Y} \\ \tau \\ L_{1Y} \\ \tau' \end{pmatrix}, \quad (\tilde{\mu}^q, \mu_2^q) \to (\mu_3^\ell, \tilde{\mu}^\ell), \qquad (\mu_3^q, \mu_1^q) \to (\mu_1^\ell, \mu_2^\ell), \quad (c_1, c_2) \to (c_4, c_3). \tag{C8}$$

2. Dark fermions ($SO(5)$-spinor fermions)

The spectrum of the KK tower of the dark fermion Ψ_{F_i} is determined by

$$C_L(1;\lambda_{i,n},c_{F_i}) C_R(1;\lambda_{i,n},c_{F_i}) - \sin^2\frac{\theta_H}{2} = 0. \tag{C9}$$

Its KK expansion is given by

$$\Psi_{F_i,R}(x,z)=\sqrt{k}z^2\sum_{n=1}^{\infty}\left\{\begin{pmatrix} f^{(n)}_{i,lR}(z)\\ 0\\ f^{(n)}_{i,rR}(z)\\ 0\end{pmatrix}F^{+(n)}_{i,R}(x)+\begin{pmatrix} 0\\ f^{(n)}_{i,lR}(z)\\ 0\\ f^{(n)}_{i,rR}(z)\end{pmatrix}F^{0(n)}_{i,R}(x)\right\},$$
$$\Psi_{F_i,L}(x,z)=\sqrt{k}z^2\sum_{n=1}^{\infty}\left\{\begin{pmatrix} f^{(n)}_{i,lL}(z)\\ 0\\ f^{(n)}_{i,rL}(z)\\ 0\end{pmatrix}F^{+(n)}_{i,L}(x)+\begin{pmatrix} 0\\ f^{(n)}_{i,lL}(z)\\ 0\\ f^{(n)}_{i,rL}(z)\end{pmatrix}F^{0(n)}_{i,L}(x)\right\}, \tag{C10}$$

where

$$\begin{pmatrix} f^{(n)}_{i,lL}(z)\\ f^{(n)}_{i,lR}(z)\end{pmatrix}=\frac{i\sin\frac{1}{2}\theta_H S_L(1)}{\sqrt{r_i}}\begin{pmatrix} C_L(z)\\ S_R(z)\end{pmatrix}=\frac{\cos\frac{1}{2}\theta_H C_R(1)}{\sqrt{r_i'}}\begin{pmatrix} C_L(z)\\ S_R(z)\end{pmatrix},$$
$$\begin{pmatrix} f^{(n)}_{i,rL}(z)\\ f^{(n)}_{i,rR}(z)\end{pmatrix}=\frac{\cos\frac{1}{2}\theta_H C_L(1)}{\sqrt{r_i}}\begin{pmatrix} S_L(z)\\ C_R(z)\end{pmatrix}=\frac{i\sin\frac{1}{2}\theta_H S_R(1)}{\sqrt{r_i'}}\begin{pmatrix} S_L(z)\\ C_R(z)\end{pmatrix},$$
$$\begin{aligned} r_i&=\int_1^{z_L}dz\left\{\sin^2\frac{1}{2}\theta_H S_L(1)^2C_L(z)^2+\cos^2\frac{1}{2}\theta_H C_L(1)^2S_L(z)^2\right\}\\ &=\int_1^{z_L}dz\left\{\sin^2\frac{1}{2}\theta_H S_L(1)^2S_R(z)^2+\cos^2\frac{1}{2}\theta_H C_L(1)^2C_R(z)^2\right\},\\ r_i'&=\int_1^{z_L}dz\left\{\cos^2\frac{1}{2}\theta_H C_R(1)^2C_L(z)^2+\sin^2\frac{1}{2}\theta_H S_R(1)^2S_L(z)^2\right\}\\ &=\int_1^{z_L}dz\left\{\cos^2\frac{1}{2}\theta_H C_R(1)^2S_R(z)^2+\sin^2\frac{1}{2}\theta_H S_R(1)^2C_R(z)^2\right\}. \end{aligned} \tag{C11}$$

Here $C_L(z)=C_L(z;\lambda_{i,n},c_{F_i})$, $S_R(z)=S_R(z;\lambda_{i,n},c_{F_i})$, etc.

APPENDIX D: GAUGE COUPLINGS

In this appendix we summarize the couplings of quarks and leptons to the gauge bosons and their KK excited states, which are necessary in evaluating dilepton events associated with the production of the Z' bosons in Sec. IV. All four-dimensional gauge couplings of quarks and leptons are obtained from

$$\int_1^{z_L}dz\sqrt{G}e_m{}^{\mu}\sum_a\bar{\tilde{\Psi}}_a\Gamma^m(g_A\tilde{A}_\mu+g_BB_\mu Q_X)\tilde{\Psi}_a \tag{D1}$$

by inserting the wave functions of gauge bosons (B4) and those of fermions in Appendix C. Contributions coming from the interactions of the brane fermions are negligibly small, and can be dropped below.

1. $\gamma\bar{f}f$ couplings

The couplings between the nth KK photon and quarks are given by

$$
\begin{aligned}
&A_\mu^{\gamma(n)}(x)\int_1^{z_L} dz g_A \sum_{i=1,2}\bar{\Psi}_i\left\{h^L_{\gamma^{(n)}}T^{3_L}+h^R_{\gamma^{(n)}}T^{3_R}+\frac{g_B}{g_A}h^B_{\gamma^{(n)}}Q_X\right\}\gamma^\mu\Psi_i \\
&\supset A_\mu^{\gamma(n)}(x)g_w\sqrt{L}\int_1^{z_L}dz\left[\bar{t}_L\gamma^\mu t_L(x)\left\{\frac{1}{2}h^L_{\gamma^{(n)}}(f_{t_L}f_{t_L}+f_{U_L}f_{U_L}-f_{B_L}f_{B_L})+\frac{1}{2}h^R_{\gamma^{(n)}}(f_{B_L}f_{B_L}+f_{U_L}f_{U_L}-f_{t_L}f_{t_L})\right.\right. \\
&\quad\left.+\frac{g_B}{3g_A}h^B_{\gamma^{(n)}}(2f_{B_L}f_{B_L}+2f_{t_L}f_{t_L}+2f_{t'_L}f_{t'_L}-f_{U_L}f_{U_L})\right\}+\bar{b}_L\gamma^\mu b_L(x)\left\{\frac{1}{2}h^L_{\gamma^{(n)}}(f_{X_L}f_{X_L}-f_{b_L}f_{b_L}-f_{D_L}f_{D_L})\right. \\
&\quad\left.\left.+\frac{1}{2}h^R_{\gamma^{(n)}}(f_{D_L}f_{D_L}-f_{X_L}f_{X_L}-f_{b_L}f_{b_L})+\frac{g_B}{3g_A}h^B_{\gamma^{(n)}}(2f_{b_L}f_{b_L}-f_{D_L}f_{D_L}-f_{b'_L}f_{b'_L}-f_{X_L}f_{X_L})\right\}\right]+(L\to R). \qquad \text{(D2)}
\end{aligned}
$$

$(L\to R)$ means that the wave functions of the left-handed fermions (f_{iL}) are changed to those of the right-handed fermions (f_{iR}). The couplings between the photon ($n=0$) and fermions are the same as those in the SM. Similarly the couplings between the nth KK photon and leptons are given by

$$
\begin{aligned}
&A_\mu^{\gamma(n)}(x)g_w\sqrt{L}\int_1^{z_L}dz\left[\bar{\nu}_{\tau L}\gamma^\mu\nu_{\tau L}(x)\left\{\frac{1}{2}h^L_{\gamma^{(n)}}(f_{\nu_{\tau L}}f_{\nu_{\tau L}}+f_{L_{3X,L}}f_{L_{3X,L}}-f_{L_{2Y,L}}f_{L_{2Y,L}})+\frac{1}{2}h^R_{\gamma^{(n)}}(f_{\nu_{\tau L}}f_{\nu_{\tau L}}+f_{L_{2Y,L}}f_{L_{2Y,L}}-f_{L_{3X,L}}f_{L_{3X,L}})\right.\right. \\
&\quad\left.-\frac{g_B}{g_A}h^B_{\gamma^{(n)}}f_{\nu_{\tau L}}f_{\nu_{\tau L}}\right\}+\bar{\tau}_L\gamma^\mu\tau_L(x)\left\{\frac{1}{2}h^L_{\gamma^{(n)}}(f_{L_{1X,L}}f_{L_{1X,L}}-f_{L_{3Y,L}}f_{L_{3Y,L}}-f_{\tau_L}f_{\tau_L})+\frac{1}{2}h^R_{\gamma^{(n)}}(f_{\tau_L}f_{\tau_L}-f_{L_{1X,L}}f_{L_{1X,L}}-f_{L_{3Y,L}}f_{L_{3Y,L}})\right. \\
&\quad\left.\left.-\frac{g_B}{g_A}h^B_{\gamma^{(n)}}(f_{\tau_L}f_{\tau_L}+f_{\tau'_L}f_{\tau'_L}+f_{L_{1X,L}}f_{L_{1X,L}})\right\}\right]+(L\to R) \\
&=A_\mu^{\gamma(n)}(x)g_w\sqrt{L}\int_1^{z_L}dz\bar{\tau}_L\gamma^\mu\tau_L(x)\left\{\frac{1}{2}h^L_{\gamma^{(n)}}(f_{L_{1X,L}}f_{L_{1X,L}}-f_{L_{3Y,L}}f_{L_{3Y,L}}-f_{\tau_L}f_{\tau_L})\right. \\
&\quad\left.+\frac{1}{2}h^R_{\gamma^{(n)}}(f_{\tau_L}f_{\tau_L}-f_{L_{1X,L}}f_{L_{1X,L}}-f_{L_{3Y,L}}f_{L_{3Y,L}})-\frac{g_B}{g_A}h^B_{\gamma^{(n)}}(f_{\tau_L}f_{\tau_L}+f_{\tau'_L}f_{\tau'_L}+f_{L_{1X,L}}f_{L_{1X,L}})\right\}+(L\to R). \qquad \text{(D3)}
\end{aligned}
$$

In the last equality, the use of the explicit form of the wave functions ν_τ and the coupling relation (B5) has been made. Neutrinos do not couple to $\gamma^{(n)}$ as expected.

2. $Z\bar{f}f$ couplings

The couplings between $Z^{(n)}$ and quarks are given by

$$
\begin{aligned}
&Z_\mu^{(n)}(x)g_w\sqrt{L}\int_1^{z_L}dz\left[\bar{t}_L\gamma^\mu t_L(x)\left\{\frac{1}{2}h^L_{Z^{(n)}}(f_{t_L}f_{t_L}+f_{U_L}f_{U_L}-f_{B_L}f_{B_L})+\frac{1}{2}h^R_{Z^{(n)}}(f_{B_L}f_{B_L}+f_{U_L}f_{U_L}-f_{t_L}f_{t_L})\right.\right. \\
&\quad\left.+\hat{h}_{Z^{(n)}}(f_{B_L}f_{t'_L}+f_{t_L}f_{t'_L})+\frac{g_B}{3g_A}h^B_{Z^{(n)}}(2f_{B_L}f_{B_L}+2f_{t_L}f_{t_L}+2f_{t'_L}f_{t'_L}-f_{U_L}f_{U_L})\right\} \\
&\quad+\bar{b}_L\gamma^\mu b_L(x)\left\{\frac{1}{2}h^L_{Z^{(n)}}(f_{X_L}f_{X_L}-f_{b_L}f_{b_L}-f_{D_L}f_{D_L})+\frac{1}{2}h^R_{Z^{(n)}}(f_{D_L}f_{D_L}-f_{X_L}f_{X_L}-f_{b_L}f_{b_L})+\hat{h}_{Z^{(n)}}(f_{D_L}f_{b'_L}-f_{X_L}f_{b'_L})\right. \\
&\quad\left.\left.+\frac{g_B}{3g_A}h^B_{Z^{(n)}}(2f_{b_L}f_{b_L}-2f_{D_L}f_{D_L}-2f_{b'_L}f_{b'_L}-f_{X_L}f_{X_L})\right\}\right]+(L\to R). \qquad \text{(D4)}
\end{aligned}
$$

Similarly the couplings between $Z^{(n)}$ and leptons are given by

$$Z_\mu^{(n)}(x) g_w \sqrt{L} \int_1^{z_L} dz \Big[\bar{\nu}_{\tau L} \gamma^\mu \nu_{\tau L}(x) \Big\{ \frac{1}{2} h^L_{Z^{(n)}} (f_{\nu_{\tau L}} f_{\nu_{\tau L}} + f_{L_{3X,L}} f_{L_{3X,L}} - f_{L_{2Y,L}} f_{L_{2Y,L}}) + \frac{1}{2} h^R_{Z^{(n)}} (f_{\nu_{\tau L}} f_{\nu_{\tau L}} - f_{L_{3X,L}} f_{L_{3X,L}} + f_{L_{2Y,L}} f_{L_{2Y,L}}) + \hat{h}_{Z^{(n)}} (f_{L_{2Y,L}} f_{\nu'_{\tau L}} + f_{L_{3X,L}} f_{\nu'_{\tau L}}) - \frac{g_B}{g_A} h^B_{Z^{(n)}} f_{\nu_{\tau L}} f_{\nu_{\tau L}} \Big\}$$
$$+ \bar{\tau}_L \gamma^\mu \tau_L(x) \Big\{ \frac{1}{2} h^L_{Z^{(n)}} (f_{L_{1X,L}} f_{L_{1X,L}} - f_{\tau_L} f_{\tau_L} - f_{L_{3Y,L}} f_{L_{3Y,L}}) + \frac{1}{2} h^R_{Z^{(n)}} (f_{\tau_L} f_{\tau_L} - f_{L_{1X,L}} f_{L_{1X,L}} - f_{L_{3Y,L}} f_{L_{3Y,L}})$$
$$+ \hat{h}_{Z^{(n)}} (f_{\tau_L} f_{\tau'_L} + f_{L_{1X,L}} f_{\tau'_L}) - \frac{g_B}{g_A} h^B_{Z^{(n)}} (f_{\tau_L} f_{\tau_L} + f_{L_{1X,L}} f_{L_{1X,L}} + f_{\tau'_L} f_{\tau'_L}) \Big\} \Big] + (L \to R). \tag{D5}$$

3. $Z_R \bar{f} f$ couplings

The couplings between $Z_R^{(n)}$ and quarks are given by

$$Z_{R\mu}^{(n)}(x) g_w \sqrt{L} \int_1^{z_L} dz \Big[\bar{t}_L \gamma^\mu t_L(x) \Big\{ \frac{1}{2} h^L_{Z_R^{(n)}} (f_{t_L} f_{t_L} + f_{U_L} f_{U_L} - f_{B_L} f_{B_L}) + \frac{1}{2} h^R_{Z_R^{(n)}} (f_{B_L} f_{B_L} + f_{U_L} f_{U_L} - f_{t_L} f_{t_L})$$
$$+ \frac{g_B}{3 g_A} h^B_{Z_R^{(n)}} (2 f_{B_L} f_{B_L} + 2 f_{t_L} f_{t_L} + 2 f_{t'_L} f_{t'_L} - f_{U_L} f_{U_L}) \Big\}$$
$$+ \bar{b}_L \gamma^\mu b_L(x) \Big\{ \frac{1}{2} h^L_{Z_R^{(n)}} (f_{X_L} f_{X_L} - f_{b_L} f_{b_L} - f_{D_L} f_{D_L}) + \frac{1}{2} h^R_{Z_R^{(n)}} (f_{D_L} f_{D_L} - f_{X_L} f_{X_L} - f_{b_L} f_{b_L})$$
$$+ \frac{g_B}{3 g_A} h^B_{Z_R^{(n)}} (2 f_{b_L} f_{b_L} - f_{D_L} f_{D_L} - f_{b'_L} f_{b'_L} - f_{X_L} f_{X_L}) \Big\} \Big] + (L \to R). \tag{D6}$$

The couplings between $Z_R^{(n)}$ and leptons are

$$Z_{R\mu}^{(n)}(x) g_w \sqrt{L} \int_1^{z_L} dz \Big[\bar{\nu}_{\tau L} \gamma^\mu \nu_{\tau L}(x) \Big\{ \frac{1}{2} h^L_{Z^{(n)}} (f_{\nu_{\tau L}} f_{\nu_{\tau L}} + f_{L_{3X,L}} f_{L_{3X,L}} - f_{L_{2Y,L}} f_{L_{2Y,L}}) + \frac{1}{2} h^R_{Z^{(n)}} (f_{\nu_{\tau L}} f_{\nu_{\tau L}} - f_{L_{3X,L}} f_{L_{3X,L}} + f_{L_{2Y,L}} f_{L_{2Y,L}}) + \hat{h}_{Z^{(n)}} (f_{L_{2Y,L}} f_{\nu'_{\tau L}} + f_{L_{3X,L}} f_{\nu'_{\tau L}}) - \frac{g_B}{g_A} h^B_{Z^{(n)}} f_{\nu_{\tau L}} f_{\nu_{\tau L}} \Big\}$$
$$+ \bar{\tau}_L \gamma^\mu \tau_L(x) \Big\{ \frac{1}{2} h^L_{Z^{(n)}} (f_{L_{1X,L}} f_{L_{1X,L}} - f_{\tau_L} f_{\tau_L} - f_{L_{3Y,L}} f_{L_{3Y,L}}) + \frac{1}{2} h^R_{Z^{(n)}} (f_{\tau_L} f_{\tau_L} - f_{L_{1X,L}} f_{L_{1X,L}} - f_{L_{3Y,L}} f_{L_{3Y,L}})$$
$$+ \hat{h}_{Z^{(n)}} (f_{\tau_L} f_{\tau'_L} + f_{L_{1X,L}} f_{\tau'_L}) - \frac{g_B}{g_A} h^B_{Z^{(n)}} (f_{\tau_L} f_{\tau_L} + f_{L_{1X,L}} f_{L_{1X,L}} + f_{\tau'_L} f_{\tau'_L}) \Big\} \Big] + (L \to R). \tag{D7}$$

4. $A^{\hat{4}} \bar{f} f$ couplings

All couplings of quarks and leptons to $A^{\hat{4}(n)}$ vanish.

5. $W \bar{f} f$ couplings

The coupling of quarks and leptons to $W^{(n)-}$ are given by

$$W_\mu^{(n)-}(x) \frac{g_w \sqrt{L}}{\sqrt{2}} \int_1^{z_L} dz [\bar{b}_L \gamma^\mu t_L(x) \{ h^L_{W^{(n)}} (f_{b_L} f_{t_L} + f_{D_L} f_{U_L}) + h^R_{W^{(n)}} (f_{b_L} f_{B_L} + f_{U_L} f_{X_L})$$
$$+ \hat{h}_{W^{(n)}} (f_{b_L} f_{t'_L} - f_{b'_L} f_{U_L}) \} \bar{\tau}_L \gamma^\mu \nu_{\tau L}(x) \{ h^L_{W^{(n)}} (f_{\tau_L} f_{\nu_{\tau L}} + f_{L_{3X,L}} f_{L_{3Y,L}}) + h^R_{W^{(n)}} (f_{L_{1X,L}} f_{\nu_{\tau L}} + f_{L_{2Y,L}} f_{L_{3Y,L}})$$
$$+ \hat{h}_{W^{(n)}} (f_{L_{3Y,L}} f_{\nu'_{\tau L}} - f_{\tau'_L} f_{\nu_{\tau L}}) \}] + (L \to R). \tag{D8}$$

The couplings of $W^{(n)+}$ are given by the Hermitian conjugate of (D8).

6. $W_R\bar{f}f$ couplings

The couplings between $W_R^{(n)-}$ and quarks are given by

$$W_{R\mu}^{(n)-}(x)\frac{g_w\sqrt{L}}{\sqrt{2}}\int_1^{z_L} dz\bar{b}_L\gamma^\mu t_L(x)\{h^L_{W_R^{(n)}}(f_{b_L}f_{t_L}+f_{D_L}f_{U_L})+h^R_{W_R^{(n)}}(f_{b_L}f_{B_L}+f_{U_L}f_{X_L})\}+(L\to R)=0. \quad \text{(D9)}$$

In the last equality the use of the explicit form for wave functions has been made. Similarly, for leptons the couplings are

$$W_{R\mu}^{(n)-}(x)\frac{g_w\sqrt{L}}{\sqrt{2}}\int_1^{z_L} dz\bar{\tau}_L\gamma^\mu \nu_{\tau L}(x)\{h^L_{W_R^{(n)}}(f_{\tau_L}f_{\nu_{\tau L}}+f_{L_{3X,L}}f_{L_{3Y,L}})+h^R_{W_R^{(n)}}(f_{\nu_{\tau L}}f_{L_{1X,L}}+f_{L_{2Y,L}}f_{L_{3Y,L}})\}+(L\to R)=0. \quad \text{(D10)}$$

In other words, the couplings between $W_R^{(n)}$ and quarks or leptons vanish.

APPENDIX E: HELICITY AMPLITUDES

Here we provide formulas useful for calculations of cross sections discussed in this paper. We begin with the following interaction between a massive gauge boson (A_μ) with mass m_A and a pair of the SM fermions,

$$\mathcal{L}_{\rm int}=J^\mu A_\mu=\bar{f}\gamma^\mu(g^A_{f_L}P_L+g^A_{f_R}P_R)fA_\mu. \quad \text{(E1)}$$

A helicity amplitude for the process $f(\alpha)\bar{f}(\beta)\to F(\delta)\bar{F}(\gamma)$ is given by

$$\mathcal{M}(\alpha,\beta;\gamma,\delta)=\frac{g_{\mu\nu}}{s-m_A^2+im_A\Gamma_A}J^\mu_{\rm in}(\alpha,\beta)J^\nu_{\rm out}(\gamma,\delta), \quad \text{(E2)}$$

where α,β (γ,δ) denote initial (final) spin states for fermion and antifermion, respectively, and Γ_A is the total decay width of the A boson. We have used the 't Hooft–Feynman gauge for the gauge boson propagator and there is no contribution from Nambu-Goldstone modes in the process with the massless initial states.

The currents for initial and final states are explicitly given by

$$J^\mu_{\rm in}(+,-)=-\sqrt{s}g^A_{f_R}(0,1,i,0),$$
$$J^\mu_{\rm in}(-,+)=-\sqrt{s}g^A_{f_L}(0,1,-i,0), \quad \text{(E3)}$$

and

$$J^\mu_{\rm out}(+,-)=-\sqrt{s}g^A_{F_R}(0,\cos\theta,-i,-\sin\theta),$$
$$J^\mu_{\rm out}(-,+)=\sqrt{s}g^A_{F_L}(0,-\cos\theta,-i,\sin\theta), \quad \text{(E4)}$$

where θ is the scattering angle and $f(F)$ denotes a flavor of the initial (final) state of fermions.

In spite of the great success of LHC experiments, we do not know whether the discovered "standard model-like" Higgs particle is really what the standard model predicts, or a particle that some new physics has in its low-energy effective theory. Also, the long-standing problems concerning the property of the Higgs and its interactions are still there, and we still do not have any conclusive argument on the origin of the Higgs itself. In this article we focus on higher-dimensional theories as new physics. First we give a brief review of their representative scenarios and closely related 4D scenarios. Among them, we mainly discuss two interesting possibilities of the origin of the Higgs: the Higgs as a gauge boson and the Higgs as a (pseudo) Nambu–Goldstone boson. Next, we argue that theories of new physics are divided into two categories, i.e., theories with normal Higgs interactions and those with anomalous Higgs interactions. Interestingly, both the candidates for the origin of the Higgs mentioned above predict characteristic "anomalous" Higgs interactions, such as the deviation of the Yukawa couplings from the standard model predictions. Such deviations can hopefully be investigated by precision tests of Higgs interactions at the planned ILC experiment. Also discussed is the main decay mode of the Higgs, $H \to \gamma\gamma$. Again, theories belonging to different categories are known to predict remarkably different new physics contributions to this important process.

Subject Index B40, B43

1. Introduction

1.1. What the discovery of the standard model-like Higgs particle means

We have heard of the very impressive results from LHC experiments that a new particle with a mass of 126 (GeV), which behaves like the Higgs particle of the standard model (SM), has been discovered at CERN. So far, the properties of the particle seem to be consistent with the Higgs of the SM, but it would be premature to conclude whether it is really the Higgs of the SM or a standard model-like Higgs particle predicted by some theory of new physics (physics beyond the standard model). In this article we discuss what the discovery of this particle means in the context of higher-dimensional theories with extra dimensions.

1.2. New physics and its "decoupling limit"

Although we are interested in the possibility that the standard model-like Higgs is some particle predicted by new physics, it is at the same time a clear fact that the SM is a very successful theory at low energies ($E \leq M_W$). We thus expect that any theory of new physics reduces into the SM at low energies. To be more precise, we can think of a "decoupling limit" in new physics theories. The limit is achieved by sending the typical mass (energy) scale of new physics, say M, to infinity: $M \to \infty$. In that limit, various new particles predicted to exist in the new physics with masses of

$\mathcal{O}(M)$ are expected to "decouple" from the low-energy sector [1], and the theories are expected to reduce into the SM. From a field theoretical point of view, the effects of new particles at low energies are described by operators with mass dimension higher than 4 (from the viewpoint of 4D spacetime), "irrelevant operators" whose Wilson coefficients are suppressed by the inverse powers of M ($1/M^2$ in the case of operators with mass dimension 6). Thus the effects of new heavy particles are suppressed and they "decouple" from the low-energy effective Lagrangian.

Let us note that, according to the argument based on dimensional analysis, marginal or relevant operators with mass dimensions equal to or less than 4 may be affected by the presence of heavy new particles. The argument of Ref. [1] is that such effects only affect the renormalization procedure and can be absorbed into the bare parameters in the process of renormalization. Let us note, however, that the hierarchy problem—to be more precise, the problem of quadratically divergent quantum correction to the Higgs mass—exactly concerns the relation between the observed Higgs mass and the corresponding bare mass(-squared) parameter. Thus, when we consider the hierarchy problem, the contributions of new heavy particles should be seriously taken into account. This is why superpartners in supersymmetry (SUSY) theory can play an important role in the solution to the hierarchy problem. Also, in a type of higher-dimensional gauge theory, "gauge–Higgs unification (GHU)" [2–7], discussed later, the summation over the contributions of all Kaluza–Klein (KK) modes makes the quantum correction to the Higgs mass-squared finite, thus solving the hierarchy problem [8].

For instance, in the MSSM (minimal supersymmetric standard model), two Higgs doubles H_u, H_d are introduced to preserve SUSY. The lighter CP-even neutral scalar particle denoted as a linear combination, $\sqrt{2}[\cos\alpha(\mathrm{Re}H_u^0 - \frac{v_u}{\sqrt{2}}) - \sin\alpha(\mathrm{Re}H_d^0 - \frac{v_d}{\sqrt{2}})]$, is identified with the SM-like Higgs. The angle α is fixed by the parameters in the Higgs potential and $v_{u,d}$ are the VEVs of the two Higgs doublets. The couplings of the SM-like Higgs with matter fermions and gauge bosons generally contain the parameters α and β, where β represents the ratio of the VEVs, $\tan\beta \equiv v_u/v_d$. The decoupling limit of the MSSM is achieved by sending the SUSY breaking mass scale M_{SUSY} to infinity. In this limit, it turns out that just a linear combination of two Higgs doublets that alone develops the VEV $v = \sqrt{v_u^2 + v_d^2}$ becomes the lighter scalar and is identified with the SM-like Higgs, as we naturally expect. Correspondingly, in this limit, $\alpha \to \beta - \frac{\pi}{2}$ and all interactions are known to reduce to those we expect in the SM, as is anticipated from the decoupling theorem [1]. We therefore conclude that the decoupling limit of the MSSM is just the SM, although, in the MSSM, in contrast to the case of the SM, the Higgs mass is "calculable", since the quartic coupling of the Higgs potential receives a contribution only from the "D-term" and the Higgs mass at the tree level is more or less equivalent to the weak gauge boson masses.

Now let us turn to the case of higher-dimensional theories. Because of the presence of the extra dimension, we now get an infinite tower of KK modes with higher extra space momenta and therefore higher 4D masses. The non-zero KK modes are new heavy particles. Hence in higher-dimensional theories the decoupling limit is achieved by

$$M_c = \frac{1}{R} \to \infty, \tag{1.1}$$

where R is a generic size of the extra dimension, being the radius when the extra space is just a circle S^1, and M_c is the corresponding "compactification" mass scale. In this limit, all (non-zero) KK modes, having masses of the order of M_c, are expected to decouple from the low-energy effective Lagrangian.

As a new feature of higher-dimensional gauge theory, it is basically possible to construct a theory in which the Higgs-like particle does not exist in the decoupling limit, i.e. the higgsless model [9]. In this

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

type of theory the KK zero-mode with vanishing extra space momentum is excluded by imposing a Dirichlet-type boundary condition for the Higgs field along an interval, as the 1D extra space. Thus all KK modes of the Higgs field have masses of $\mathcal{O}(M_c)$, while the violation of the unitarity of the scattering amplitude of the (longitudinal components of) weak gauge bosons is remedied at higher energies by the presence of a tower of massive non-zero KK modes of the gauge bosons. The decoupling limit of the higgsless theory does not contain SM-like Higgs.

Now we know that at least an SM-like Higgs has been discovered; the higgsless scenario thus seems to be excluded unless a theory with lower M_c is possible without contradicting various experimental data.

Also ruled out is the theory where, even though the decoupling limit is the SM, the modification of the Higgs sector (Higgs interaction) is so huge that it already contradicts reality. The GHU model with H-parity [10,11] is probably such a theory. H-parity is a discrete symmetry under which, among SM fields, only the Higgs field has odd parity while the other fields have even parities. This symmetry exists only when the weak scale and the compactification scale are comparable:

$$x \equiv \frac{g_4}{2}\pi R v = \pi \frac{M_W}{M_c} = \frac{\pi}{2}, \tag{1.2}$$

where g_4 is the 4D gauge coupling constant. Note that, even though M_c is near the weak scale, the masses of non-zero KK modes can be sufficiently large due to the presence of the warp factor when the theory is formulated on the Randall–Sundrum space-time [12–17]. Just as the R-parity implies in the MSSM, the H-parity implies that a single Higgs particle cannot decay into ordinary SM particles, thus making the Higgs stable. As the recently discovered SM-like Higgs particle decays into 2 photons, this interesting scenario seems to be inconsistent with the data.

There still remain other interesting higher-dimensional scenarios. It should be noticed that some of these scenarios are not only consistent with the data, having the SM at their decoupling limits, but they also predict some characteristic deviations from the SM predictions, as we will see below.

Even though the properties of the SM-like Higgs particle seem to be consistent with that of the SM Higgs, we still have a strong motivation to investigate further the properties of the Higgs. Namely, in the SM, in clear contrast to the sector of gauge interaction, the Higgs sector is mysterious, having several long-standing problems, such as the hierarchy problem, as already mentioned, and the problem of many arbitrary parameters in the sector of Higgs interactions, such as Yukawa couplings. We still do not understand the origin of the generation-dependent hierarchical fermion masses and generation (flavor) mixings. These problems all come from the fact that, in contrast to the case of the gauge interactions, there is no guiding principle (symmetry?) to restrict the interactions of the Higgs. Let us note that, even though many of the new physics theories have been proposed mainly in order to solve the hierarchy problem, not all of them have mechanisms to restrict the Yukawa coupling. For instance, in the MSSM there is no principle to restrict the couplings (except for gauge invariance) and the Yukawa couplings are free parameters to start with.

These problems suggest that we have not (fully) understood the origin of the Higgs itself. From such points of view, it will be of crucial importance to study how new physics theories predict the Higgs interactions and to perform precision tests of those interactions. As mentioned above, some higher-dimensional theories and also some closely related 4D theories make very specific predictions concerning the Higgs interactions, i.e. "anomalous Higgs interactions".

Such precision tests will not be easy to perform at the LHC experiment and are expected to be done at the planned ILC experiment.

2. Brief review of higher-dimensional theories

We now summarize very briefly some of the representative scenarios of new physics based on higher-dimensional theories. Also discussed are 4D scenarios closely related to higher-dimensional gauge theory, i.e. the scenarios in which Higgs is a (pseudo) Nambu–Goldstone (NG) boson due to some global symmetries. Since solving the hierarchy problem has been the main motivation for many new physics theories, we categorize the scenarios depending on their attitudes concerning the hierarchy problem.

2.1. Theory without a solution to the hierarchy problem

The representative and popular scenario of this type is the so-called "universal extra dimension (UED)". It is a straightforward extension of the SM to its higher-dimensional version [18]. All SM particles are allowed to propagate universally in the higher-dimensional bulk space. The extra dimension is assumed to be an orbifold torus divided by its discrete symmetry, such as S^1/Z_2 or T^2/Z_4, in order to realize a chiral (left–right asymmetric) theory needed to incorporate the SM. The theory has a discrete symmetry called KK-parity, under which particles of even (odd) KK numbers have even (odd) KK-parities. Thus the lightest first KK mode, having odd KK-parity, cannot decay into ordinary SM particles with even KK-parities and thus becomes stable, just like the LSP in the MSSM with R-parity; it therefore is a candidate for the dark matter. This KK-parity makes the production of a single first KK excited state impossible at ILC. On the other hand, the production of a second KK excited state with even KK-parity is possible through the KK-number violating processes induced by the quantum loop effects [19].

2.2. Theories with a mechanism to solve the hierarchy problem not invoking any symmetry

We now discuss the scenarios formulated in higher-dimensional space-time that aim to solve the hierarchy problem, namely, to explain naturally the hierarchy between the Planck scale $M_{\rm pl}$ and M_W. The scenarios we discuss are the ADD model with large extra dimension [20] and the Randall–Sundrum model with warped extra dimension [21]. In both scenarios, the SM particles live in a 4D space-time (a brane), not an extra dimension, and only gravity propagates in the bulk. This property leads to new types of solutions to the hierarchy problem, not seen in the theories in ordinary 4D space-time. The mechanism to solve the hierarchy problem does not invoke any symmetry.

Let us first discuss the ADD model. When Einstein proposed his unified theory of gravity and electromagnetism along the idea of Kaluza and Klein, the extra dimension was assumed to be small, i.e. $M_c \simeq M_{\rm pl}$: a "small extra dimension". The basic reason for this is that, in the unified field theory, electromagnetic interaction originates from gravity interaction. Thus the electric charge e is inevitably proportional to the (square root of) the Newton constant G_N. On the other hand, the source of the gravity is the energy-momentum and the electric charge should also be proportional to the extra-dimensional momentum of the order of M_c. In this way, we obtain the relation

$$e = \frac{4\sqrt{\pi G_N}}{R} \to R = \frac{4\sqrt{\pi G_N}}{e} \simeq 4 \times 10^{-32}\ (\text{cm}). \tag{2.1}$$

In the ADD model, all the SM particles, including the photon, are assumed to live in the brane, and the size of the extra dimension is free from the constraint coming from the value of the electric charge. In this scenario, the original higher-dimensional Planck scale $M_{\rm pl}^{(0)}$ is of the order of the weak scale $M_{\rm pl}^{(0)} \sim M_W$, and, to begin with, there is no hierarchy between the Planck scale and the weak scale. Too small a Planck scale may lead to an unacceptably strong gravitational force. This potential

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

difficulty is solved by assuming a large extra dimension. Namely, the "gravitational flux" is spread toward the direction of the large extra dimension, thus recovering ordinary very weak 4D gravity. Assuming the presence of an n-dimensional extra dimension, the 4D Planck scale $M_{\rm pl}$ is given as

$$M_{\rm pl}^2 \sim M_{\rm pl}^{(0)2+n} \cdot R^n. \tag{2.2}$$

Assuming that $M_{\rm pl}^{(0)} \sim 1$ (TeV), we get $R \sim 0.1$ (mm) for $n = 2$ (for $n = 1$ the obtained R is unacceptably large). This is the scenario of the "large extra dimension".

While the gravity at distances larger than the compactification size reduces to ordinary Newtonian gravity, at shorter distances, the gravity recovers the original higher-dimensional one whose mass scale is not $M_{\rm pl}$ but $M_{\rm pl}^{(0)} \sim M_W$. Thus the most stringent bound for the ADD model comes from the data from LHC. A search for the anomalous jet + missing E_T events at CMS has put a bound $M_{\rm pl}^{(0)} > 3.0$–5.0 (TeV) for $n = 2$–6 (for higher n the bound is less stringent) [22].

This scenario, however, faces its own new hierarchy problem: the size of the extra dimension 0.1 (mm) for $n = 2$ means $M_c = 2 \times 10^{-2}$ (eV), which implies a new hierarchy $M_c/M_W \sim 10^{-13}$!

Randall and Sundrum pointed out that the new hierarchy problem in the ADD model can be solved once we allow that the bulk space-time is a curved one [21]. They assume that 5D space-time is anti-de Sitter with a negative cosmological constant, while the extra space is compactified on an orbifold S^1/Z_2. The solution to the Einstein equation has a "warp factor":

$$g_{MN} = \begin{pmatrix} e^{-2\kappa|y|} \cdot \eta_{\mu\nu} & 0 \\ 0 & 1 \end{pmatrix}, \tag{2.3}$$

where, in the warp factor $e^{-2\kappa|y|}$, κ is a parameter of the theory of $\mathcal{O}(M_{\rm pl})$ and y is the extra space coordinate. The warp factor may be understood as the factor of "space-like inflation". In fact it mimics the factor e^{Ht} (H: Hubble constant) in the inflationary universe caused by a positive cosmological constant. The sign difference of the cosmological constant may be attributed to the sign difference of the time and space components of the metric tensor. The absolute value $|y|$ in the warp factor is due to the orbifolding of the extra space S^1/Z_2.

Assuming that the SM particles all live in the 4D brane at $y = \pi R$ ("visible brane"), the hierarchy between the Planck scale and the weak scale is naturally realized by the warp factor without any hierarchy between the input parameters of the theory:

$$\frac{M_W}{M_{\rm pl}} \sim e^{-\kappa\pi r_c} \tag{2.4}$$

where r_c is the radius of the circle.

The theory predicts the presence of graviton non-zero KK modes, whose masses are spaced by $\mathcal{O}$ (TeV) and whose gravity couplings are suppressed not by $M_{\rm pl}$ but by $\mathcal{O}$ (TeV). Therefore, such new KK gravitons can be searched for at LHC as the resonance states in the l^+l^- and $\gamma\gamma$ final states. The current lower bound on the KK graviton mass ranges from 0.9 (TeV) to 2.1 (TeV) depending on the parameter of the theory [23,24].

Incidentally, how can this Randall–Sundrum model solve the hierarchy problem at the quantum level, i.e. the problem of quadratic divergence in the quantum correction to the Higgs mass, without relying on some symmetry? Though an explicit argument cannot be found in the literature, the quadratic divergence will also be accompanied by the warp factor after the renormalization of the Higgs field as $\Lambda^2 e^{-2\kappa\pi r_c}$ and the divergence will be harmless.

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

2.3. Theories with a mechanism to solve the hierarchy problem invoking some symmetry

The hierarchy problem concerns a very small number. The smallness of the physical observable can be "naturally" preserved under its quantum correction provided that some symmetry is enhanced in the action of the theory when that observable is switched off. This is because, in the case in which the condition is met, even if the observable is induced at quantum level, it should be inevitably proportional to that small number, such that the correction goes away at the limit of exact symmetry.

We now discuss a few representative scenarios of this sort in the context of higher-dimensional theories. Some of them can actually be formulated in 4D space-time, but are closely related to a kind of higher-dimensional gauge theory.

2.3.1. Gauge–Higgs unification. We first discuss the scenario of "gauge–Higgs unification (GHU)". Einstein attempted to unify the gravity and electromagnetic interactions known at that time mediated by bosons with spin $s = 2, 1$ in the framework of 5D gravity theory. We now know that there is also Higgs interaction. So it is natural to expect that gauge and Higgs interactions mediated by $s = 1, 0$ bosons are unified in the framework of higher-dimensional gauge theories. For instance, in the simplest 5D U(1) gauge theory, the gauge field A_M is decomposed into

$$A_M = (A_\mu, A_y) \tag{2.5}$$

where A_μ corresponds to the 4D gauge field (and its non-zero KK partners), while the extra space component A_y—to be more precise, its KK zero mode, behaving as a 4D scalar—is identified with the (SM-like) Higgs field. This is the GHU scenario, the idea of which is not new [2–7]. In particular, Hosotani proposed a mechanism of dynamical spontaneous gauge symmetry breaking due to the VEV of A_y for the non-Abelian case, the "Hosotani mechanism" [5–7].

One pleasing aspect of this scenario is that it provides a new avenue for the solution to the hierarchy problem by virtue of higher-dimensional local gauge symmetry under which A_y transforms inhomogeneously: $A_y \to A_y + \partial_y \lambda$, λ being a y-dependent gauge parameter [8]. We know that a photon never acquires mass, even at the quantum level, since the local mass-squared operator $m_A^2 A_\mu A^\mu$ is forbidden by local gauge symmetry. In the same way, the Higgs (the zero-mode of A_y) never has a local mass-squared operator, thus eliminating the quadratic divergence. What was stressed in Ref. [8] was the importance of the summation over all KK modes at the quantum correction of the Higgs mass. It is frequently argued that, when we consider low-energy effective theories, only KK zero-modes should be taken into account, probably relying on the wisdom of the decoupling theorem [1]. However, as has already been pointed out in the introduction, when we consider the hierarchy problem, heavy new particles play important roles. Also, we should note that a momentum cutoff spoils local gauge invariance. If we truncate the KK modes at some level, it is equivalent to the cutoff of the extra-dimensional momentum. This is why the summation over all KK modes is crucial to get the finite quantum correction to the Higgs mass.

Actually, the Higgs acquires a finite mass at the quantum level. This is because the zero-mode of A_y, i.e. the Higgs, has a physical interpretation as an Aharonov–Bohm (AB) phase or the phase of a Wilson loop. Let us note that the VEV of the Higgs in this scenario is nothing but a constant gauge field, which gives a vanishing field strength and therefore seems to be just a pure gauge configuration. However, in the case in which the extra dimension is a non-simply-connected space like a circle S^1, the constant gauge field can be interpreted as a component of the vector potential generated by the magnetic flux, penetrating inside the circle. Thus the Higgs field is not a pure gauge but has a physical meaning as the AB phase or the phase of the Wilson loop W. At the quantum level, the

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

Higgs potential is induced as (the real part of) the polynomial of W. Note that $W = \mathrm{P}(e^{i\frac{g}{2}\oint A_y dy})$ is of course a gauge invariant but global (not local) operator, which has nothing to do with UV divergence. This is why we get a finite but non-vanishing Higgs mass in GHU, which disappears at the "decompactification limit $R \to \infty$", where the Wilson loop is trivial. The situation is very similar to the case of finite temperature field theory. At finite temperature the Coulomb potential of a photon is known to have a mass of $\mathcal{O}(T)$ (T: temperature). The mass disappears as $T \to 0$, corresponding to the decompactification limit.

Another pleasing aspect of GHU is that it may shed some light on the problem of arbitrary Yukawa couplings, for instance. In this scenario the Higgs is originally a gauge field. Therefore Yukawa coupling is gauge coupling to start with and, if we succeed in constructing a realistic model, the Yukawa couplings are expected to be constrained by the gauge principle. On the other hand, it is a non-trivial question how the hierarchical fermion masses are realized starting from the gauge coupling, which is universal for all generations. Fortunately, as a new feature of higher-dimensional gauge theories, when orbifold S^1/Z_2 is adopted as the extra dimension, the so-called Z_2-odd bulk mass term of the form

$$-\epsilon(y) M \bar{\psi}\psi \tag{2.6}$$

is allowed. Here $\epsilon(y)$ is a sign function (± 1 depending on the sign of y), which mimics the kink-like configuration of some scalar field and causes the localization of Weyl fermions at two different fixed points of the orbifold depending on its chirality: the mode functions of the KK zero-mode of right- and left-handed fermions behave as $\propto e^{-M|y|}$, $\propto e^{-M|y-\pi R|}$ (R is the radius of S^1). Since the Yukawa coupling is the overlap integral of these mode functions of different chiralities, we eventually get the exponentially suppressed fermion masses behaving as (M_i being flavor-dependent bulk masses)

$$\sim M_W(\pi R M_i) e^{-\pi R M_i} (R : \text{ the radius of } S^1) \tag{2.7}$$

for lighter (1st and 2nd) generations. We thus have a mechanism to realize the hierarchical fermion masses without any hierarchical structure of the parameters M_i. It is interesting to note that, if we plot the logarithm of observed quark masses as a function of generation number, they align along a straight line, roughly speaking. If we take this seriously, this suggests that the quark masses were all equal before the exponential suppression, which is exactly what GHU implies starting from the universal Yukawa couplings. A study pursuing this line of argument is now ongoing.

For the scenario of GHU to be viable, we need to construct a minimal model based on this scenario, just as the MSSM in the case of SUSY. In this attempt, one non-trivial feature arises. In the case of the MSSM, the SM was just made supersymmetric with the same gauge group SU(2) $\times$ U(1) for the electroweak sector. In the case of GHU, however, this gauge group should be inevitably extended. This is because in this scenario the Higgs is originally a gauge field and therefore belongs to an adjoint representation of the gauge group, while, as is well known, the Higgs in the SM is an SU(2) doublet, i.e. a fundamental representation of SU(2). The breakthrough of this problem is to extend the gauge group a little. The simplest choice is to adopt SU(3) as the electroweak sector. A minimal SU(3) GHU (electroweak) model has been discussed [25,26].

The minimal model is formulated in 5D space-time with an orbifold S^1/Z_2 as its extra dimension. The orbifold is defined by the identification of two points on the circle connected by Z_2 transformation,

$$Z_2 : y \to -y, \tag{2.8}$$

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

where y is the coordinate along S^1. We have two fixed points, $y = 0, \pi R$, which are invariant under the transformation. The main motive for adopting the orbifold, not just a manifold like S^1, is the realization of chiral theory by "orbifolding". By identification under Z_2, the degree of freedom of the extra space points becomes one half and, correspondingly, either the right or left Weyl fermion survives as the fermion zero mode.

Another merit of adopting the orbifold is that, by assigning different Z_2-parities for each element of the irreducible representation of SU(3), the gauge symmetry can be explicitly broken by the orbifolding [27], as is explained now.

To realize the mechanism, we assign the Z_2-parities for the elements of the SU(3) triplet representation as follows:

$$\Psi(-y) = -\mathcal{P}\gamma^5\Psi(y) \quad \left(\mathcal{P} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -1 \end{pmatrix}\right), \tag{2.9}$$

where the triplet ψ contains the quark fields

$$\psi = \begin{pmatrix} u_L \\ d_L \\ d_R \end{pmatrix}. \tag{2.10}$$

The matrix $\mathcal{P}$ represents the Z_2-parities of the elements of the triplet. Let us note that, as is seen in (2.9), Z_2 has an aspect of chiral transformation for fermions. Thus the zero-mode, having even Z_2-parity, of the upper two elements of ψ is a left-handed fermion, while the zero-mode of the lowest element is right-handed. Thus a chiral theory needed to accommodate the SM is realized. Now it is clear that an ordinary bulk mass term of the form $M\bar{\psi}\psi$ is not allowed, since Z_2 contains a chiral transformation. This is why the Z_2-odd bulk mass term (2.6) is introduced to be consistent with the orbifolding.

The KK zero-mode of the 4D gauge boson sector is given as

$$A_\mu^{(0)} = \frac{1}{2}\begin{pmatrix} W_\mu^3 + \dfrac{B_\mu}{\sqrt{3}} & \sqrt{2}W_\mu^+ & 0 \\ \sqrt{2}W_\mu^- & -W_\mu^3 + \dfrac{B_\mu}{\sqrt{3}} & 0 \\ 0 & 0 & -\dfrac{2}{\sqrt{3}}B_\mu \end{pmatrix}. \tag{2.11}$$

Namely, only the gauge bosons connecting the elements of ψ with the same Z_2-parities have even Z_2-parity and therefore the zero-modes. It is now clear that the zero-mode sector of the gauge bosons is exactly what we need in the SM. In this way, SU(3) gauge symmetry is broken into SU(2) $\times$ U(1) by the orbifolding [27].

The zero-mode sector of the 4D scalar is given as

$$A_y^{(0)} = \frac{1}{\sqrt{2}}\begin{pmatrix} 0 & 0 & \phi^+ \\ 0 & 0 & \phi^0 \\ \phi^- & \phi^{0*} & 0 \end{pmatrix}. \tag{2.12}$$

We find that, this time, only the "broken generator" part G/H ($G = \mathrm{SU}(3)$, $H = \mathrm{SU}(2) \times \mathrm{U}(1)$) has zero-modes. This is because A_μ and A_y should have opposite Z_2-parities, just as x^μ and y have. The "off-diagonal" elements of (2.12) just correspond to the SU(2) doublet of the Higgs field in the SM.

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

Thus by orbifolding we just get both the necessary gauge fields and the Higgs doublet of the SM, and nothing else. This seems to suggest that the adjoint representation of SU(3) has been prepared in order to accommodate the gauge–Higgs sector of the SM: $8 \to 3 + 1 + 2 \times 2$.

2.3.2. Higgs as a pseudo Nambu–Goldstone boson. So far, we have discussed supersymmetry and gauge symmetry (the Higgs as a gauge boson in the case of GHU) as possible symmetries for solving the hierarchy problem. There remains a third possibility, i.e. global symmetry: the Higgs as a (pseudo) Nambu–Goldstone (NG) boson. A representative scenario based on this idea is the "little Higgs (LH)".

Quite interestingly, there seems to be a close relation between the GHU and LH scenarios, although the LH is a theory in 4D space-time.

There are a few pieces of "circumstantial evidence" to imply such a close relation:

(a) In both scenarios, the gauge group of the SM is enlarged to some larger group G, which is broken to some subgroup H, and the Higgs is identified with the NG boson of G/H in the case of LH, and A_y of G/H in GHU, as we have seen.
(b) The coupling of A_y to fermions in 5D GHU takes the form $g\bar{\psi}(i\gamma_5)\psi \cdot A_y$, which mimics the pseudo scalar coupling of NG bosons, such as pions.
(c) Both have shift symmetries,

$$A_y \to A_y + \partial_y \lambda \text{ (for GHU)}, \quad G \to G + \text{const. (for LH)}, \tag{2.13}$$

where the former transformation is a higher-dimensional local gauge transformation and the latter is the transformation of some global symmetry.

Actually, the LH scenario was inspired by the so-called "dimensional deconstruction" scenario, which may be regarded as a "latticized" GHU, as we will see below. So, once we make the scenario of dimensional deconstruction into the bridge between GHU and LH, their mutual relation becomes more solid.

One may wonder how global and local symmetries can be "closely related". The point is that in the LH and also in dimensional deconstruction there is a repetition of a global symmetry, $\mathrm{SU}(m) \times \mathrm{SU}(m) \times \cdots \times \mathrm{SU}(m) = (\mathrm{SU}(m))^N$ with gauge parameters λ_i $(i = 1, 2, \ldots N)$. On the other hand, in the GHU, higher-dimensional local gauge symmetry is described by a gauge parameter $\lambda(y)$. If we treat the integer i of λ_i as a "discretized extra space coordinate", it can be identified. This argument suggests that dimensional deconstruction (and also LH) may be understood, roughly speaking, as a sort of "latticized" GHU.

Dimensional deconstruction

Before going into the LH scenario, we briefly discuss the scenario of dimensional deconstruction [28,29], and its close relationship with the GHU.

The scenario has the following remarkable features:

(a) The Higgs is a pseudo NG boson, a bound state of fermions, just as pions in QCD.
(b) There is a repetition of gauge symmetries: $(G \times G_s)^N$ $(G = \mathrm{SU}(m), G_s = \mathrm{SU}(n))$.
(c) The quantum correction to the Higgs mass is finite (for $N \geq 3$) without relying on SUSY.

The model has N pairs of (say, left-handed) Weyl fermions as matter fields with the bi-fundamental representations of

$$(m, \bar{n}), \ (\mathrm{SU}_i(m), \mathrm{SU}_i(n))$$
$$(\bar{m}, n) \ (\mathrm{SU}_{i+1}(m), \mathrm{SU}_i(n)) \ (i = 1 - N), \tag{2.14}$$

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

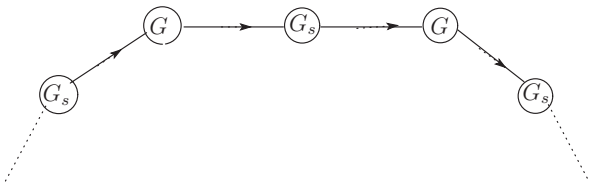

Fig. 1. The moose diagram.

where periodic boundary conditions $\mathrm{SU}_{N+1}(m) = \mathrm{SU}_1(m)$ etc. are imposed. The structure of the theory is represented by a so-called "moose diagram", shown in Fig. 1, where each oriented line corresponds to a Weyl fermion with either the $(m, \bar{n})$ or $(\bar{m}, n)$ representation, depending on whether the blob denoting the gauge group G_s is to the right or left of the line.

Both SU(m) and SU(n) have asymptotically free gauge symmetry with typical mass scales Λ, Λ_s. Assuming $\Lambda \ll \Lambda_s$, the SU(n) interaction becomes strong at higher energy, thus forming a bound state of these Weyl fermions just like the hadrons in QCD. At lower energies, $E \leq \Lambda_s$, the effective low-energy theory is described by pseudo scalars, à la the pion π_i, as (pseudo) NG bosons due to the spontaneous breaking of the chiral symmetry $\mathrm{SU}_i(m) \times \mathrm{SU}_{i+1}(m)$:

$$U_i = \exp^{i\frac{\pi_i^a T_a}{f}} \ (T_a : \text{generators of SU}(m)), \tag{2.15}$$

where f corresponds to the pion decay constant. The non-linear realization U_i behaves as a bi-fundamental representation of the chiral symmetry, i.e. $(m, \bar{m})$ under $(\mathrm{SU}_i(m), \mathrm{SU}_{i+1}(m))$.

Actually, SU(m) has been gauged and the effective action is a gauged non-linear sigma model:

$$S = \int d^4x \left(-\frac{1}{2g^2} \sum_{j=1}^{N} tr(F_j^{\mu\nu})^2 + f^2 \sum_{j=1}^{N} tr[(D_\mu U_j)^\dagger (D^\mu U_j)] \right), \tag{2.16}$$

with the covariant derivative

$$D_\mu U_j = \partial_\mu U_j - i A_\mu^j U_j + i U_j A_\mu^{j+1}. \tag{2.17}$$

Here A_μ^j are gauge bosons of SU(m) and $F_j^{\mu\nu}$ are their field strengths.

This is nothing but 5D SU(m) pure non-Abelian gauge theory, with extra space being latticized: U_j may be regarded as the link variable (the "Wilson line" along the extra dimension). Indeed, in the simplified Abelian case

$$D_\mu U_j \to i[\partial_\mu \pi - g f (A_\mu^{j+1} - A_\mu^j)] U_j, \tag{2.18}$$

and identifying the lattice spacing a of the extra dimension as

$$a = \frac{1}{gf}, \tag{2.19}$$

$D_\mu U_j$ just corresponds to the field strength $F_{\mu y}$ in the GHU:

$$D^\mu U_j \to \partial_\mu A_y - \partial_y A_\mu = F_{\mu y} \ (\pi \equiv A_y). \tag{2.20}$$

Thus, the extra dimension has been constructed by the dynamics in 4D space-time. It should be noticed that above Λ_s the theory recovers to original renormalizable theory, in clear contrast to the non-renormalizable higher-dimensional gauge theory, which the GHU is formulated on.

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

The theory has gauge symmetry $(\mathrm{SU(m)})^N$ that is spontaneously broken into a single SU(m):

$$\langle U_i \rangle = 1 \to g_i \langle U_i \rangle g_{i+1}^\dagger = \langle U_i \rangle, \text{ only when } g_i = g_{i+1}, \tag{2.21}$$

where g_i is an element of $\mathrm{SU}_i(m)$. Thus, among U_i $(i = 1, 2, \ldots, N)$, $N-1$ pieces are "eaten" by the Higgs mechanism, and there remains only one physical (pseudo) NG boson, which is identified as the Higgs. The remaining Higgs,

$$\mathrm{Tr}(U_1 U_2 \cdots U_N), \tag{2.22}$$

is invariant under the gauge transformation, $U_1 U_2 \cdots U_N \to g_1 (U_1 U_2 \cdots U_N) g_1^\dagger$ $(g_{N+1} = g_1)$, and therefore cannot be "gauged away" by taking the unitary gauge.

In the Abelian case, $U_1 U_2 \ldots U_N = e^{\frac{i}{f}(\pi_1 + \cdots \pi_N)}$ $(\phi = \frac{\pi_1 + \pi_2 + \cdots \pi_N}{\sqrt{N}})$, and the field ϕ just corresponds to the zero-mode of A_y, or the phase of the Wilson loop, in GHU: $W = e^{i\frac{g}{2}\oint A_y dy}$.

The field ϕ is a pseudo NG boson. In fact, at the quantum level, its potential is induced:

$$V(\phi) = -\frac{9}{4\pi^2} g^4 f^4 \sum_1^\infty \frac{\cos\left(\frac{2n\sqrt{N}\phi}{f}\right)}{n(n^2N^2-1)(n^2N^2-4)} + \text{constant}. \tag{2.23}$$

This potential is known to be finite for $N \geq 3$, which can be easily shown by using relations such as $\sum_n \cos(\frac{2\pi}{N} n) = 0$ $(-\frac{N}{2} < n \leq \frac{N}{2})$. Let us note that such summation over all possible n just corresponds to the summation over all KK modes in the GHU, which led to the finite Higgs mass [8]. Thus we may also understand that the scenario of dimensional deconstruction provides a very reasonable regularization scheme for the KK mode sum: we do not have to take the sum over an infinite number of KK modes; instead, just a few modes are enough to guarantee the finiteness of the Higgs mass.

The potential reduces to that in GHU [5–8,25,26] in the limit $N \to \infty$:

$$V(A_y) = \frac{9}{4\pi^2} \frac{1}{(2\pi R)^4} \sum_{n=1}^\infty \frac{\cos(n g A_y 2\pi R)}{n^5}. \tag{2.24}$$

Little Higgs

The purpose of the little Higgs (LH) scenario is to construct a 4D theory including SM, where the Higgs is a pseudo NG boson, while the quadratic divergence of the quantum correction to the Higgs mass cancels out without relying on SUSY. Though LH is a scenario inspired by dimensional deconstruction, in this approach the NG boson need not be a bound state of fermions. So the remnant of the higher-dimensional theory is not apparent. Nevertheless, there still remains some close relation between the LH and GHU scenarios, as has already been mentioned in this subsection. (The correspondence may be rigorously argued once we utilize AdS–CFT correspondence.)

There are various versions of LH models. but here we discuss "the simplest little Higgs" [30] in order to understand the key ingredient of the scenario, "collective breaking".

Interestingly, in the LH the gauge symmetry should also be enlarged. This is basically because the scenario needs a global symmetry that is larger than $SU(2) \times U(1)$, so that even after the Higgs mechanism physical NG bosons remain. Thus, let us consider the simplest SU(3) model with triplet

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

scalar ϕ. (The model is eventually extended to that with additional U(1)$_X$. However, for simplicity, here we ignore it.) The VEV

$$\langle \phi \rangle = \begin{pmatrix} 0 \\ 0 \\ f \end{pmatrix} \tag{2.25}$$

causes a spontaneous breaking of global symmetry SU(3) $\to$ SU(2), and the resultant NG bosons are written as

$$\pi = \begin{pmatrix} -\frac{\eta}{2} & 0 & \phi^+ \\ 0 & -\frac{\eta}{2} & \phi^0 \\ \phi^- & \phi^{0*} & \eta \end{pmatrix}, \tag{2.26}$$

where $h = (\phi^+,\ \phi^0)^t$ is identified with the Higgs doublet. In this model, however, h and η are all absorbed by massive gauge bosons by the Higgs mechanism in the process of spontaneous breakdown of SU(3) $\to$ SU(2), and no physical Higgs remains.

Then we enlarge the model a little and introduce two copies of triplet scalars ϕ_1 and ϕ_2, and introduce covariant derivatives D_μ with the same SU(3) gauge bosons A_μ for both:

$$\mathcal{L} = |D_\mu \phi_1|^2 + |D_\mu \phi_2|^2 \ (D_\mu = \partial_\mu - igA_\mu) \tag{2.27}$$

where two triplet scalars are non-linearly realized:

$$\phi_1 = \exp^{i\frac{\pi_1}{f}} \begin{pmatrix} 0 \\ f \end{pmatrix}, \quad \phi_2 = \exp^{i\frac{\pi_2}{f}} \begin{pmatrix} 0 \\ f \end{pmatrix}. \tag{2.28}$$

For simplicity the decay constants of $\phi_{1,2}$ are taken to be the same: f.

Each sector of the two scalars $\phi_{1,2}$ has its own global SU(3) symmetry. But, once gauge interaction is switched on, the global symmetry is explicitly broken to the "diagonal" $SU(3)$: When each of ϕ_1 and ϕ_2 transforms as

$$\phi_1 \to U_1 \phi_1,\ \phi_2 \to U_2 \phi_2, \tag{2.29}$$

the gauge fields should transform as

$$A_\mu \to U_1 A_\mu U_1^\dagger, \quad A_\mu \to U_2 A_\mu U_2^\dagger. \tag{2.30}$$

Since one gauge field A_μ couples with both triplets, for consistency it is necessary that $U_1 = U_2$.

The NG boson corresponding to this diagonal SU(3) remains exactly massless, but is "eaten" by the Higgs mechanism. The orthogonal one, in particular its doublet component h, is identified with the Higgs and acquires a mass, since the relevant global symmetry is explicitly broken by the presence of the gauge interaction.

Let us note that, to break the global symmetry explicitly by the gauge interaction, SU(3)^2 $\to$ SU(3), gauge couplings of A_μ to both U_1 and U_2 are necessary, Namely, the gauge couplings with both triplets collectively break the global symmetry. This is what "collective breaking" means. The physically remaining Higgs is not a real NG boson but a pseudo NG boson, acquiring a mass due to the breaking of the global symmetry. The collective breaking in turn means that, even if the Higgs acquires a mass at quantum level, it should be induced by Feynman diagrams where the gauge interactions with both triplets are included. Thus the diagram leading to the quadratic divergence of the Higgs mass is not allowed (at least at the one-loop level) and the Higgs does not suffer from the

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

quadratically divergent quantum correction to the Higgs mass. This is the mechanism of collective breaking in order to remove the quadratic divergence.

Let us note that, in order for the collective breaking to work, the repetition of fields is essential, which seems to correspond to the presence of KK modes in GHU. Also, the quadratic divergence of the Higgs mass disappears as a result of the repetition of fields in the LH model, just as in the case of GHU, where the sum over all KK modes provides a finite Higgs mass [8].

2.4. Close relation between GHU and superstring theory

The GHU also has a very close relation to the superstring theory. In fact, the (bosonic part of the) point particle limit of open superstring theory, i.e. 10D SUSY Yang–Mills theory, may be understood as a sort of GHU.

Pure SUSY Yang–Mills theory with a gauge multiplet alone is possible only for specific space-time dimensionality $D = 3, 4, 6$, and 10, just because the matching of physical degrees of freedom of the gauge boson and the gauge fermion is realized in these dimensions:

$$D - 2 = r\, 2^{[\frac{D-2}{2}]}\ (r = \frac{1}{2} \text{ for Majorana–Weyl}). \tag{2.31}$$

This means that the 10D SUSY Yang–Mills theory (with $r = \frac{1}{2}$) is formulated as a pure SUSY Yang–Mills theory without any need to introduce an additional matter field. Therefore, the only possible origin of the Higgs field is the gauge field, or to be more precise the extra-dimensional component of the 10D gauge field. This is nothing but GHU.

Although it is usually argued that, in supersymmetric theory, the hierarchy problem of quadratic divergence is solved by SUSY, if the theory is regarded as that inspired by superstring, the hierarchy problem may be solved by the mechanism in the GHU as well. In fact, if the mode sum over all KK modes is performed, the quantum correction to the Higgs mass is finite even after the SUSY breaking.

3. Normal vs. anomalous Higgs interactions

Now that a new particle, which behaves like the Higgs particle in the standard model (SM), has been discovered at CERN, only the theory with the SM as its decoupling limit should be acceptable as the theory of new physics. In order to determine which type of theory we should pursue among the remaining candidates, a precision test of the Higgs interaction is quite important. This may not be easy at LHC and we hope that it can be performed at the planned ILC experiment.

Interestingly, representative new physics theories show some sort of deviation of Higgs interactions from those predicted by the SM. For instance, in the MSSM, the couplings of the Higgs interactions generally depend on the parameters β and α. For instance, the ratios of the Yukawa coupling of the SM-like Higgs to that of the SM for the third generation are given as

$$\frac{f_t^{(\mathrm{MSSM})}}{f_t^{(\mathrm{SM})}} = \frac{\cos\alpha}{\sin\beta}, \tag{3.1}$$

$$\frac{f_b^{(\mathrm{MSSM})}}{f_b^{(\mathrm{SM})}} = \frac{f_\tau^{(\mathrm{MSSM})}}{f_\tau^{(\mathrm{SM})}} = -\frac{\sin\alpha}{\cos\beta}. \tag{3.2}$$

Although the Yukawa couplings generally deviate from the predictions of the SM, the deviation is universal for all generations. This is an important prediction of the MSSM. It should also be noted that, at the decoupling limit $\alpha \to \beta - \frac{\pi}{2}$, the deviations just go away, as we anticipated.

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

Let us now discuss higher-dimensional theories. We will see that in the gauge–Higgs unification (GHU) and also in the related theories (dimensional deconstruction, little Higgs (LH) and probably superstring) we expect really "anomalous" Higgs interactions, qualitatively different from those in the SM and MSSM, coming from the very fact that the Higgs is not a scalar particle, but is originally a gauge field or a pseudo NG boson.

From the viewpoint of the precision test of the Higgs interactions, it seems to be quite interesting that new physics theories are divided into two categories concerning the Higgs interactions, i.e. theories with normal Higgs interactions and theories with anomalous Higgs interactions. We discuss these two categories separately below.

3.1. Theory with normal Higgs interactions

The higher-dimensional new physics theory of this type that we discuss here is the scenario of the universal extra dimension (UED) [18]. This theory is obtained by simply making the SM higher-dimensional, although to get a chiral theory the extra dimension is assumed to be orbifold, not just a circle or sphere. In particular, its Higgs sector is just as in the SM: no additional Higgs doublet is introduced, in contrast to the case of the MSSM, and the Higgs is just an elementary scalar field even in the bulk, in clear contrast to the case of GHU or LH. Thus the KK zero mode of the Higgs field has just the same Yukawa couplings as those in the SM.

3.2. Theories with anomalous Higgs interactions

GHU

We first discuss gauge–Higgs unification (GHU), as a typical example of the new physics theory with anomalous Higgs interactions. In GHU (we work in 5D space-time), the SM-like Higgs H is the zero-mode of A_y, $A_y^{(0)}$, and has a physical meaning as the Wilson loop phase (the AB phase), coming from the fact that the circle is a non-simply-connected space, as was discussed in the previous section:

$$W = e^{i\frac{g}{2}\oint A_y dy} = e^{ig_4\pi R A_y^{(0)}} \quad \text{(for the Abelian case)}, \tag{3.3}$$

where R is the radius of the circle and, in the line integral along the circle, only the zero mode contribution remains.

The fact that the Higgs should be regarded as an AB phase (or Wilson loop phase) as seen in (3.3) leads to the anomalous Higgs interactions.

To see this, we start from a general argument on the fermion masses and Yukawa couplings that, in any gauge theories with spontaneous gauge symmetry breaking, the fermion mass term is written as

$$m(v)\bar{\psi}\psi, \tag{3.4}$$

where $m(v)$ is a function, say the "mass function", of the VEV $v = \langle H \rangle$. The interaction of the physical Higgs field h with the fermion is expected to be provided by a replacement $v \to v + h$, since the Higgs is the field to denote the shift of H from its VEV. Thus, Yukawa coupling f of h with the (KK zero mode of the) fermion is expected to be given by

$$f = \frac{dm(v)}{dv}. \tag{3.5}$$

This prescription works perfectly in the case of the SM, where $m(v)$ is a linear function of v, $m(v) = fv$. In the case of GHU, the story is a little more complicated. Even if we consider only one flavor,

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

the fermion still has an infinite number of KK modes. Thus the mass term and Yukawa couplings are written in the form of matrices in the base of KK modes. Provided that the VEV v is fixed, each KK mode should be given as an eigenvector of the mass matrix determined by v. Thus in the base of KK modes the mass matrix (the matrix form of the mass terms) is diagonalized. The unusual thing, however, is that the matrix denoting the Yukawa couplings is generally non-diagonal even in the base of the mass eigenstates [31]. This characteristic feature of the GHU is closely related to the fact that the mass function $m(v)$ of KK zero mode, for instance, can be a non-linear function, such as trigonometric function, in general reflecting that the Higgs is a phase, as we will see below. Thus, to be precise, the prescription given in (3.5) is only for the diagonal elements of the Yukawa coupling matrix (valid for all KK modes, incidentally).

Since in the GHU the Higgs should be understood as a phase (AB phase), we expect that all physical observables have periodicity in the Higgs field H:

$$v \to v + \frac{2}{g_4 R} \ (g_4 : \text{4D gauge coupling}). \tag{3.6}$$

In fact, we find for the zero mode quarks of light (1st and 2nd) generations (together with the b quark), the quark masses are exponentially suppressed as in (2.7), but in addition, their dependence on the VEV v is approximately a trigonometric function:

$$m(v) \propto \sin\left(\frac{g_4}{2}\pi R v\right), \tag{3.7}$$

which is non-linear in v. Then, the prescription (3.5) yields

$$f \propto \cos\left(\frac{g_4}{2}\pi R v\right). \tag{3.8}$$

It is a remarkable fact that the Yukawa coupling even vanishes for a specific value of the VEV,

$$x \equiv \frac{g_4}{2}\pi R v = \frac{\pi}{2}, \tag{3.9}$$

as was first claimed by Hosotani et al. [10,11].

Although such a drastic case does not seem to be consistent with the recent data from the LHC experiments, it is still possible that GHU predicts anomalous Yukawa couplings for light quarks for a general value of x. In fact, the ratio of the Yukawa coupling predicted by GHU to that predicted by the SM for light quarks is known to be very well approximated by an analytic formula [31],

$$\frac{f_{\text{GHU}}}{f_{\text{SM}}} \simeq x \cot x. \tag{3.10}$$

Note that, at the "decoupling limit",

$$x = \frac{g_4}{2} v \pi R \ll 1 \leftrightarrow M_W \ll \frac{1}{R}, \tag{3.11}$$

the SM prediction is recovered, as is easily seen in (3.10).

Actually, when the bulk mass M_i is switched off, the mass function $m(v)$ becomes a linear function of x, as is seen in Fig. 2(a), just as in the SM, so the Yukawa coupling does not deviate from the SM prediction for $x < \frac{\pi}{2}$. In this case, the periodicity of the mass eigenvalue is realized by a level crossing of the zero mode with the first KK mode at $x = \frac{\pi}{2}$ (see Fig. 2(a)). Namely, at $x = \frac{\pi}{2}$, the zero mode is replaced by the first KK mode whose mass eigenvalue decreases as x increases. For $M_i = 0$, however, mixing between these two modes will not appear because of the conservation of the (absolute value of the) extra space component of the momentum. If we switch on the bulk mass M_i, the translational

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

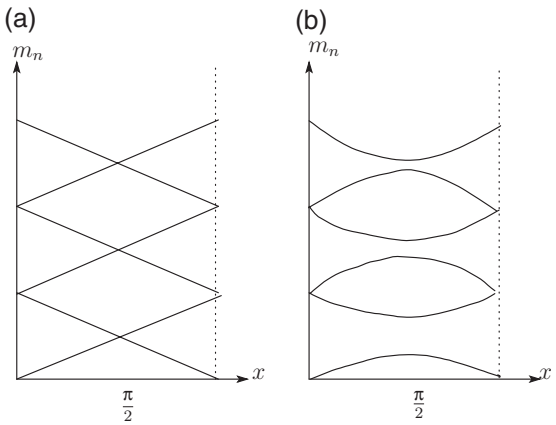

Fig. 2. The mass eigenvalues of KK modes for vanishing bulk mass (Fig. 2(a)) and non-vanishing bulk mass (Fig. 2(b)).

invariance along the extra space is violated by the presence of the bulk mass term (2.6), thus causing mixing between the two modes. Due to the mixing, the degeneracy of the two mass eigenvalues at the level crossing is lifted and a deviation of the mass function from the linearity appears, leading to the trigonometric function for sufficiently large bulk mass M_i, as is seen in Fig. 2(b).

Thus, even though the original seed of the anomalous Higgs interaction is the periodicity characteristic of GHU, more directly it may be attributed to the violation of translational invariance in the extra dimension. From this point of view, it may be worth noting that on the Randall–Sundrum background, the translational invariance is *always* (universally) violated by the presence of the warp factor $e^{-\kappa|y|}$. This should be the reason why, on the Randall–Sundrum background, the Higgs interactions with massive gauge bosons, W and Z, are also anomalous [32,33], while on the flat space-time it is "almost normal" (normal for $x < \frac{\pi}{2}$), as in the gauge–Higgs sector there is no parameter violating translational invariance in the case of flat space-time [31].

From a field theoretical point of view, the reason why we get such non-linearity in the mass function like (3.7) is that, due to the non-diagonal Yukawa couplings mentioned earlier, there appear mixings between the zero mode and non-zero modes, which leads to higher-mass-dimensional operators at tree level of the form $h^{2n+1}\bar{\psi}\psi$ $(n = 1, 2, \ldots)$ (just like the dimension 5 operator in the see-saw mechanism). The coefficients of these higher-mass-dimensional operators are suppressed by the inverse powers of $M_c = \frac{1}{R}$, and as we have already seen, the effects of such "irrelevant" operators disappear at the decoupling limit $M_c \to \infty$.

3.3. Dimensional deconstruction

As we have seen in the previous section, though it is formulated on the ordinary 4D space-time, the scenario of dimensional deconstruction may be understood as a "latticized" GHU. We thus expect that the anomalous Higgs interaction is also expected in this scenario. To be more specific, in this case, even if we adopt just periodic boundary conditions for fields like $A_\mu^{N+1} = A_\mu^1$, corresponding to the choice of a circle, not an orbifold, as the extra dimension in GHU, still the latticizing itself breaks the (continuous) translational invariance, which should lead to anomalous Higgs interactions. In fact, the mass eigenvalues in this scenario generally behave as trigonometric functions:

$$m_n(v) = \frac{2}{a}\sin\left(\frac{n\pi}{N} + \frac{g_4 a v}{4}\right) \ (a : \text{lattice spacing}), \tag{3.12}$$

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

which are basically the same as the eigenfrequencies of a system of springs and balls. As can easily be seen, (3.12) reduces to linear functions of v in the continuum limit $a \to 0$, $N \to \infty$, keeping the circumference of the circle $L \equiv Na$ a constant; $m_n(v) \to \frac{2\pi}{L}n + \frac{g_4 v}{2}$. Work on the anomalous interactions in dimensional deconstruction pursuing this line of argument is now in progress (N. Kurahashi et al., work in progress).

3.4. Little Higgs

We have also argued that the scenario of little Higgs (LH) has a close relationship with GHU. Just as in the case of GHU, the Higgs is non-linearly realized,

$$U = \exp^{i\frac{H}{v}}, \tag{3.13}$$

and therefore periodicity and non-linearity concerning the Higgs field seem to arise very naturally. Thus we again expect anomalous Higgs interactions in the scenario of LH, though more complete analyses are clearly desirable in this case.

4. $H \to \gamma\gamma$

$H \to \gamma\gamma$ is the clean decay mode of the Higgs, important for the identification of the Higgs particle. This di-photonic decay is induced at the quantum level since the photon is a massless particle, and is a very good testing ground for new physics. It is also sensitive to the Higgs interactions with fermions and gauge bosons running inside the loop diagrams, thus providing useful information on the properties of Higgs interactions, whether they are normal or anomalous, as was discussed in some detail in the previous section. The gluon fusion process $gg \to H$, a main process of Higgs production, is also induced at the quantum level and has some similarity to the photonic Higgs decay, though gauge bosons do not contribute in this case.

In this section we focus on two higher-dimensional new physics scenarios with considerably different properties, as we have already seen in the previous sections: UED and GHU. We will pay a great deal of attention to the differences in the predictions these two scenarios make about the photonic decay.

Recently, there has been an interesting claim that the contribution of the non-zero KK modes of the top quark to the decay amplitude of $H \to \gamma\gamma$ has an opposite sign to that of the top quark in the SM and to that of the KK modes of the top quark in UED [34]. The origin of such a qualitative difference may be rather easily understood once we rely on the operator analysis. Let us assume $M_c = 1/R \gg v$. At first glance, the relevant operator for the photonic decay seems to be $hF_{\mu\nu}F^{\mu\nu}$, with $F_{\mu\nu}$ being the field strength of the photon. If this is the case, the coefficient should be divergent in the process of the KK mode sum, since the mass dimension of the operator is 5. But this operator is not gauge invariant under $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$. So, actually the decay amplitude is dominated by a gauge invariant operator of mass dimension 6 written in terms of the Higgs doublet ϕ:

$$\phi^\dagger \phi F_{\mu\nu}F^{\mu\nu}. \tag{4.1}$$

Note that, when one of the Higgs doublets is replaced by its VEV, this yields the dimension 5 operator mentioned above. Now the coefficient of the operator (4.1) is finite, at least for 5D space-time.

Also note that the operator in (4.1) comes from the diagram shown in Fig. 3, obtained by inserting the Higgs doublet ϕ twice to the self-energy diagram of the photon, that is responsible for the, quantum correction to the operator $F_{\mu\nu}F^{\mu\nu}$. So, by utilizing the background field method, the Wilson coefficient of the operator (4.1) is obtainable just by calculating the self-energy diagram with the

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

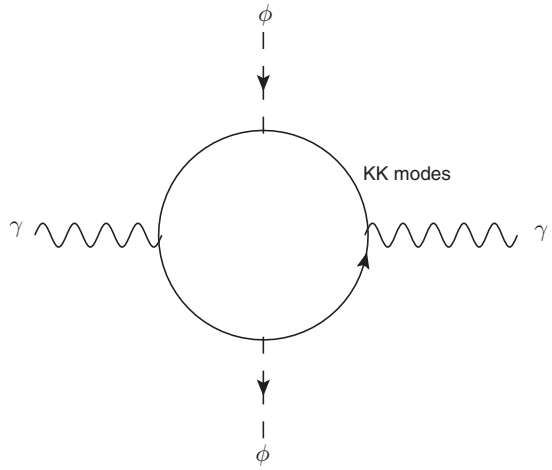

Fig. 3. A diagram contributing to the operator that describes the Higgs decay.

top quark (or its KK modes) inside the loop, having masses given by the VEV v, and finally taking the second derivative with respect to v. Since the coefficient of the self-energy diagram depends logarithmically on the mass of the virtual state, the coefficient of (4.1) is given as

$$C \propto \frac{d^2}{dv^2} \log m_n^2|_{v=0}, \tag{4.2}$$

where m_n are the mass eigenvalues of the nth KK mode.

Now we are ready to discuss the differences between the predictions of UED and GHU. In each scenario, the mass eigenvalue of a fermion is given as follows:

$$m_n = \begin{cases} \sqrt{\left(\frac{n}{R}\right)^2 + (fv)^2} & \text{for UED} \\ \frac{n}{R} + fv & \text{for GHU} \end{cases}. \tag{4.3}$$

Here, for brevity, we have ignored the possible bulk mass, and f is the Yukawa coupling for the zero mode fermion. Then the procedure of (4.2) gives results that are just opposite in sign for the two scenarios:

$$C \propto \begin{cases} 2\frac{f^2}{(\frac{n}{R})^2} & \text{for UED} \\ -2\frac{f^2}{(\frac{n}{R})^2} & \text{for GHU} \end{cases}. \tag{4.4}$$

There is a claim that the new physics contributions of the theories with a mechanism to solve the hierarchy problem invoking some symmetry tend to reduce, e.g., the amplitude of the gluon fusion process. Intuitively, the reason might be the following. In the case of gluon fusion, the field strength in (4.1) is that of the gluon field. Since the QCD sector has no direct connection with the Higgs sector, even if we take off the gluonic field the operator is still gauge invariant and it just becomes the mass-squared operator for the Higgs field. On the other hand, any theories that aim to solve the problem of quadratic divergence of the Higgs mass should have a mechanism to reduce the quantum correction to the Higgs mass-squared by introducing, e.g. super-partners, KK modes, etc. Thus it will be natural to expect some destructive contributions from new heavy particles in this type of theory.

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

Let us also note that the operator (4.1) is easily generalized by replacing $\phi^\dagger\phi$ by its arbitrary function $V(\phi)$: i.e. $V(\phi)F^{\mu\nu}F_{\mu\nu}$. If we take off $F^{\mu\nu}F_{\mu\nu}$ again, we just get a Higgs potential $V(\phi)$. On the other hand, in the GHU the potential is completely finite [5–8]. Maru thus claims that the decay amplitude of $H \to \gamma\gamma$ is finite irrespective of the space-time dimension [37].

For a more recent detailed analysis concerning the di-photonic decay in GHU, refer to Ref. [35]. For a recent argument on the contribution of the non-zero KK modes of the top quark in the SO(5) x U(1) GHU on the Randall–Sundrum background, refer to Ref. [36].

Usually, the contributions of lighter generations (1st and 2nd generations) to the photonic Higgs decay are more or less negligible, since their Yukawa couplings are strongly suppressed by very small quark masses. This is why only the contribution of the top quark is seriously taken into account. In the GHU, however, the story is not so simple. Namely, the contribution of each non-zero KK mode of lighter generations of quarks is not strongly suppressed by the corresponding small quark masses. This is because only the mode function of the zero mode exhibits localization at a fixed point and the Yukawa couplings of non-zero KK modes are not exponentially suppressed, being of the order of gauge coupling. So we naturally expect possible significant contributions to the photonic decay from lighter generations as well.

Fortunately or unfortunately, it turns out that, although each KK mode makes a significant contribution to the decay amplitude, as we expected, after the summation over the contributions of all KK modes, the factor suppressed by $1/M_c^2 = 1/(1/R)^2$ (which we expect from the decoupling theorem) just goes away, and the remaining contribution is exponentially suppressed as $e^{-M_i R}$ (M_i : bulkmass) (K. Hasegawa et al., manuscript in preparation).

We recall that a similar exponential suppression factor due to a relatively large bulk mass was found in the process of the calculation of the quantum correction to the Higgs mass-squared [8]. This may not be so surprising, since, as we have argued above, the operator relevant to the photonic decay has some similarity to that of the Higgs potential. We may also notice that the exponential factor mimics the Boltzmann factor in the case of finite-temperature field theory. This factor goes away at the decompactification limit $R \to \infty$, thus suggesting that it comes from a non-local gauge invariant operator due to the Wilson loop. In fact, this should be the reason why we find a finite decay amplitude in GHU irrespective of the dimensionality of the space-time, as was demonstrated in Ref. [37]. We may also understand that the factor is the contribution from the sector with non-zero winding numbers at the Poisson re-summation, which clearly shows the contributions of distances larger than R and is thus suppressed by the exponential factor $e^{-M_i R}$, present in the Yukawa potential.

5. Summary

In spite of the great success of the LHC experiments in discovering a particle consistent with the Higgs of the SM, it is still premature to conclude that the particle *is* the Higgs of the SM. It may be some SM-like Higgs particle predicted by some new physics theory. Also, the Higgs sector of the SM is still mysterious, having a few important long-standing problems, such as the hierarchy problem and the problem of too many arbitrary parameters present in the sector. Thus we should continue to ask what the origin of the Higgs is.

In this article, we have focused on higher-dimensional new physics theories. Also discussed were 4D theories, such as little Higgs (LH) and dimensional deconstruction, which possess some close relationship with the higher-dimensional theory, especially with the gauge–Higgs unification (GHU). Some important common features shared by these scenarios are the presence of the "shift symmetry",

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

which guarantees the finiteness of the Higgs mass at the quantum level, and the periodicity: physical observables are periodic in the Higgs field. In GHU the origin of the Higgs field is a gauge field and in the LH and dimensional deconstruction the origin is a (pseudo) Nambu–Goldstone boson.

In order to investigate the origin of the Higgs, precision tests of Higgs interactions will be of crucial importance. We have discussed that new physics theories are divided into two categories: theories with normal Higgs interactions, and theories with anomalous Higgs interactions.

From this point of view, we have demonstrated that, in the scenario of GHU and the related LH and dimensional deconstruction scenarios, the periodicity mentioned above (together with the breakdown of translational invariance along the extra dimension) leads to very characteristic anomalous Higgs interactions, which are never shared by the SM. This should be a very important observation in the attempt to deeply understand the origin of the Higgs particle.

The difference, i.e. normal (as in the case of UED) or anomalous Higgs interactions, also makes the new physics contribution to the main decay mode of the Higgs, $H \to \gamma\gamma$, qualitatively different.

Such crucial precision tests of the Higgs interactions may not be easy at the LHC experiment, but we hope that they will be performed at the planned ILC experiment.

We consider a possibility that the Higgs field in the Standard Model (SM) serves as an inflaton when its value is around the Planck scale. We assume that the SM is valid up to an ultraviolet cutoff scale Λ, which is slightly below the Planck scale, and that the Higgs potential becomes almost flat above Λ. Contrary to the ordinary Higgs inflation scenario, we do not assume the huge non-minimal coupling, of $O(10^4)$, of the Higgs field to the Ricci scalar. We find that Λ must be less than 5×10^{17} GeV in order to explain the observed fluctuation of the cosmic microwave background, no matter how we extrapolate the Higgs potential above Λ. The scale 10^{17} GeV coincides with the perturbative string scale, which suggests that the SM is directly connected with string theory. For this to be true, the top quark mass is restricted to around 171 GeV, with which Λ can exceed 10^{17} GeV. As a concrete example of the potential above Λ, we propose a simple log-type potential. The predictions of this specific model for the e-foldings $N_* = 50$–60 are consistent with the current observation, namely, the scalar spectral index is $n_s = 0.977$–0.983 and the tensor to scalar ratio $0 < r < 0.012$–0.010. Other parameters, $\mathrm{d}n_s/\mathrm{d}\ln k$, n_t, and their derivatives, are also consistent.

1. Introduction

It is more and more plausible that the particle discovered at the CERN Large Hadron Collider (LHC) [1,2] around 126 GeV is the Standard Model (SM) Higgs boson. Its couplings to the W and Z gauge bosons, to the top and bottom quarks, and to the tau lepton are all consistent to those in the SM within one standard deviation, even though their values vary by two orders of magnitude; see, e.g., Ref. [3]. No hint of new physics beyond the SM has been found so far at the LHC up to 1 TeV. It is important to examine up to what scale the SM can be a valid effective description of nature.

The determination of the Higgs mass finally fixes all the parameters in the SM. We can now obtain the *bare* parameters at the ultraviolet cutoff scale Λ. These parameters are important. If an ultraviolet (UV) theory such as string theory fails to fit them, it is killed.

The parameters in the SM are dimensionless except for the Higgs mass (or equivalently its vacuum expectation value [VEV]). The dimensionless bare coupling constants can be approximated by the running ones at Λ; see, e.g., the appendix of Ref. [4]. Once the low-energy inputs are given, we can evaluate the running couplings through the renormalization group equations (RGEs) of the SM. Detailed RGE study of the SM tells us that both the Higgs quartic coupling and its beta function

become tiny at the same scale, $\sim 10^{17}$ GeV, for the input value of the Higgs mass around 126 GeV; see, e.g., Refs. [4–11] for the latest analyses.

After fixing all the dimensionless bare couplings, the last remaining parameter in the SM is the bare Higgs mass. The quadratically divergent bare Higgs mass is found to be suppressed too when the UV cutoff is $\Lambda \gtrsim 10^{17}$ GeV [4]; see also Refs. [10,12–14], and Refs. [15–19]. The absence of the bare mass at Λ, along with the vanishing quartic coupling and its beta function, implies that the Higgs potential is approximately flat there and that its height is suppressed compared to (the fourth power of) the cutoff scale.

Following the evidence of the top quark with mass $174 \pm 10^{+13}_{-12}$ GeV [20] in 1994, Froggatt and Nielsen have predicted [21] that the top and Higgs masses are 173 ± 5 GeV and 135 ± 9 GeV, respectively. This prediction is based on the multiple point principle (MPP) that the SM Higgs potential must have another minimum at the Planck scale and that its height is (order-of-magnitude-wise [22,23]) degenerate to the SM one. This assumption is equivalent to the vanishing Higgs quartic coupling and its beta function at the Planck scale. The success of this prediction indicates that at least the top–Higgs sector of the SM remains unaltered up to a very high UV cutoff scale Λ.[1]

In the MPP, it is assumed that there are two vacua that are separated by a potential barrier, as illustrated in the lowermost (green) solid and dashed lines in Fig. 2. In this paper, we consider the case where there is no potential barrier, as illustrated in the middle (blue) and uppermost (red) lines in Fig. 2, so that the Higgs potential can be used for an inflation. In order to have an inflation consistent with the current observational data, we assume that the low-energy SM Higgs potential, depicted by the solid lines, is smoothly connected to an almost flat potential, depicted by the dot-dashed lines, around the UV cutoff scale Λ.[2]

Some of the concrete examples of the flat potential above the cutoff are the following: In the gauge–Higgs unification scenario, the potential for $\langle A_5 \rangle$ is almost flat for large field values $\langle A_5 \rangle \gg R^{-1}$ because of the gauge invariance and is bounded from above by $O(R^{-4})$ [28]; a similar mechanism can be expected in string compactification [29,30]; see also Refs. [31–35]. Another example is the Coleman–Weinberg potential [36] with an explicit momentum cutoff Λ. For a field value beyond Λ, we get a log potential, as we explain in Appendix B. (This possibility is pursued in Sect. 4.2.)

The latest cosmological data [37] constrains the scalar fluctuation amplitude A_s, the spectral index n_s, and the tensor-to-scalar ratio r; see also Ref. [38] for a recent review. By assuming the slow-roll inflation, these values are completely fixed by the potential height $\mathcal{V}_*$ and its derivatives $\mathcal{V}'_*$ and $\mathcal{V}''_*$ at a field value φ_* corresponding to a given e-folding $N_* \simeq 60$. If we allow an arbitrary shape for the Higgs potential in the whole range beyond the electroweak scale, we can trivially satisfy these constraints. In our case, however, the SM potential in the range $\varphi < \Lambda$ is fixed by the known SM parameters. In order to avoid the graceful exit problem [39–41], the potential must be monotonically increasing in the entire region, both below and above Λ. In particular, the value of the SM potential at the cutoff must satisfy $\mathcal{V}_{\rm SM}(\varphi = \Lambda) < \mathcal{V}_*$. As a result, we get an upper bound: $\Lambda \lesssim 10^{17}$ GeV,

[1] As a possible modification, the classically conformal $B - L$ model is considered in [24–26]. This model can realize the "flat" potential at the Planck scale and solve the hierarchy problem [27].

[2] In the original argument of the MPP [21], the partition function was maximized as a function of the bare Higgs mass. In the more recent Ref. [23], Nielsen has generalized their argument and considered several possibilities of the function to be maximized. In the context of Ref. [23], our approach could be regarded as the maximization of the entropy of the universe by requiring the occurrence of the inflation.

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

when the top quark mass is $M_t \lesssim 171\,\mathrm{GeV}$, irrespectively of the extrapolation of the potential above the cutoff $\varphi > \Lambda$.

As stated above, we propose a possible extrapolation of the potential beyond Λ, log plus constant, motivated by the Coleman–Weinberg potential with the cutoff Λ. We show predictions of the spectral indices, their derivatives, etc. of the cosmic microwave background (CMB) in this model.

Our scenario differs from the conventional Higgs inflation scenario [42–47], which achieves the flatness of the Higgs potential by the huge Higgs coupling to the Ricci scalar: $\xi\,|\phi|^2\,\mathcal{R}$ with $\xi \sim 10^4$. The idea of the Higgs inflation is attractive, but it would be even better if we can realize it without such a coupling to gravity. See also Ref. [48,49] for the unitarity issue of the conventional Higgs inflation, which necessitates new particles above M_P/ξ.[3]

This paper is organized as follows. In Sect. 2, we review the constraints from the cosmological observations including the latest results from the Planck experiment. In Sect. 3, we present the RGE running of the dimensionless couplings in the SM in the modified minimal subtraction ($\overline{\mathrm{MS}}$) scheme; we also show the bare Higgs mass-squared parameter at Λ. Then we show that the SM Higgs potential can become flat around 10^{17} GeV. In Sect. 4, we examine a necessary condition that the Higgs field in the SM can serve as an inflaton assuming arbitrary shape of the potential above Λ. In the last section, we summarize our results.

2. Constraints on inflation models

We briefly review and summarize our notation on the cosmological constraints from the CMB data observed at the Planck experiment, basically following Ref. [37]. The curvature and tensor power spectra are expanded around a pivot scale k_* as

$$\mathcal{P}_\mathcal{R} = A_s \left(\frac{k}{k_*}\right)^{n_s - 1 + \frac{1}{2}\frac{\mathrm{d}n_s}{\mathrm{d}\ln k}\ln\frac{k}{k_*} + \frac{1}{3!}\frac{\mathrm{d}^2 n_s}{\mathrm{d}\ln k^2}\left(\ln\frac{k}{k_*}\right)^2 + \cdots}, \quad \mathcal{P}_t = A_t \left(\frac{k}{k_*}\right)^{n_t + \frac{1}{2}\frac{\mathrm{d}n_t}{\mathrm{d}\ln k}\ln\frac{k}{k_*} + \cdots}. \tag{1}$$

We take the slow-roll approximation hereafter. The slow-roll parameters at a given position φ of the inflaton potential $\mathcal{V}$ are defined as

$$\epsilon_V = \frac{M_P^2}{2}\frac{\mathcal{V}_\varphi^2}{\mathcal{V}^2}, \quad \eta_V = M_P^2\frac{\mathcal{V}_{\varphi\varphi}}{\mathcal{V}}, \quad \xi_V^2 = M_P^4\frac{\mathcal{V}_\varphi \mathcal{V}_{\varphi\varphi\varphi}}{\mathcal{V}^2}, \quad \varpi_V^3 = M_P^6\frac{\mathcal{V}_\varphi^2 \mathcal{V}_{\varphi\varphi\varphi\varphi}}{\mathcal{V}^3}. \tag{2}$$

The number of e-folding before the end of inflation t_{end} from a time t_* becomes

$$N_* = \int_{t_*}^{t_{\mathrm{end}}} \mathrm{d}t\, H = \int_{\varphi_*}^{\varphi_{\mathrm{end}}} \frac{\mathrm{d}\varphi}{\dot\varphi} H = \frac{1}{M_P^2}\int_{\varphi_{\mathrm{end}}}^{\varphi_*} \frac{\mathcal{V}}{\mathcal{V}_\varphi}\mathrm{d}\varphi = \frac{1}{M_P}\int_{\varphi_{\mathrm{end}}}^{\varphi_*} \frac{\mathrm{d}\varphi}{\sqrt{2\epsilon_V}}, \tag{3}$$

where we have taken $\mathcal{V}_\varphi > 0$ in the last step. The end of inflation is defined by the field value φ_{end} below which the slow roll condition is violated:

$$\max\left\{\epsilon_V(\varphi_{\mathrm{end}}),\ \left|\eta_V(\varphi_{\mathrm{end}})\right|\right\} = 1. \tag{4}$$

For most reasonable inflation models, the scale that we are observing from the CMB data corresponds to the e-folding in the range [37]

$$50 < N_* < 60. \tag{5}$$

In the following, we evaluate the slow-roll parameters at φ_* that satisfies Eq. (5). (We will also consider the range $40 < N_* < 50$ in Sect. 4.2 for comparison.)

[3] The authors of Refs. [50,51] have proposed a Higgs inflation model in which the Higgs kinetic term is modified; the unitarity issue of this scenario, which involves higher derivatives of the Higgs field, would also be interesting to study.

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

The cosmological parameters are given by[4]

$$A_s = \frac{\mathcal{V}}{24\pi^2 M_P^4 \epsilon_V}, \quad A_t = \frac{2\mathcal{V}}{3\pi^2 M_P^4}, \quad r = \frac{A_t}{A_s} = 16\epsilon_V, \tag{6}$$

$$n_s = 1 + 2\eta_V - 6\epsilon_V, \quad n_t = -2\epsilon_V,$$

$$\frac{\mathrm{d}n_s}{\mathrm{d}\ln k} = 16\epsilon_V\eta_V - 24\epsilon_V^2 - 2\xi_V^2, \quad \frac{\mathrm{d}n_t}{\mathrm{d}\ln k} = -4\epsilon_V\eta_V + 8\epsilon_V^2,$$

$$\frac{\mathrm{d}^2 n_s}{\mathrm{d}\ln k^2} = -192\epsilon_V^3 + 192\epsilon_V^2\eta_V - 32\epsilon_V\eta_V^2 - 24\epsilon_V\xi_V^2 + 2\eta_V\xi_V^2 + 2\varpi_V^3, \tag{7}$$

where the quantities are evaluated at the field value φ_*.

At the pivot scale $k_* = 0.05\,\mathrm{Mpc}^{-1}$, the scalar amplitude A_s and the spectral index n_s are constrained by the Planck+WMAP data as [37]

$$A_s = \left(2.196^{+0.051}_{-0.060}\right) \times 10^{-9}, \tag{8}$$

$$n_s = 0.9603 \pm 0.0073, \tag{9}$$

assuming $\mathrm{d}n_s/\mathrm{d}\ln k = \mathrm{d}^2 n_s/\mathrm{d}\ln k^2 = r = 0$.

If we include the tensor-to-scalar ratio r as an extra parameter, the Planck+WMAP+high-ℓ data [37] at the pivot scale $k_* = 0.002\,\mathrm{Mpc}^{-1}$ give the 1σ range for n_s and the 95% CL limit on r as

$$n_s = 0.9600 \pm 0.0071, \quad r < 0.11. \tag{10}$$

On the other hand, if we include $\mathrm{d}n_s/\mathrm{d}\ln k$ as an extra parameter, we obtain the constraint at the pivot scale $k_* = 0.05\,\mathrm{Mpc}^{-1}$ [37]

$$n_s = 0.9561 \pm 0.0080, \quad \frac{\mathrm{d}n_s}{\mathrm{d}\ln k} = -0.0134 \pm 0.0090. \tag{11}$$

One may vary both r and $\mathrm{d}n_s/\mathrm{d}\ln k$ to fit the Planck + WMAP data at the pivot scale $k_* = 0.05\,\mathrm{Mpc}^{-1}$, obtaining [37]

$$n_s = 0.9583 \pm 0.0081, \quad r < 0.25, \quad \frac{\mathrm{d}n_s}{\mathrm{d}\ln k} = 0.021 \pm 0.012, \tag{12}$$

where the constraint on r is given at 95% CL.[5]

We note that the upper bound on r gives that of the inflaton energy scale [37]

$$\mathcal{V}_{\max} = \frac{3\pi^2 A_s}{2} r_{\max} M_P^4 = 1.3 \times 10^{65}\,\mathrm{GeV}^4 \times \left(\frac{r_{\max}}{0.11}\right). \tag{13}$$

[4] Eq. (17) of Ref. [37] contains a typo (an overall wrong sign for $\mathrm{d}n_s/\mathrm{d}\ln k$). Also note that in the case of $\Lambda\mathrm{CDM} + r + \mathrm{d}n_s/\mathrm{d}\ln k$ in Table 5 of Ref. [37], there is a minus sign missing from the front of the mean value of $\mathrm{d}n_s/\mathrm{d}\ln k$ for Planck + WP and Planck + WP + lensing. We thank the referee for bringing this point to our attention, and Finelli Fabio for his kind clarification.

[5] In terms of the slow-roll parameters, these conditions become

$$\epsilon_V < 0.015, \quad \eta_V = -0.014^{+0.015}_{-0.011}, \quad \left|\xi_V^2\right| = 0.009 \pm 0.006,$$

where the constraint on ϵ_V is given at 95% CL.

3. SM Higgs potential

The SM Higgs potential much above the electroweak scale but below the cutoff scale Λ is governed by the RGE running of the Higgs quartic coupling λ, which highly depends on the top Yukawa coupling y_t. Therefore we first review how y_t is determined; then we show the numerical results of the RGEs; finally we present the resultant Higgs potential around Λ.

3.1. *Coupling constants at the electroweak scale*

The most precise determination of the top quark mass is given by a combination of the Tevatron data for the invariant mass of the top quark decay products [52]:

$$M_t^{\rm inv} = 173.20 \pm 0.87\,{\rm GeV}. \tag{14}$$

The problem of the Tevatron determination (14) is that the invariant mass, which is reconstructed from the color singlet final states, cannot be the pole mass of the colored top quark [8]. Instead, the authors of Ref. [8] proposed to get the top mass by fitting the $t\bar{t}+X$ inclusive cross section, and obtained the pole mass:[6]

$$M_t = 173.3 \pm 2.8\,{\rm GeV}. \tag{15}$$

The numerical value of the $\overline{\rm MS}$ Yukawa coupling at the top mass scale can be read off from Ref. [7] as

$$y_t(M_t) = 0.93669 + 0.01560\left(\frac{M_t - 173.3\,{\rm GeV}}{2.8\,{\rm GeV}}\right) - 0.00041\left(\frac{\alpha_s(M_Z) - 0.1184}{0.0007}\right) - 0.00001\left(\frac{M_H - 125.6\,{\rm GeV}}{0.4\,{\rm GeV}}\right) \pm 0.00200_{\rm th}, \tag{16}$$

where we have employed a combined Higgs mass $M_H = 125.6 \pm 0.4\,{\rm GeV}$. The electroweak gauge couplings at the Z mass scale are [59]

$$g_Y(M_Z) = 0.357418(35), \quad g_2(M_Z) = 0.65184(18). \tag{17}$$

The $\overline{\rm MS}$ strong and quartic couplings at the top mass scale are [7]

$$g_s(M_t) = 1.1644 + 0.0031\left(\frac{\alpha_s(M_Z) - 0.1184}{0.0007}\right) - 0.0013\left(\frac{M_t - 173.3\,{\rm GeV}}{2.8\,{\rm GeV}}\right), \tag{18}$$

$$\lambda(M_t) = 0.12699 + 0.00082\left(\frac{M_H - 125.6\,{\rm GeV}}{0.4\,{\rm GeV}}\right) - 0.00012\left(\frac{M_t - 173.3\,{\rm GeV}}{2.8\,{\rm GeV}}\right) \pm 0.00140_{\rm th}. \tag{19}$$

3.2. *Numerical results of SM RGEs*

We use the two-loop RGEs in the SM which are summarized in Ref. [4].

[6] As clarified in Refs. [53,54], currently there are two ways to define the $\overline{\rm MS}$ running top mass for a given $\overline{\rm MS}$ running Yukawa $y_t(\mu)$. The $\overline{\rm MS}$ mass used in QCD [8,55,56], which we call $m_t^{\rm QCD}(\mu)$, can be approximately written as $m_t^{\rm QCD}(\mu) \simeq y_t(\mu)V/\sqrt{2}$ with $V = 246.22\,{\rm GeV}$, up to electroweak corrections less than 1%. In Refs. [57,58], $\overline{\rm MS}$ mass is defined as $m_t(\mu) := y_t(\mu)v(\mu)/\sqrt{2}$, where $v(\mu)$ is given by the relation $-m^2(\mu) = \lambda(\mu)\,v^2(\mu)$, with $m^2(\mu)$ being the running mass parameter in the tree potential in the $\overline{\rm MS}$ scheme: $\mathcal{V} = m^2(\mu)\,\phi^\dagger\phi + \lambda(\mu)\,(\phi^\dagger\phi)^2$. There is $\sim 7\%$ difference between $m_t^{\rm QCD}(M_t)$ and $m_t(M_t)$ [58], which is mainly due to the tadpole contribution from the top quark. Though the bound on the pole mass (15) has been derived from that on $m_t^{\rm QCD}(M_t) = 163.3 \pm 2.7\,{\rm GeV}$ [8], it is consistent to use Eq. (15) in obtaining the Yukawa coupling (16) since the pole mass M_t should be the same in both schemes.

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

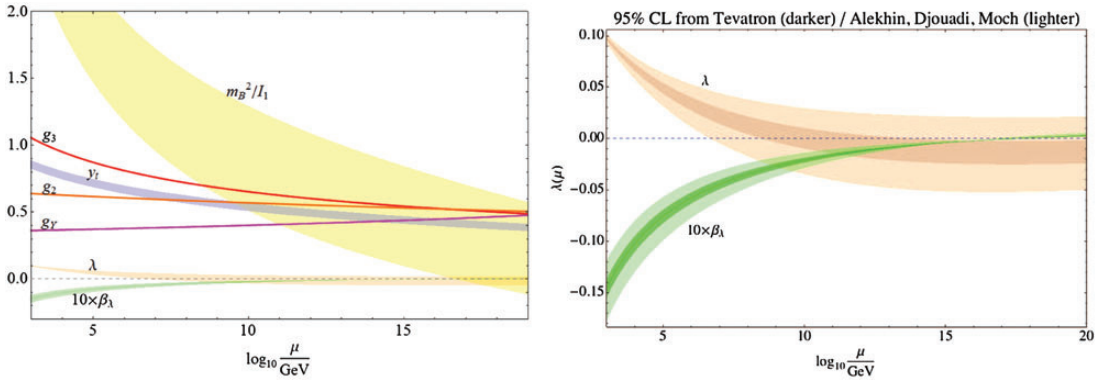

Fig. 1. Left: $\overline{\text{MS}}$ running couplings. The 95% confidence intervals are given for m_B^2/I_1, $y_t(\mu)$, $\lambda(\mu)$, and $10\beta_\lambda(\mu)$; see text for more details. The intervals for the gauge couplings g_Y, g_2, and g_3 are too small to be seen. Right: Enlarged view around the horizontal axis of the graph to the left. Darker bands are the 95% confidence intervals under the (theoretically unjustified) assumption that the Tevatron mass (14) can be identified with the top pole mass M_t.

We show our result of running $\overline{\text{MS}}$ couplings in Fig. 1. The gauge couplings g_Y, g_2, g_3 are drawn by thick lines. The thickness of the curves for y_t, λ, and β_λ comes from the 1.96σ variation of M_t (15), where $\alpha_s(M_z)$ and M_H are fixed to their central values. Similarly, we plot the bare Higgs mass-squared m_B^2, divided by the quadratically divergent integral $I_1 = \Lambda^2/16\pi^2$, as a function of Λ [4,53]. Note that the bare mass m_B^2 is *not* the running mass.

We see that the Higgs quartic coupling λ has a minimum around 10^{17} GeV. This is due to the fact that the beta function of λ receives less negative contribution from the top loop since y_t becomes smaller at high scales.

We can fit the parameters at the reduced Planck scale[7] $M_P := 1/\sqrt{8\pi G} = 2.4 \times 10^{18}$ GeV as

$$\lambda(M_P) = -0.015 - 0.019\left(\frac{M_t - 173.3\,\text{GeV}}{2.8\,\text{GeV}}\right) + 0.002\left(\frac{\alpha_s(M_Z) - 0.1184}{0.0007}\right) + 0.001\left(\frac{M_H - 125.6\,\text{GeV}}{0.4\,\text{GeV}}\right), \tag{20}$$

$$\frac{m_B^2}{M_P^2/16\pi^2} = 0.26 + 0.18\left(\frac{M_t - 173.3\,\text{GeV}}{2.8\,\text{GeV}}\right) - 0.02\left(\frac{\alpha_s(M_Z) - 0.1184}{0.0007}\right) - 0.01\left(\frac{M_H - 125.6\,\text{GeV}}{0.4\,\text{GeV}}\right), \tag{21}$$

$$\beta_\lambda = 0.000103 + 0.000069\left(\frac{M_t - 173.3\,\text{GeV}}{2.8\,\text{GeV}}\right) + 0.000028\left(\frac{M_t - 173.3\,\text{GeV}}{2.8\,\text{GeV}}\right)^2 - 0.000013\left(\frac{M_H - 125.6\,\text{GeV}}{0.4\,\text{GeV}}\right), \tag{22}$$

where the dependence of β_λ on $\alpha_s(M_Z)$ is of $O(10^{-7})$ and is not shown.

[7] In this definition, the graviton fluctuation $h_{\mu\nu}$ around the flat Minkowski spacetime $g_{\mu\nu} = \eta_{\mu\nu} + 2M_P^{-1}h_{\mu\nu}$ becomes canonically normalized.

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

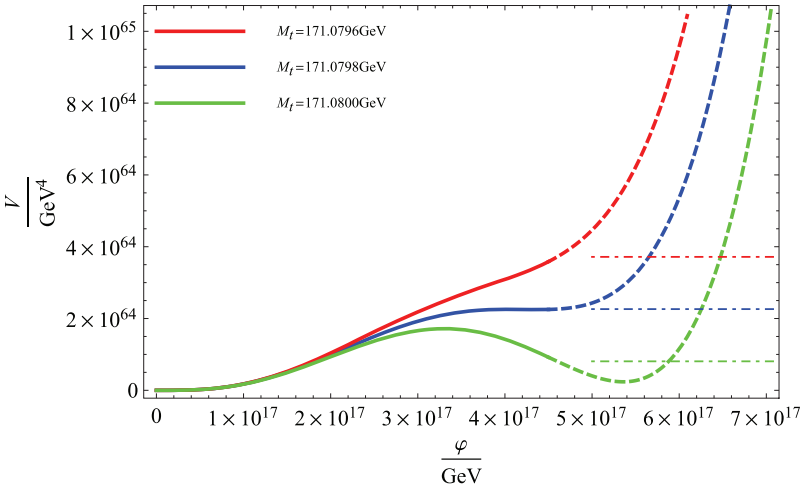

Fig. 2. RGE improved Higgs potential (23), with $M_H = 125.6\,\mathrm{GeV}$ and $\alpha_s = 0.1184$. The solid and dashed lines are the SM Higgs potential (23). Beyond the UV cutoff Λ, which we have taken in this figure to be $4.5 \times 10^{17}\,\mathrm{GeV}$ as an illustration, we assume that the potential becomes flat as depicted by the dot-dashed lines.

3.3. *Higgs inflation?*

We have seen in Fig. 1 that both the Higgs self coupling λ and its beta function β_λ become very small at high scales $\mu \gtrsim 10^{17}\,\mathrm{GeV}$. This fact suggests that the SM Higgs field could be identified as an inflaton. In the following, we show that the SM Higgs potential becomes flat around $10^{17}\,\mathrm{GeV}$ if we tune the top quark mass. However, we will see that it is difficult to reconcile this potential with the cosmological observation [23,60].

For a field value $V = 246.22\,\mathrm{GeV} \ll \varphi < \Lambda$, the Higgs potential becomes, with RGE improvement,

$$\mathcal{V}_{\mathrm{SM}}(\varphi) = \frac{\lambda(\varphi)}{4}\varphi^4. \tag{23}$$

Around the scale $10^{17}\,\mathrm{GeV}$, this potential strongly depends on the top quark mass, which we show by the solid and dashed lines in Fig. 2. The dot-dashed lines are irrelevant to the argument of this subsection.

If we fine-tune the top mass, we can have a saddle point in the Higgs potential: $\mathcal{V}_\varphi(\varphi) = \mathcal{V}_{\varphi\varphi}(\varphi) = 0$, as indicated by the middle (blue) line in Fig. 2. When we slightly lower the top mass, the saddle point disappears and the potential becomes monotonically increasing, as the upper (red) line. On the contrary, when we slightly raise the top mass, there appears another minimum at a high scale, as the lower (green) line [61,62].

The middle (blue) line case, $M_t = 171.0798\,\mathrm{GeV}$, gives the potential

$$\mathcal{V}_c = 6.0 \times 10^{-10} M_P^4 \sim \left(10^{16}\,\mathrm{GeV}\right)^4 \tag{24}$$

at the saddle point $\varphi_c = 4.2 \times 10^{17}\,\mathrm{GeV}$. One might think of using this saddle point for a Higgs inflation, but it is impossible due to the following reasons: With Eq. (8), this height of potential necessitates $\epsilon_V \sim 10^{-3}$. However, the point of $N_* \gtrsim 50$ becomes too close to the saddle point and gives $\epsilon_V \ll 10^{-3}$.

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

In order to avoid this problem, one might try lowering the top mass slightly to reproduce the value of $\epsilon_V \sim 10^{-3}$ at the inflection point $\mathcal{V}_{\varphi\varphi} = 0$. This still does not work because we cannot have enough e-foldings, $N_* \gtrsim 50$, at the inflection point.

As the third trial, one might choose ϵ_V freely at the inflection point so that one can have enough e-folding in passing the inflection point. In this case, one tries to reproduce $\epsilon_V \sim 10^{-3}$ at the higher point with $N_* \sim 50$. However, η_V at this point turns out to be too large to satisfy the slow-roll condition.

We present more detailed discussion in Appendix A.

Note that the precise value of M_t to give the saddle point in Fig. 2 depends on M_H, the details of the RGEs, etc.; the digits of M_t should not be taken literally, but be regarded as an indication of how finely M_t must be tuned to yield a saddle point in the SM. Also, the height of the potential at the saddle point varies when we change, e.g., M_H within the 95% CL, $M_H = (124.8 - 126.4)$ GeV, as

$$\mathcal{V}_c = (1.5\text{–}32.) \times 10^{-10} M_P^4. \tag{25}$$

Therefore the value (24) should be taken as an indication of the order of magnitude.

4. Minimal Higgs inflation

We pursue the possibility that the Higgs potential above Λ becomes sufficiently flat to realize a viable inflation, as the dot-dashed lines in Fig. 2. The inflaton potential is bounded from above as in Eq. (8). In order to avoid the graceful exit problem, the Higgs potential must be monotonically increasing in all the range below and above Λ. Therefore, even if we allow an arbitrary modification above Λ, we still can get a bound: $\Lambda < 5 \times 10^{17}$ GeV. As a concrete example of the modification above Λ, we propose a log-type potential and study its cosmological implications.

4.1. Constraint on top mass from minimal Higgs inflation

We have seen that the scale 10^{17} GeV gives the vanishing beta function β_λ. This scale is close to the string scale in the conventional perturbative superstring theory. Above the string scale, a conventional local field theory is altered. We have shown that the bare Higgs mass becomes very small around this scale [4]. This fact strongly suggests that the Higgs boson is a zero mass state of string theory. If it is the case, after integrating out all the massive stringy states, we get the effective potential, which is meaningful for field values beyond the string scale. The resultant potential beyond the string scale would be greatly modified from that in the SM.[8]

As we discussed in Sect. 1, it is plausible that the effective potential for the field value beyond Λ becomes almost flat. This opens up a possibility that this flat potential can be used for the inflation. In this subsection we first consider a necessary condition for the SM potential at $\varphi < \Lambda$ to allow such a modification in the region $\varphi > \Lambda$.

[8] On the contrary, if the Higgs boson had a string-scale bare mass, it would come from a string massive mode. Then considering the effective potential would become meaningless, as it would become one of the fields to be integrated out.

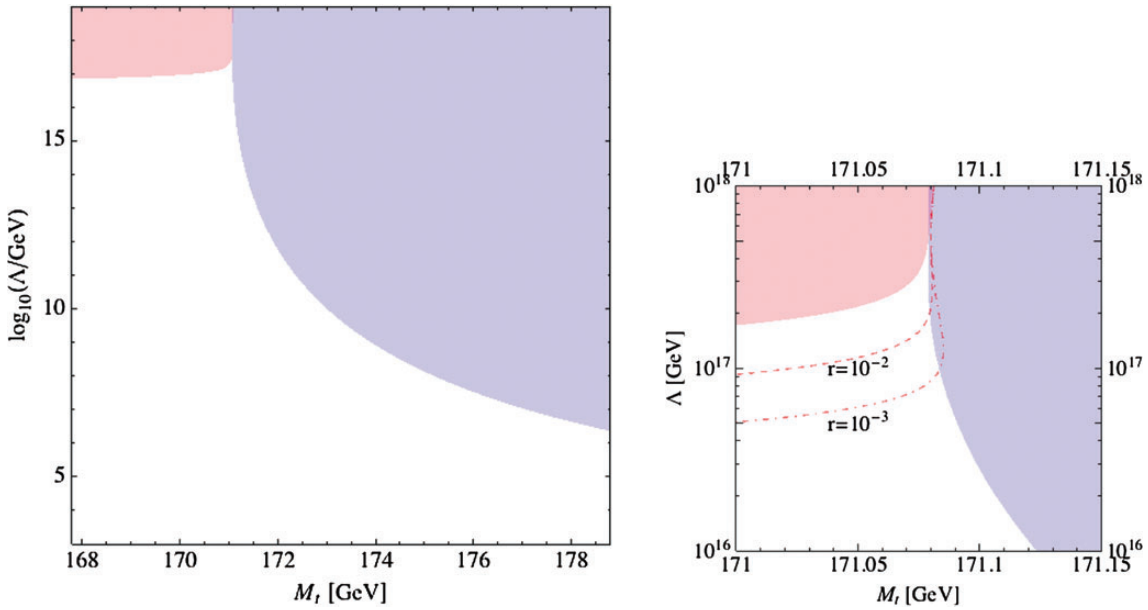

Fig. 3. Left: Regions excluded by Eq. (27) (red, left) and by Eq. (26) (blue, right) in the $\log_{10}(\Lambda/\mathrm{GeV})$ vs M_t plane. Right: Enlarged view for Λ vs M_t. Expected future exclusion limits within 95% CL of $r < 10^{-2}$ and 10^{-3} are also presented by dashed and dot-dashed lines, respectively.

To avoid the graceful exit problem [39–41], the Higgs potential must be a monotonically increasing function of φ in all the range below and above Λ.[9] Therefore, we have

$$\frac{\mathrm{d}\mathcal{V}_{\mathrm{SM}}}{\mathrm{d}\varphi} = \frac{1}{4}\left(\beta_\lambda + 4\lambda\right)\varphi^3 > 0, \tag{26}$$

for all the scales below the cutoff: $\varphi < \Lambda$, and the upper bound (13) leads to

$$\mathcal{V}_{\mathrm{SM}}(\Lambda) < \mathcal{V}_{\max}. \tag{27}$$

We show excluded regions on the Λ–M_t plane from the above two constraints in the left panel of Fig. 3. The left (red) region is excluded by the condition (27) within 95% CL, and the right (blue) region is forbidden by Eq. (26). The right panel is an enlarged view. The dashed and dot-dashed lines correspond to the exclusion limits at the 95% CL, $r < 10^{-2}$ and 10^{-3}, that are expected from the future experiments EPIC [63] and COrE [64], respectively.

We see that the top quark mass needs to be $M_t \lesssim 171$ GeV if we want to have the cutoff scale to be at the string scale $\Lambda \sim 10^{17}$ GeV. If the top quark mass turns out to be heavier, say $M_t \gtrsim 173$ GeV, then this minimal scenario breaks down. However, it is possible that there exists an extra gauge-singlet scalar X that couples to the SM Higgs boson, e.g. as

$$\mathcal{L} = -\frac{\rho}{4!}X^4 - \frac{\kappa}{2}\phi^\dagger\phi X^2, \tag{28}$$

[9] If there is a potential barrier, then the phase transition becomes first order. This is problematic: the false vacuum decays only through the tunneling. The bubbles of true vacuum expand with the speed of light in the exponentially expanding medium of the false vacuum. They can hardly collide with each other. See also Ref. [9] for a possible false vacuum inflation assuming a lowered Planck scale, which we do not employ in this paper.

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

where ρ and κ are coupling constants. Then X contributes to the running of λ positively, and the vacuum stability condition becomes milder. Such a scalar naturally arises in the Higgs portal dark matter scenario; see, e.g., Refs. [65–69].[10]

4.2. *Log-type potential*

So far we have not specified anything about the potential shape above Λ. In the following, let us examine the log-type potential:

$$\mathcal{V}(\varphi) = \mathcal{V}_1 \left(C + \ln \frac{\varphi}{M_P} \right). \tag{29}$$

We note that the Coleman–Weinberg potential with an explicit momentum cutoff Λ leads to a log-type potential; see Appendix B.[11] The potential (29) leads to the slow-roll parameters

$$\begin{aligned} \epsilon_V &= \frac{1}{2}\left(\frac{M_P}{\varphi}\right)^2 \left(\frac{1}{C + \ln \frac{\varphi}{M_P}}\right)^2, \quad \eta_V = -\left(\frac{M_P}{\varphi}\right)^2 \frac{1}{C + \ln \frac{\varphi}{M_P}}, \\ \xi_V^2 &= 2\left(\frac{M_P}{\varphi}\right)^4 \left(\frac{1}{C + \ln \frac{\varphi}{M_P}}\right)^2, \quad \varpi_V^3 = -6\left(\frac{M_P}{\varphi}\right)^6 \left(\frac{1}{C + \ln \frac{\varphi}{M_P}}\right)^3. \end{aligned} \tag{30}$$

The end point of the inflation is determined from Eq. (4) for a given constant C:

$$\varphi_{\rm end} = \begin{cases} \dfrac{M_P}{\sqrt{2}\, W\left(e^C/\sqrt{2}\right)} & \text{for } 0 < C < 0.153, \\ \sqrt{\dfrac{2}{W\left(2e^{2C}\right)}}\, M_P & \text{for } C > 0.153, \end{cases} \tag{31}$$

where W is the Lambert function defined by $z = W(z)e^{W(z)}$. Equivalently, the constant C is fixed as a function of $\varphi_{\rm end}$:

$$C = \begin{cases} \dfrac{M_P}{\sqrt{2}\varphi_{\rm end}} - \ln \dfrac{\varphi_{\rm end}}{M_P} & \text{for } \varphi_{\rm end} \geq \sqrt{2} M_P, \\ \left(\dfrac{M_P}{\varphi_{\rm end}}\right)^2 - \ln \dfrac{\varphi_{\rm end}}{M_P} & \text{for } \varphi_{\rm end} \leq \sqrt{2} M_P. \end{cases} \tag{32}$$

The e-folding becomes

$$\begin{aligned} N_* &= \frac{2C-1}{4}\frac{\varphi_*^2 - \varphi_{\rm end}^2}{M_P^2} + \frac{\varphi_*^2}{2M_P^2} \ln \frac{\varphi_*}{M_P} - \frac{\varphi_{\rm end}^2}{2M_P^2} \ln \frac{\varphi_{\rm end}}{M_P} \\ &= \frac{\varphi_*^2}{2M_P^2} \ln \frac{\varphi_*}{\varphi_{\rm end}} - \frac{\varphi_*^2 - \varphi_{\rm end}^2}{4M_P^2} \times \begin{cases} \left(1 - \sqrt{2} M_P/\varphi_{\rm end}\right) & \text{for } \varphi_{\rm end} \geq \sqrt{2} M_P, \\ \left(1 - 2M_P^2/\varphi_{\rm end}^2\right) & \text{for } \varphi_{\rm end} \leq \sqrt{2} M_P. \end{cases} \end{aligned} \tag{33}$$

To summarize: For a given $\varphi_{\rm end}$, we fix the constant C by Eq. (32). Then we can obtain the slow-roll parameters from Eq. (30) at any field value φ. The field value φ_* corresponding to a relevant e-folding N_* is determined from Eq. (33).

[10] Whether X is included or not, our scenario is not altered by the right-handed neutrinos if their Dirac Yukawa couplings are $\lesssim 0.1$.

[11] In terms of the parameters given there, $C = \frac{\mathcal{V}_0}{\mathcal{V}_1} + \ln \frac{M_P}{\Lambda}$.

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

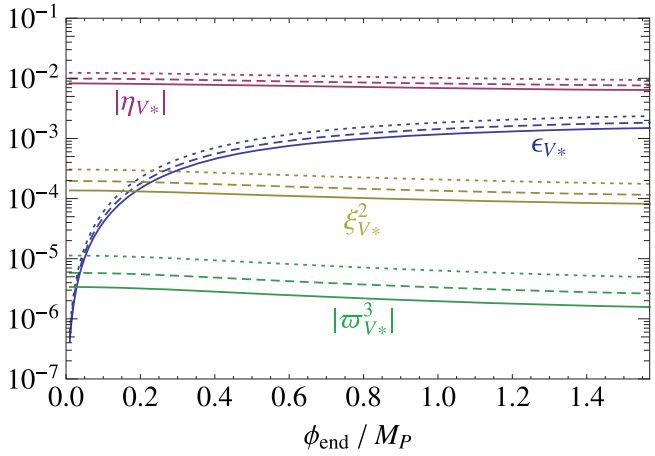

Fig. 4. Slow-roll parameters ϵ_{V*}, η_{V*}, ξ^2_{V*}, and ϖ^3_{V*} as functions of $\varphi_{\rm end}/M_P$ within the range $0.01 < \varphi_{\rm end}/M_P < 1.57$. The dotted, dashed, and solid lines correspond to $N_* = 40$, 50, and 60, respectively.

In this way the slow-roll parameters (30) at a given N_* are completely fixed. Note that they are independent of $\mathcal{V}_1$, the overall normalization of the potential. In Fig. 4, we plot the slow-roll parameters ϵ_V, η_V, ξ^2_V, and ϖ^3_V at the field value φ_* as functions of $\varphi_{\rm end}/M_P$. The dotted, dashed, and solid lines correspond to the values $N_* = 40$, 50, and 60, respectively.[12]

Once the slow-roll parameters are given, the spectral indices, their running, and their running of running are completely fixed. In Fig. 5, we plot them as functions of $\varphi_{\rm end}$. The solid (dotted) lines represent the values for N_* from 50 to 60 (40 to 49). The values for N_* below 50 are just for reference; e.g., late-time thermal inflation [70] can reduce the corresponding N_* to the observed value of k_*; see Ref. [71] for related discussions. When we vary N_* and $\varphi_{\rm end}$ within the ranges $50 \leq N_* \leq 60$ and $0 < \varphi_{\rm end} < 1.57 M_P$, we get

$$
\begin{aligned}
&0.980\text{–}0.984 > n_s > 0.974\text{–}0.979, \quad 0 < r < 0.029\text{–}0.024, \\
&-(4.0\text{–}2.7) \times 10^{-4} > \frac{{\rm d}n_s}{{\rm d}\ln k} > -(5.3\text{–}3.7) \times 10^{-4}, \quad 0 > n_t > -(3.7\text{–}3.0) \times 10^{-3}, \\
&-(1.6\text{–}0.9) \times 10^{-5} > \frac{{\rm d}^2 n_s}{{\rm d}\ln k^2} > -(2.2\text{–}1.2) \times 10^{-5}, \quad 0 < \frac{{\rm d}n_t}{{\rm d}\ln k} < (8.2\text{–}5.6) \times 10^{-5}, \qquad (34)
\end{aligned}
$$

where the order of the inequality corresponds to that of $0 < \varphi_{\rm end} < 1.57 M_P$; the range of numbers denoted by the en-dash "–" corresponds to the range $N_* = 50$–60.

So far we have not considered $\mathcal{V}_1$, since it is sufficient to fix C to determine the slow-roll parameters. Now we determine $\mathcal{V}_1$ by the magnitude of the density perturbation (6):

$$
\mathcal{V}_1 = 12\pi^2 A_s M_P^4 \left(\frac{M_P}{\varphi_*}\right)^2 \left(\frac{1}{C + \ln \frac{\varphi_*}{M_P}}\right)^3 . \qquad (35)
$$

Then the potential and its derivatives at an e-folding N_* are completely fixed. In Fig. 6, we plot φ_*, $\mathcal{V}_{\rm end}$, and $\mathcal{V}_*$ as functions of $\varphi_{\rm end}$. We indicate N_* as in Fig. 5.

[12] We have chosen the highest end point of the horizontal axis of Fig. 4 to be $\varphi_{\rm end}/M_P = {\rm e}^{W(1/\sqrt{2})} = 1.57$ at which $C = 0$ and $\mathcal{V}(\Lambda) = 0$. In this case, we cannot connect the potential $\mathcal{V}$ to $\mathcal{V}_{\rm SM}$, even if the latter were zero at Λ.

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

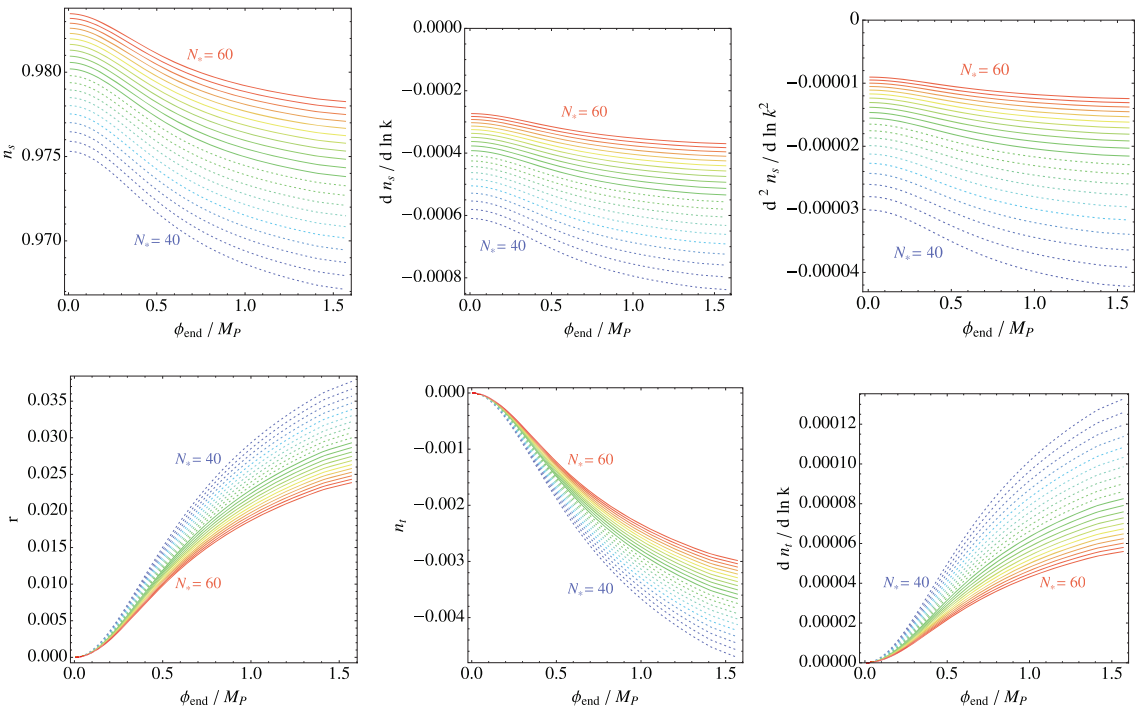

Fig. 5. n_s, $\frac{\mathrm{d}n_s}{\mathrm{d}\ln k}$, $\frac{\mathrm{d}^2 n_s}{\mathrm{d}\ln k^2}$, r, n_t, and $\frac{\mathrm{d}n_t}{\mathrm{d}\ln k}$ as functions of $\varphi_{\rm end}/M_P$.

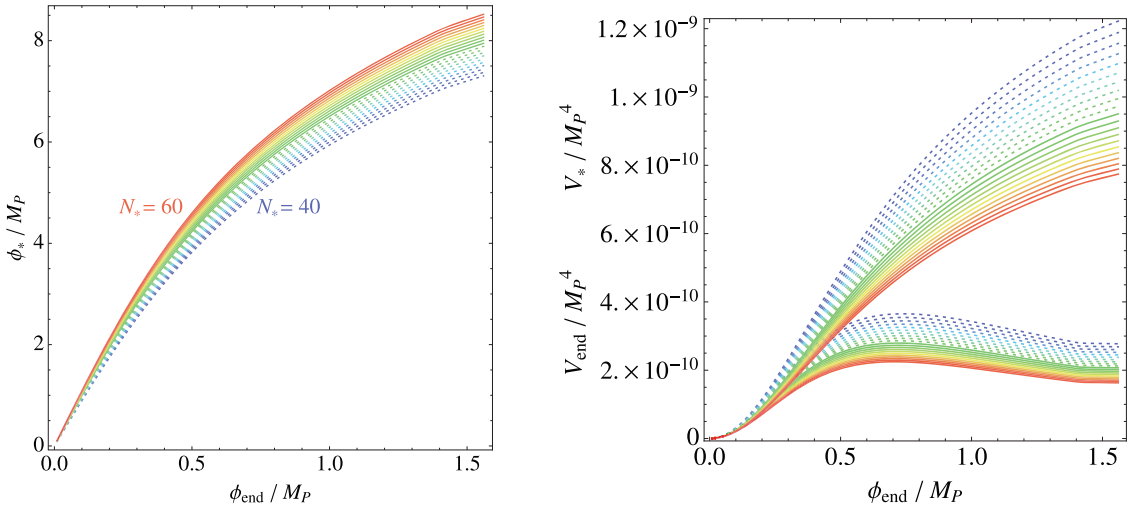

Fig. 6. Left: φ_*/M_P as a function of $\varphi_{\rm end}/M_P$. Right: Potential values, $\mathcal{V}_* = \mathcal{V}(\varphi_*)$ and $\mathcal{V}_{\rm end} = \mathcal{V}(\varphi_{\rm end})$, as functions of $\varphi_{\rm end}/M_P$. The larger (smaller) values correspond to $\mathcal{V}_*/M_P^4$ ($\mathcal{V}_{\rm end}/M_P^4$). We indicate N_* as in Fig. 5.

For a given $\varphi_{\rm end}$ we have obtained the constants $\mathcal{V}_1$ and C. If we demand that the high scale potential (B1), fixed by these values, is directly connected with the SM potential at Λ, then we can fix Λ by

$$\mathcal{V}_1\left(C + \ln\frac{\Lambda}{M_P}\right) = \mathcal{V}_{\rm SM}(\Lambda). \tag{36}$$

In Fig. 7 we present the left- and right-hand sides of Eq. (36) for $N_* = 50$ and $M_t = 170.5\,\mathrm{GeV}$ to illustrate the situation. We see that the low-energy SM potential can be directly connected to the

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

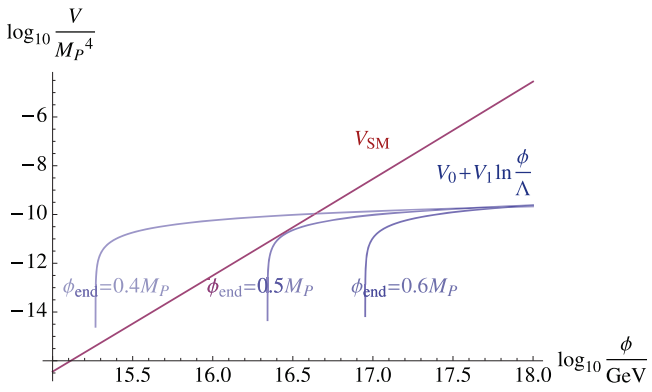

Fig. 7. High-energy potential (B1) for $\varphi_{\rm end} = 0.4M_P$, $0.5M_P$, and $0.6M_P$ with $N_* = 50$ (three blue curves). The red line is the SM potential (23) with the top quark mass $M_t = 170.5\,\text{GeV}$.

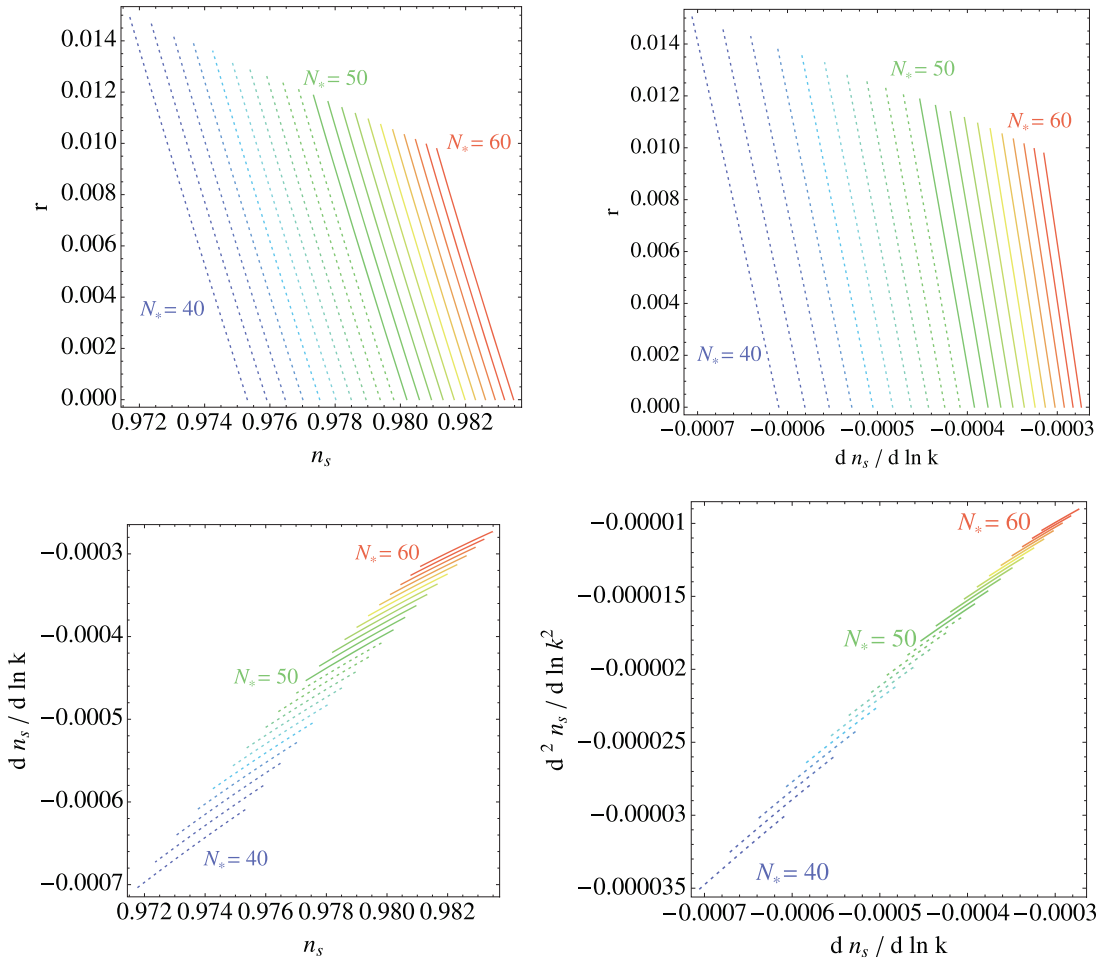

Fig. 8. At the upper-left, upper-right, lower-left, and lower-right, respectively, we have plotted r vs n_s, r vs $\frac{dn_s}{d\ln k}$, $\frac{dn_s}{d\ln k}$ vs n_s, and $\frac{d^2n_s}{d\ln k^2}$ vs $\frac{dn_s}{d\ln k}$ for the potential (B1) with $0 < \varphi_{\rm end} < 0.5M_P$.

high-energy one when and only when $\varphi_{\rm end} \lesssim 0.5M_P$. This critical value of $\varphi_{\rm end}$ is not sensitive to the choice of N_* and M_t.

Then we plot r vs n_s, r vs $\frac{dn_s}{d\ln k}$, $\frac{dn_s}{d\ln k}$ vs n_s, and $\frac{d^2n_s}{d\ln k^2}$ vs $\frac{dn_s}{d\ln k}$ for $0 < \varphi_{\rm end} < 0.5M_P$ in Fig. 8, which can be compared with Figs. 1–5 in Ref. [37]. When we vary N_* and $\varphi_{\rm end}$ within the ranges

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

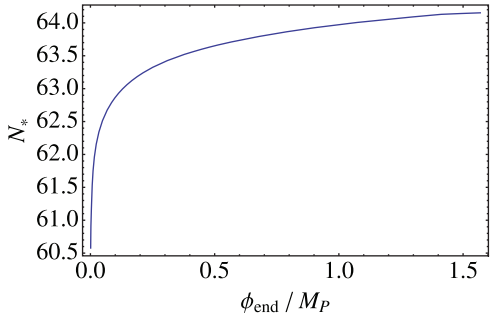

Fig. 9. The e-foldings N_* as a function of $\varphi_{\rm end}/M_P$ corresponding to the pivot scale $k_* = 0.002\,{\rm Mpc}^{-1}$ in the instantaneous decay approximation; see text.

$N_* = 50$–60 and $0 < \varphi_{\rm end} < 0.5 M_P$, we get

$$\begin{aligned}
&0.980\text{–}0.983 > n_s > 0.977\text{–}0.981, \quad 0 < r < 0.012\text{–}0.010,\\
&-(3.9\text{–}2.7)\times 10^{-4} > \frac{{\rm d}n_s}{{\rm d}\ln k} > -(4.5\text{–}3.1)\times 10^{-4}, \quad 0 > n_t > -(1.5\text{–}1.2)\times 10^{-3},\\
&-(1.6\text{–}0.9)\times 10^{-5} > \frac{{\rm d}^2 n_s}{{\rm d}\ln k^2} > -(1.8\text{–}1.0)\times 10^{-5}, \quad 0 < \frac{{\rm d}n_t}{{\rm d}\ln k} < (3.1\text{–}2.2)\times 10^{-5}, \qquad (37)
\end{aligned}$$

where the order of the inequality corresponds to that of $0 < \varphi_{\rm end} < 0.5 M_P$; see Eq. (34).

From Fig. 5, we see that we need rather small $N_* \sim 40$ for $0 < \varphi_{\rm end} < 0.5 M_P$ in order to account for the observed value of n_s in Eq. (10).

We note that a large field inflation with scale $\gtrsim 10^{17}$ GeV tends to require a relatively high value of N_*, barring the late-time thermal inflation mentioned above. When we approximate that the Higgs field decays into the SM modes instantaneously after the inflation [42], the reheating temperature is given by[13]

$$\frac{\pi^2}{30} g_* T_{\rm reh}^4 = \mathcal{V}_{\rm end}, \qquad (38)$$

where $g_* \simeq 106.75$ is the effective number of degrees of freedom in the SM; the resultant reheating temperature is $T_{\rm reh} \simeq 4 \times 10^{15}$ GeV for $\varphi_{\rm end} = 0.5 M_P$. Then the e-folding number, corresponding to the pivot scale $k_* = 0.002\,{\rm Mpc}^{-1}$ and the Hubble parameter $H_0 = 67.3\,{\rm km\,s^{-1}Mpc^{-1}}$, is given by [37]:

$$N_* \simeq 69 + \frac{1}{4}\ln\frac{\mathcal{V}_*}{M_P^4} + \frac{1}{4}\ln\frac{\mathcal{V}_*}{\mathcal{V}_{\rm end}}. \qquad (39)$$

Using the values of $\mathcal{V}_*$ and $\mathcal{V}_{\rm end}$ as depicted in Fig. 6, we get the e-folding number as a function of $\varphi_{\rm end}$, which is plotted in Fig. 9. This indicates that the large field inflation requires $N_* \gtrsim 60$.

On the other hand, as we have seen around Eq. (36) and Eq. (37), we need a small value of $N_* \sim 40$ if we want to directly connect the log potential with the SM one. To do so, $\varphi_{\rm end}$ needs to be relatively small, $\varphi_{\rm end} < 0.5 M_P$, and N_* should be around 40 in order to obtain a realistic value of n_s.

[13] We note that the scale $\varphi_{\rm end}$ is beyond Λ, which is the UV cutoff scale of the SM. Generically one expects that, above Λ, extra degrees of freedom appear besides the SM modes. In general, these modes, say excited string modes in string theory, decay with the rate of the order of Λ times a coupling constant, and we assume that these modes in the decay chain do not affect the result very much.

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

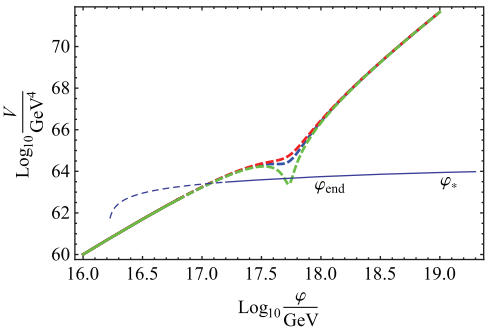

Fig. 10. Log potential (29) plus the correction (40) as a function of φ is drawn in the log-log plot as the solid line to the right, which is the modification of the line for $\varphi_{\mathrm{end}} = 0.5 M_P$ in Fig. 7; φ_* and φ_{end} are also indicated. The SM lines are as in Fig. 2, but the SM cutoff is taken to be slightly smaller: $\Lambda \simeq 10^{17}$ GeV.

There are two ways to solve this apparent inconsistency. One is to note that indeed we do not have to connect the log potential to $\mathcal{V}_{\mathrm{SM}}$ so strictly, as it is unclear what happens around $\varphi \sim \Lambda$.[14] All we need is that the end-point value of the inflaton potential is larger than the SM potential at its UV cutoff scale: $\mathcal{V}_{\mathrm{end}} > \mathcal{V}_{\mathrm{SM}}(\Lambda)$ for $\varphi_{\mathrm{end}} > \Lambda$. Then we can take larger φ_{end} to obtain smaller values of n_s.

The other is adding a small correction to the log potential:

$$\Delta\mathcal{V} = \mathcal{V}_1 \left(c_1 \frac{\varphi}{M_P} + c_2 \frac{\varphi^2}{M_P^2} + \cdots \right). \tag{40}$$

For example, if we choose $\mathcal{V}_1 = 4 \times 10^{-11} M_P^4$, $C = 5$, $c_1 = 0.1$, $c_2 = -0.01$, and $c_n = 0$ for $n \geq 3$, then we get $\varphi_{\mathrm{end}} = 0.48\, M_P$, $\varphi_* = 4.7 M_P$, $N_* = 64$, $r = 0.008$, and $n_s = 0.978$. The resultant potential is illustrated in Fig. 10.

5. Summary and discussions

The Higgs potential in the Standard Model (SM) can have a saddle point around 10^{17} GeV, and its height is suppressed because the Higgs quartic coupling becomes small. These facts suggest that the SM Higgs field may serve as an inflaton, without assuming the very large coupling to the Ricci scalar of order 10^4 which is necessary in the ordinary Higgs inflation scenario. In this paper, we have pursued the possibility that the Higgs potential becomes almost flat above the UV cutoff Λ.

Since a first-order phase transition at the end of the inflation leads to the graceful exit problem, the Higgs potential must be monotonically increasing in the whole range below and above Λ. From this condition, we get an upper bound on Λ of the order of 10^{17} GeV.

We have briefly sketched the possible log-type potential above Λ. We present the motivation for this shape in Appendix B, that is, the Coleman–Weinberg one-loop effective potential becomes of this type above Λ when the momentum integral is cut off by Λ. The predictions on the parameters of the cosmic microwave background at the e-foldings $N_* = 50$–60 are: the scalar spectral index, 0.980–$0.983 > n_s > 0.977$–0.981; the tensor to scalar ratio, $0 < r < 0.012$–0.010; the running scalar index, $-(4.5\text{–}3.1) \times 10^{-4} < \mathrm{d}n_s/\mathrm{d}\ln k < -(3.9\text{–}2.7) \times 10^{-4}$; the running of running

[14] For example, the Coleman–Weinberg potential that has an explicit momentum cutoff Λ turns into the log-type potential only at large field values $\varphi \gg \Lambda$, as shown in Appendix B.

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

scalar index, $-(1.6\text{–}0.9)\times 10^{-5} > \mathrm{d}^2 n_s/\mathrm{d}\ln k^2 > -(1.8\text{–}1.0)\times 10^{-5}$; the tensor spectral index, $0 > n_t > -(1.5\text{–}1.2)\times 10^{-3}$; and the running tensor index, $0 < \mathrm{d}n_t/\mathrm{d}\ln k < (3.1\text{–}2.2)\times 10^{-5}$.

In this paper we have pursued the bottom-up approach from the latest Higgs data, without assuming any other structure than the SM below Λ. We have shown in Fig. 3 that even if we allow arbitrary potential above Λ, still the restriction is rather severe to achieve this minimal Higgs inflation scenario.

It is curious that the upper bound on Λ from the minimal Higgs inflation coincides with the scale where the quartic coupling λ and its beta function (and possibly the bare Higgs mass) vanish. This coincident scale $\sim 10^{17}$ GeV is close to the string scale in the conventional perturbative superstring scenario.[15] This fact may suggest that the physics of the SM, string theory, and the universe are all directly connected.

There are possibilities that realize the flatness from the gauge symmetry as in the gauge–Higgs unification scenario [31–35]—see also Refs. [29,30] for other stringy attempts. Furthermore, Refs. [72,73] derive the log potential of the type (B1). It would be interesting to construct a realistic string model that breaks the supersymmetry at string scale[16] and realizes the flat Higgs potential above Λ consistent with the cosmological observations. One can even go beyond the symmetry argument of the ordinary quantum field theory/string theory to realize the flat potential, such as with the MPP [21–23], the classical conformality around Λ [24–27,77], the multiverse [78], the anthropic principle [79], etc.

Appendix A. SM Higgs as inflaton

To see more explicitly the argument shown in Sect. 3.3 for the difficulty in directly using the SM Higgs field as an inflaton, we first show how to make a saddle point. Let us expand the potential around the point φ_0 ($\sim 10^{17}$ GeV) of vanishing beta function $\beta_\lambda = 0$:

$$\mathcal{V}|_{\varphi\sim\varphi_0} = \frac{\varphi^4}{4}\left[\lambda_0 + b_2\left(\ln\frac{\varphi}{\varphi_0}\right)^2 + b_3\left(\ln\frac{\varphi}{\varphi_0}\right)^3 + \cdots\right], \tag{A1}$$

where b_i are given by

$$b_2 = \frac{1}{2}\frac{\mathrm{d}^2\lambda}{\mathrm{d}\ln\mu^2} = \frac{1}{2}\sum_i \beta_i\frac{\partial\beta_\lambda}{\partial\lambda_i}, \quad b_n = \frac{1}{n!}\frac{\mathrm{d}^n\lambda}{\mathrm{d}\ln\mu^n} = O\left(\left(16\pi^2\right)^{-n}\right), \tag{A2}$$

with λ_i representing [4] the Yukawa coupling squared, y_t^2 etc., the gauge coupling squared, g_Y^2, g_2^2, g_3^2, and the quartic coupling λ. Note that each $\beta_i = \mathrm{d}\lambda_i/\mathrm{d}\ln\mu$ has a loop suppression factor $1/16\pi^2$. We see that the SM Higgs potential can always have a saddle point by choosing a particular value of λ_0 by adjusting the top quark mass. For example, when we approximate $b_3 = 0$, the saddle point is

[15] See, e.g., Refs. [29,30] for trials to explain the smallness of the quartic coupling in the string theory context.

[16] Generally, the number of superstring vacua that break supersymmetry at string scale is much larger than those that preserves supersymmetry [74–76].

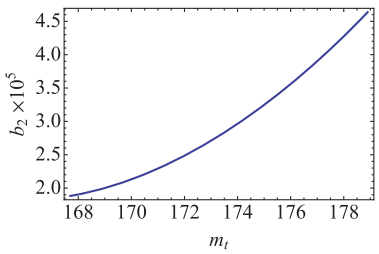

Fig. A1. Running of the beta function b_2 at the scale Λ_0 of vanishing beta function as a function of top pole mass M_t.

realized at $\varphi = e^{-1/4}\varphi_0$ by choosing $\lambda_0 = b_2/16$. In the SM, b_2 takes values $b_2 \simeq (1.9\text{–}4.6) \times 10^{-5}$ for the 95% confidence interval from the top quark mass (15)—see Fig. A1.

In order to show the difficulty of the inflection point inflation with the SM Higgs potential, it suffices to expand the potential around its inflection point φ_c that satisfies $\mathcal{V}_c'' := \mathcal{V}_{\varphi\varphi}(\varphi_c) = 0$:

$$\mathcal{V}(\varphi) = \mathcal{V}_c + \mathcal{V}_c'(\varphi - \varphi_c) + \frac{\mathcal{V}_c'''}{3!}(\varphi - \varphi_c)^3 + \cdots, \tag{A3}$$

where $\mathcal{V}_c''' := \mathcal{V}_{\varphi\varphi\varphi}(\varphi_c)$ and we tune the top quark mass in order to make $\mathcal{V}_c' := \mathcal{V}_\varphi(\varphi_c)$ very small. The e-folding from $\varphi_c + \delta\varphi_*$ to $\varphi_c - \delta\varphi_{\rm end}$ becomes

$$N_* = \sqrt{\frac{2}{\mathcal{V}_c'\mathcal{V}_c'''}}\frac{\mathcal{V}_c}{M_P^2}\left[\arctan\left(\sqrt{\frac{\mathcal{V}_c'''}{2\mathcal{V}_c'}}\delta\varphi_{\rm end}\right) + \arctan\left(\sqrt{\frac{\mathcal{V}_c'''}{2\mathcal{V}_c'}}\delta\varphi_*\right)\right] + \frac{2\mathcal{V}_c'}{3M_P^2\mathcal{V}_c'''}\ln\frac{2\mathcal{V}_c' + \mathcal{V}_c'''\delta\varphi_*^2}{2\mathcal{V}_c' + \mathcal{V}_c'''\delta\varphi_{\rm end}^2} + \frac{\delta\varphi_*^2 - \delta\varphi_{\rm end}^2}{6M_P^2}. \tag{A4}$$

In the following, we discuss in detail the three cases that are sketched in the text:

- The first possibility is to put $\mathcal{V}_c' = 0$ and earn the e-folding near the saddle point. The e-folding (A4) for $\delta\varphi_{\rm end} > 0$ and $\delta\varphi_* < 0$ becomes

$$N_* = \frac{2\mathcal{V}_c}{M_P^2\mathcal{V}_c'''}\left(\frac{1}{|\delta\varphi_*|} - \frac{1}{\delta\varphi_{\rm end}}\right) - \frac{\delta\varphi_{\rm end}^2 - \delta\varphi_*^2}{6M_P^2} \simeq \frac{2\mathcal{V}_c}{M_P^2\mathcal{V}_c'''|\delta\varphi_*|}. \tag{A5}$$

  Close to the saddle point, we have

$$\epsilon_V = \frac{M_P^2\left(\mathcal{V}_c'''\right)^2}{8\mathcal{V}_c^2}\delta\varphi_*^4 + O\left(\delta\varphi_*^7\right). \tag{A6}$$

  Putting Eq. (A5) into Eq. (A6), the slow-roll parameter reads

$$\epsilon_V = \frac{2\mathcal{V}_c^2}{N_*^4 M_P^6\left(\mathcal{V}_c'''\right)^2}, \tag{A7}$$

  and hence the scalar perturbation becomes

$$A_s = \frac{N_*^4 M_P^2\left(\mathcal{V}_c'''\right)^2}{48\pi^2\mathcal{V}_c}. \tag{A8}$$

  From Eq. (A1), we can compute the values in the SM:

$$\mathcal{V}_c''' \sim 10^{-5}\varphi_c \sim 10^{-6}M_P, \tag{A9}$$

  which results in $A_s \gg 1$, far larger than the allowed value (8).

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

- As a second possibility, one might introduce small $\mathcal{V}_c' \sim 10^{-11} M_P^3$ at φ_c, in order to realize the value of the correct density perturbation at φ_c. For the SM values $\mathcal{V}_c \sim 10^{-9} M_P^4$ and $\mathcal{V}_c''' = 10^{-6} M_P$, we obtain from Eq. (A4) the e-folding

$$N_* \sim 1. \tag{A10}$$

  This does not work.
- Finally, one may take very tiny $\mathcal{V}_c'$ at φ_c to earn enough e-folding, in order to realize the inflection point inflation scenario [80–89], while obtaining the necessary amount of ϵ_V at a point above the inflection point: $\varphi_c + \delta\varphi_*$ with $\delta\varphi_* > 0$. In passing through the inflection point φ_c from φ_* ($> \varphi_c$) to $\varphi_{\rm end}$ ($< \varphi_c$), we earn the e-folding

$$N_* = \sqrt{\frac{2\pi^2 \mathcal{V}_c^2}{M_P^4 \mathcal{V}_c' \mathcal{V}_c'''}} + O\left(\left(\mathcal{V}_c'\right)^0\right), \tag{A11}$$

  and hence we can have as large an e-folding as we want by tuning $\mathcal{V}_c'$ small. More concretely, we need

$$\mathcal{V}_c' \sim 10^{-15} M_P^3 \tag{A12}$$

  to get $N_* \sim 50$ with Eq. (A9). However, to keep the slow-roll parameter

$$\eta_V = \frac{M_P^2 \mathcal{V}_c'''}{\mathcal{V}_c} \delta\varphi_* + O\left(\delta\varphi_*^2\right) \tag{A13}$$

  sufficiently small, we need to be close to the inflection point:

$$\delta\varphi_* \ll \frac{\mathcal{V}_c}{M_P^2 \mathcal{V}_c'''}. \tag{A14}$$

  Within this range, we get

$$\epsilon_V = \frac{\mathcal{V}_c^2 \eta_V^4}{8 M_P^6 \left(\mathcal{V}_c'''\right)^2} \ll \frac{\mathcal{V}_c^2}{8 M_P^6 \left(\mathcal{V}_c'''\right)^2}. \tag{A15}$$

  - When $\delta\varphi_*^2 \gg 2\mathcal{V}_c'/\mathcal{V}_c'''$, we have the same expression as Eq. (A6). From Eq. (A15), we get

$$A_s = \frac{\mathcal{V}_c}{24\pi^2 M_P^4 \epsilon_V} \gg \frac{M_P^2 \left(\mathcal{V}_c'''\right)^2}{3\pi^2 \mathcal{V}_c}. \tag{A16}$$

    Using the SM values, this results in $A_s \gg 10^{-5}$, which is far larger than the observation (8).
  - On the contrary, when $\delta\varphi_*^2 \ll 2\mathcal{V}_c'/\mathcal{V}_c'''$, we get $\epsilon_V = M_P^2 \left(\mathcal{V}_c'\right)^2 / 2\mathcal{V}_c^2$ and hence

$$A_s = \frac{\mathcal{V}_c^3}{12\pi^2 M_P^6 \left(\mathcal{V}_c'\right)^2} \sim 1, \tag{A17}$$

    where we have used Eq. (A12). We see that this is too large again.

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

Appendix B. Motivating the log-type toy model

We present a motivation for the toy model with the log-type potential at $\varphi > \Lambda$:

$$\mathcal{V} = \mathcal{V}_0 + \mathcal{V}_1 \ln \frac{\varphi}{\Lambda} =: \widetilde{\mathcal{V}}_0 + \mathcal{V}_1 \ln \frac{\varphi}{M_P}. \tag{B1}$$

In the bare perturbation theory (see, e.g., Ref. [4]), the one-loop effective potential for the Higgs field φ is given by

$$\mathcal{V}_{\rm eff}(\varphi) = \frac{m_B^2}{2}\varphi^2 + \frac{\lambda_B}{4}\varphi^4 + \sum_i \frac{N_i}{2} \int \frac{{\rm d}^4 p}{(2\pi)^4} \ln \frac{p^2 + c_i\varphi^2}{p^2}, \tag{B2}$$

where the integration is performed over Euclidean four-momentum.[17] Since we are interested in the behavior of the potential at a field value φ very much larger than the electroweak scale $\varphi \gg V = 246.22\,{\rm GeV}$, we work in the symmetric phase by setting the Higgs VEV to be zero: $V = 0$. The number of degrees of freedom, N_i, and the coupling to the Higgs, c_i, are summarized in Table B1 for species i that have non-negligible coupling to the Higgs. h and χ are the physical and Nambu–Goldstone modes of the Higgs around the field value φ, respectively.[18] Assuming the existence of an underlying gauge-invariant regularization, such as string theory, let us cut off the integral by $|p| < \Lambda$:

$$\frac{{\rm d}\mathcal{V}_{\rm eff}}{{\rm d}\varphi^2} = \frac{1}{2}\left[m_B^2 + \lambda_B\varphi^2 + \sum_i \frac{N_i c_i}{16\pi^2}\left(\Lambda^2 - c_i\varphi^2 \ln \frac{\Lambda^2 + c_i\varphi^2}{c_i\varphi^2} \right) \right]. \tag{B3}$$

The bare Higgs mass m_B^2 is tuned to yield the desired value of the low-energy mass-squared parameter,

$$m_R^2 := 2\left.\frac{{\rm d}\mathcal{V}_{\rm eff}}{{\rm d}\varphi^2}\right|_{\varphi^2 \to 0}, \tag{B4}$$

to be zero: $m_R^2 = 0$; see, e.g., Ref. [4].[19] Then we get

$$m_B^2 = -\frac{\Lambda^2}{16\pi^2}\sum_i N_i c_i. \tag{B5}$$

To summarize, we generally have

$$\frac{{\rm d}\mathcal{V}_{\rm eff}}{{\rm d}\varphi^2} = \frac{\varphi^2}{2}\left[\lambda_B - \sum_i \frac{N_i c_i^2}{16\pi^2} \ln \frac{\Lambda^2 + c_i\varphi^2}{c_i\varphi^2} \right]. \tag{B6}$$

We see that the bare mass drops out of the effective potential, as it should. The form (B6) corresponds to the one-loop correction to λ_B. As a side remark, we comment that the condition $m_B^2 = 0$ at this one-loop order, namely $\sum_i N_i c_i = 0$, is the celebrated Veltman condition [4,90].

Rigorously speaking, the effective potential (B2) or (B6) can be trusted only when the field-dependent mass in the loop integral is sufficiently small: $c_i\varphi^2 \ll \Lambda^2$. Nonetheless, let us venture to assume that the expression (B2) or (B6) is still valid even for field values much larger than the

[17] In Eq. (B2), we have tuned the cosmological constant so that we get $\mathcal{V}_{\rm eff} \to 0$ as $\varphi \to 0$.

[18] Though we show our results in the Landau gauge, we can explicitly show that in the R_ξ gauge, depending on the external field φ, the one-loop result (B2) is independent of the gauge parameter ξ if we expand it by $c_i\varphi^2 \ll \Lambda^2$.

[19] Recall that we are working in the symmetric phase.

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

Table B1. Constants given in Eq. (B2) for species i providing large c_i.

i	h	χ	W	Z	t
N_i	1	3	6	3	$-4N_c$
c_i	$3\lambda_B$	λ_B	$g_{2B}^2/4$	$(g_{2B}^2+g_{YB}^2)/4$	$y_{tB}^2/2$

cutoff Λ.[20] When we can take $c_j\varphi^2 \gg \Lambda^2$ for some species j, say $j = W, Z, t$, and $c_i\varphi^2 \ll \Lambda^2$ for others i, then

$$\frac{d\mathcal{V}_{\rm eff}}{d\varphi^2} \to \frac{1}{2}\left[m_B^2 + \lambda_B^2\varphi^2 + \frac{\Lambda^4}{16\pi^2\varphi^2}\sum_{j:c_j\varphi^2\gg\Lambda^2}\frac{N_j}{2}\right]. \tag{B7}$$

We note that the bare mass reappears in this limit. As one can see from Fig. 1, both the bare coupling λ_B, approximated by the $\overline{\rm MS}$ one $\lambda(\Lambda)$, and the bare mass m_B^2 are very close to zero for $\Lambda \gtrsim 10^{17}$ GeV. If the UV theory somehow chooses the bare mass to be zero, as is proposed by Veltman, and also $\lambda_B = 0$, then the effective potential becomes

$$\mathcal{V}_{\rm eff} \to \mathcal{V}_0 + \frac{\Lambda^4}{16\pi^2}\ln\frac{\varphi}{\Lambda}\sum_{j:c_j\varphi^2\gg\Lambda^2}\frac{N_j}{2} \tag{B8}$$

at $c_j\varphi^2 \gg \Lambda^2$, where $\mathcal{V}_0$ is an integration constant. We see that the potential at very high scales takes the form of Eq. (B1).

We can read off the coefficient $\mathcal{V}_1$ in Eq. (B1) from Eq. (B8):

$$\mathcal{V}_1 = -\frac{3}{32\pi^2}\Lambda^4 \tag{B9}$$

when we put $j = W, Z, t$. We see that we need to add extra scalar fields coupling to the Higgs to make $\mathcal{V}_1$ positive at high scales, as in the Higgs portal dark matter scenario. As an illustration, we assume hereafter that the Higgs potential is not modified up to the cutoff Λ and is connected to Eq. (B1) directly at Λ with arbitrary constants $\mathcal{V}_0$ and $\mathcal{V}_1$, though generally the RGE itself can be changed by the inclusion of the extra scalar fields.

Appendix C. Limiting behavior

We show the limiting behavior of the high-energy potential Eq. (B1).

- In the limit $\mathcal{V}_1 \ll \widetilde{\mathcal{V}}_0$, we get $\widetilde{\mathcal{V}}_0 \to \mathcal{V}_0$,

$$\epsilon_V \to \frac{1}{2}\left(\frac{M_P}{\varphi}\right)^2\left(\frac{\mathcal{V}_1}{\mathcal{V}_0}\right)^2, \quad \eta_V \to -\left(\frac{M_P}{\varphi}\right)^2\frac{\mathcal{V}_1}{\mathcal{V}_0},$$
$$\xi_V^2 \to 2\left(\frac{M_P}{\varphi}\right)^4\left(\frac{\mathcal{V}_1}{\mathcal{V}_0}\right)^2, \quad \varpi_V^3 \to -6\left(\frac{M_P}{\varphi}\right)^6\left(\frac{\mathcal{V}_1}{\mathcal{V}_0}\right)^3, \tag{C1}$$

  and hence

$$\frac{\varphi_{\rm end}}{M_P} \to \sqrt{\frac{\mathcal{V}_1}{\mathcal{V}_0}} \ll 1, \quad N_* \to \frac{\mathcal{V}_0}{2\mathcal{V}_1}\left(\frac{\varphi_*}{M_P}\right)^2, \quad n_s \to 1 - \frac{1}{N_*}, \quad r \to \frac{4\mathcal{V}_1}{N_*\mathcal{V}_0}. \tag{C2}$$

[20] As is suggested in Ref. [91], the number of effective degrees of freedom may be greatly reduced above the string scale. If this is the case, the naive cutoff removing the modes $|p| > \Lambda$ might be a good illustration of the correct picture.

Downloaded from http://ptep.oxfordjournals.org/ at Osaka Daigaku Ningen on January 18, 2017

For an observed value of A_s, we get

$$\frac{\mathcal{V}_0}{M_P^4} = \sqrt{\frac{6\pi^2 A_s \mathcal{V}_1}{N_* M_P^4}}. \tag{C3}$$

Or if we remove $\mathcal{V}_1 = \mathcal{V}_0 \varphi_*^2 / 2N_* M_P^2$,

$$\frac{\mathcal{V}_0}{M_P^4} = \frac{3\pi^2 A_s}{N_*^2} \frac{\varphi_*^2}{M_P^2}. \tag{C4}$$

Or else, we can rewrite $\mathcal{V}_1 = \left(\frac{\varphi_{\rm end}}{M_P}\right)^2 \mathcal{V}_0$ to yield

$$\mathcal{V}_0 = \frac{6\pi^2 A_s}{N_*} \varphi_{\rm end}^2 M_P^2, \quad \mathcal{V}_1 = \frac{6\pi^2 A_s}{N_*} \varphi_{\rm end}^4, \quad \varphi_* = \sqrt{2N_*}\, \varphi_{\rm end}. \tag{C5}$$

- In the opposite limit $\widetilde{\mathcal{V}}_0 \ll \mathcal{V}_1$, we get

$$\epsilon_V \to \frac{1}{2}\left(\frac{M_P}{\varphi}\right)^2 \left(\frac{1}{\ln \frac{\varphi}{M_P}}\right)^2, \quad \eta_V = -\left(\frac{M_P}{\varphi}\right)^2 \frac{1}{\ln \frac{\varphi}{M_P}},$$
$$\xi_V^2 = 2\left(\frac{M_P}{\varphi}\right)^4 \left(\frac{1}{\ln \frac{\varphi}{M_P}}\right)^2, \quad \varpi_V^3 = -6\left(\frac{M_P}{\varphi}\right)^6 \left(\frac{1}{\ln \frac{\varphi}{M_P}}\right)^3. \tag{C6}$$

We define the end point of the inflation by the condition: $\max\{\epsilon_V, |\eta_V|\} = \epsilon_V = 1$, to get:

$$\varphi_{\rm end} = {\rm e}^{W(1/\sqrt{2})} M_P = 1.57 M_P. \tag{C7}$$

Then the e-folding number becomes

$$N_* \to -\frac{\varphi_*^2 - \varphi_{\rm end}^2}{M_P^2} + \frac{\varphi_*^2}{2M_P^2} \ln \frac{\varphi_*}{M_P} - \frac{\varphi_{\rm end}^2}{2M_P^2} \ln \frac{\varphi_{\rm end}}{M_P}, \tag{C8}$$

which gives $\varphi_* = 8.54 M_P$ $(7.96 M_P)$ for $N_* = 60$ (50), and hence

$$n_s \to 0.994 \ \ (0.993), \quad r \to 6.2 \times 10^{-3} \ \ (7.2 \times 10^{-3}). \tag{C9}$$

This limit $\widetilde{\mathcal{V}}_0 \ll \mathcal{V}_1$ gives the log-only potential. Note that

$$\mathcal{V}_{\rm end} = W(1/\sqrt{2})\, \mathcal{V}_1 = 0.45\, \mathcal{V}_1. \tag{C10}$$

We also get

$$\mathcal{V}_* = \mathcal{V}_1 \ln \frac{\varphi_*}{M_P} = 24\pi^2 A_s \epsilon_V M_P^4, \tag{C11}$$

which gives $\mathcal{V}_1 = 1.23 \times 10^{-9} M_P^4$ $(1.46 \times 10^{-9} M_P^4)$ and $\mathcal{V}_{\rm end} = 3.23 \times 10^{-9} M_P^4$ $(3.75 \times 10^{-9} M_P^4)$ for $N_* = 60$ (50).

ABSTRACT

The $SO(5) \times U(1)$ gauge-Higgs unification in the Randall–Sundrum warped space with the Higgs boson mass $m_H = 126$ GeV is constructed. A universal relation is found between the Kaluza–Klein (KK) mass scale $m_{\rm KK}$ and the Aharonov–Bohm (AB) phase θ_H in the fifth dimension; $m_{\rm KK} \sim 1350\ {\rm GeV}/(\sin\theta_H)^{0.787}$. The cubic and quartic self-couplings of the Higgs boson become smaller than those in the standard model (SM), having universal dependence on θ_H. The decay rates $H \to \gamma\gamma, gg$ are evaluated by summing contributions from KK towers. Corrections coming from KK excited states are finite and about 0.2% (2%) for $\theta_H = 0.12$ (0.36), branching fractions of various decay modes of the Higgs boson remaining nearly the same as in the SM. The signal strengths of the Higgs decay modes relative to the SM are $\sim \cos^2\theta_H$. The mass of the first KK Z is predicted to be 5.9 (2.4) TeV for $\theta_H = 0.12$ (0.36). We also point out the possible enhancement of $\Gamma(H \to \gamma\gamma)$ due to the large $U(1)_X$ charge of new fermion multiplets.

With the discovery of a Higgs-like boson at LHC [1,2] it is emergent to pin down its properties to see if it is the Higgs boson in the standard model (SM). The mechanism of electroweak (EW) symmetry breaking is at issue. It is not clear if the EW symmetry is spontaneously broken in a way described in the SM. The mass of the discovered boson is about 126 GeV. Its couplings to other fields, however, may or may not be the same as in the SM. The excess in the decay mode $H \to \gamma\gamma$ has been reported, though more data are necessary for the issue to be settled [3,4].

Many alternative mechanisms for the EW symmetry breaking have been proposed with new physics beyond the SM. Supersymmetry with a light Higgs boson has been a popular scenario in the past, though no evidence has been found so far. It has been discussed that the value $m_H = 126$ GeV can lead to the direct connection to physics at the Planck scale through the vacuum stability of the SM or conformality [5–7]. Many scenarios have been proposed to account for the apparent excess rate for the Higgs decay to two photons at LHC [8–16].

The gauge-Higgs unification scenario is one of the models with new physics at the TeV scale, in which the 4D Higgs boson is identified with the zero mode of the extra-dimensional component of the gauge fields [17–19]. In this Letter we show that the value of the Higgs boson mass $m_H = 126$ GeV has profound implications in the gauge-Higgs unification. We evaluate the decay rates $H \to \gamma\gamma, gg$ by summing contributions from all Kaluza–Klein (KK) excited states of the W boson and fermions in the internal loops. Surprisingly there arises no divergence associated with the infinite sum, thanks to destructive interference in the amplitude. The corrections to the decay rates $H \to \gamma\gamma, gg$ are finite and small, being independent of a cutoff scale. With $m_H = 126$ GeV as an input, the deviation of the branching fractions of the H decay from the values in the SM is found to be 2% or less.

In the $SO(5) \times U(1)$ gauge-Higgs unification model [20] the 4D neutral Higgs field appears as 4D fluctuations of the AB, or Wilson line, phase θ_H along the fifth dimension in the Randall–Sundrum (RS) warped space–time. In the minimal model with quark and lepton multiplets in the vector representation of $SO(5)$ [21,22] the effective potential $V_{\rm eff}(\theta_H)$ is minimized at $\theta_H = \pm\frac{1}{2}\pi$, where the Higgs boson becomes absolutely stable [23]. This is due to the emergence of the H parity invariance [24]. To have an unstable Higgs boson with a mass $m_H = 126$ GeV the model need to be modified by breaking the H parity. Further in the minimal model the consistency with the electroweak precision measurements requires a large warp factor z_L, which typically leads to a larger value $m_H \sim 135$ GeV [25]. The Higgs mass can be made smaller in the supersymmetric version of the model [26].

To solve these problems we introduce n_F fermion multiplets, Ψ_F, in the spinor representation of $SO(5)$ in the model specified in Ref. [22]. The metric of the RS is given by $ds^2 = e^{-2\sigma(y)}\eta_{\mu\nu}\,dx^\mu\,dx^\nu + dy^2$ where $\sigma(y) = k|y|$ for $|y| \leqslant L$ and

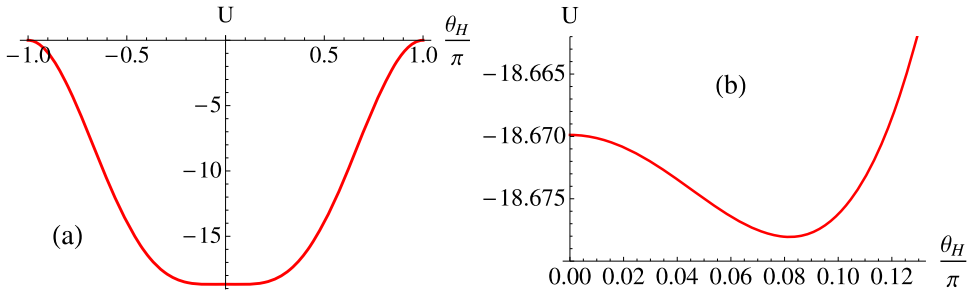

Fig. 1. $V_{\rm eff}(\theta_H)$ for $n_F = 3$, $c_F = 0.353$, $z_L = 10^7$ and $\xi = 1$. $U = (4\pi)^2(kz_L^{-1})^{-4}V_{\rm eff}$ is plotted. The minimum is located at $\theta_H = \pm 0.082\pi = \pm 0.258$. (a): $-\pi \leqslant \theta_H \leqslant \pi$, (b): $0 \leqslant \theta_H \leqslant 0.13\pi$.

Table 1
Values of the various quantities determined from $m_H = 126$ GeV with given z_L for $n_F = 3$. Universal relations among θ_H, $m_{\rm KK}$ and $m_{Z^{(1)}}$, independent of n_F, are observed. See the text.

z_L	θ_H	$m_{\rm KK}$ (TeV)	k (GeV)	c_t	c_F	$m_{F^{(1)}}$ (TeV)	$m_{Z^{(1)}}$ (TeV)
10^{12}	1.02	1.54	4.90×10^{14}	0.413	0.476	0.155	1.19

$\sigma(y+2L) = \sigma(y)$. The warp factor is $z_L = e^{kL} \gg 1$. Ψ_F satisfies the boundary conditions $\Psi_F(x,-y) = \gamma_5 P \Psi_F(x,y)$ and $\Psi_F(x, L-y) = -\gamma_5 P \Psi_F(x, L+y)$ where $P = \mathrm{diag}(1,1,-1,-1)$ acts on $SO(5)$ spinor indices. Then the mass spectrum $m_n = k\lambda_n$ of the KK tower of Ψ_F is determined by $S_L(1;\lambda_n,c_F)S_R(1;\lambda_n,c_F) + \cos^2\frac{1}{2}\theta_H = 0$. Here $S_{L,R}(z;\lambda,c) = \mp\frac{1}{2}\pi\lambda\sqrt{zz_L}F_{c\pm(1/2),c\pm(1/2)}(\lambda z, \lambda z_L)$, where the upper (bottom) sign refers to L (R). $F_{\alpha,\beta}(u,v) = J_\alpha(u)Y_\beta(v) - Y_\alpha(u)J_\beta(v)$ where J_α, Y_α are Bessel functions. It has been shown that all 4D anomalies in the model of Ref. [22] cancel. This property is not spoiled by the addition of Ψ_F multiplets, as 4D fermions of Ψ_F are vectorlike.

The effective potential $V_{\rm eff}(\theta_H)$ is cast in a simple form of an integral. The relevant part of $V_{\rm eff}(\theta_H)$ is given by

$$
\begin{aligned}
&V_{\rm eff}(\theta_H;\xi,c_t,c_F,n_F,k,z_L)\\
&\quad= 2\big(3-\xi^2\big)I[Q_W] + \big(3-\xi^2\big)I[Q_Z] + 3\xi^2 I[Q_S]\\
&\qquad - 12\big\{I[Q_{\rm top}] + I[Q_{\rm bottom}]\big\} - 8n_F I[Q_F],\\
&I\big[Q(q;\theta_H)\big] = \frac{(kz_L^{-1})^4}{(4\pi)^2}\int_0^\infty dq\, q^3 \ln\big\{1+Q(q;\theta_H)\big\},\\
&Q_W = \cos^2\theta_W\, Q_Z = \frac{1}{2}Q_S = \frac{1}{2}Q_0\Big[q;\frac{1}{2}\Big]\sin^2\theta_H,\\
&Q_{\rm top} = \frac{Q_{\rm bottom}}{r_t} = \frac{Q_0[q;c_t]}{2(1+r_t)}\sin^2\theta_H,\\
&Q_F = Q_0[q;c_F]\cos^2\frac{1}{2}\theta_H,\\
&Q_0[q;c] = \frac{z_L}{q^2\hat{F}_{c-\frac{1}{2},c-\frac{1}{2}}(qz_L^{-1},q)\hat{F}_{c+\frac{1}{2},c+\frac{1}{2}}(qz_L^{-1},q)}.
\end{aligned}
\tag{1}
$$

Here $\hat{F}_{\alpha,\beta}(u,v) = I_\alpha(u)K_\beta(v) - e^{-i(\alpha-\beta)\pi}K_\alpha(u)I_\beta(v)$, where I_α, K_α are modified Bessel functions. ξ is a gauge parameter in the generalized R_ξ gauge introduced in Ref. [22]. The formula for $V_{\rm eff}$ in the $\xi = 1$ gauge without the $I[Q_F]$ term has been given in Refs. [21] and [23]. c_t and c_F are the bulk mass parameters for the top-bottom multiplets and Ψ_F, respectively. $r_t \sim (m_b/m_t)^2$ where m_b and m_t are the masses of the bottom and top quark. $V_{\rm eff}(-\theta_H) = V_{\rm eff}(\theta_H)$. Further in the absence of $I[Q_F]$, $V_{\rm eff}$ has symmetry $V_{\rm eff}(\frac{1}{2}\pi+\theta_H) = V_{\rm eff}(\frac{1}{2}\pi-\theta_H)$, representing the H parity invariance. The $I[Q_F]$ term breaks this symmetry. The contributions from light quarks and leptons are negligible.

In the pure gauge theory without fermions $V_{\rm eff}$ is minimized at $\theta_H = 0, \pi$ where the EW symmetry remains unbroken. The top quark contribution has minima at $\theta_H = \pm\frac{1}{2}\pi$, dominating over the gauge field contribution. The fermion Ψ_F shifts the minima toward $\theta_H = 0$. The minimum at $0 < |\theta_H| < \frac{1}{2}\pi$ gives desired phenomenology. The number of the fermion multiplets Ψ_F, n_F, affects the shape of $V_{\rm eff}$ significantly. It will be shown below that the resulting physics, however, is almost independent of n_F. The mass of the Higgs boson, m_H, is given by

$$
m_H^2 = \frac{1}{f_H^2}\frac{d^2V_{\rm eff}}{d\theta_H^2}\bigg|_{\rm min}, \qquad f_H = \frac{2}{g_w}\sqrt{\frac{k}{L(z_L^2-1)}} \tag{2}
$$

where the second derivative of $V_{\rm eff}$ is evaluated at the minimum of $V_{\rm eff}$, and g_w is the 4D weak $SU(2)_L$ coupling. The experimental data dictate $m_H \sim 126$ GeV.

The parameters of the model are specified in the following manner. Pick values for n_F and z_L. The parameters, k, two gauge coupling constants associated with $SO(5)\times U(1)$, c_t, r_t, and c_F are self-consistently determined such that at the minimum θ_H of $V_{\rm eff}$, m_Z, $\sin^2\theta_W$, $\alpha(m_Z)$, m_t, m_b and $m_H = 126$ GeV are reproduced. We note that all of k, c_t, r_t and c_F implicitly depend on θ_H as well. The KK mass scale is given by $m_{\rm KK} = \pi k z_L^{-1}$. Hence $m_{\rm KK}$ and θ_H, for instance, are determined as functions of n_F and z_L. $V_{\rm eff}(\theta_H)$ for $n_F = 3$ and $z_L = 10^7$ is displayed in Fig. 1.

The AB phase θ_H is the key parameter in gauge-Higgs unification, which controls the couplings of the Higgs boson to other fields. In Table 1 the values for z_L, θ_H, $m_{\rm KK}$, k, c_t, c_F, $m_{F^{(1)}}$ and

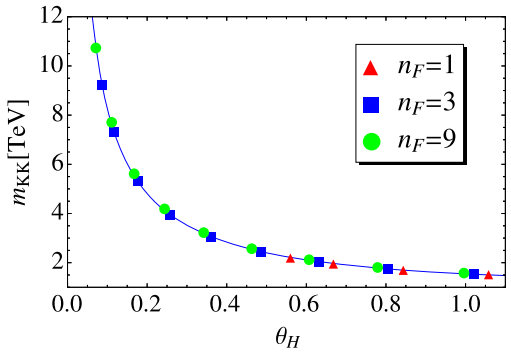

Fig. 2. The relation between θ_H and m_{KK} for $\xi = 1$. Triangles, squares, and circles are for $n_F = 1, 3$ and 9, respectively. The solid curve represents the universal relation (3).

$m_{Z^{(1)}}$ are summarized for $n_F = 3$, where $m_{F^{(1)}}$ is the mass of the lowest mode in the KK tower of Ψ_F and $m_{Z^{(1)}}$ is the mass of the first KK Z boson. As z_L is decreased, θ_H becomes smaller whereas m_{KK} becomes larger. There appears a critical value for z_L below which $m_H = 126$ GeV cannot be realized.

Both θ_H and m_{KK} are physical quantities. They are functions of n_F and z_L. The relation between them are plotted in Fig. 2 for various values of n_F and z_L. As the number of the extra fermions n_F is increased, the location of the minimum of $V_{\rm eff}$ is shifted toward the origin. Nevertheless the relation between θ_H and m_{KK} remains universal. It is approximately given by

$$m_{KK} \sim \frac{1350\ \text{GeV}}{(\sin\theta_H)^{0.787}}, \tag{3}$$

irrespective of n_F and z_L. We note that $m_Z \sim m_{KK}|\sin\theta_H|/(\pi\cos\theta_W\sqrt{kL})$, in which θ_H and $kL = \ln z_L$ are not independent, once m_H is fixed. There must be an underlying reason for the universality relation (3), which remains as a mystery and is left for future investigation. The relation between θ_H and m_{KK}, with $m_{KK} > 3$ TeV for the consistency with low energy data, implies that $\theta_H < 0.3$, which also satisfies the S parameter constraint [20] and the tree-level unitarity constraint [27]. For $\theta_H = 0.1 \sim 0.3$, m_{KK} is predicted to be around $3 \sim 7$ TeV, in a region which can be explored at LHC in the coming years. We have also checked that the m_{KK}–θ_H relation in the $\xi = 0$ gauge is almost the same as in the $\xi = 1$ gauge.

The gauge-Higgs unification model has one parameter, θ_H, to be determined from experiments. With θ_H fixed, all physical quantities are evaluated. By expanding $V_{\rm eff}(\theta_H + (H/f_H))$ in a power series in H around the minimum, one finds $\lambda_n H^n$ couplings. These couplings λ_3 and λ_4 are plotted in Fig. 3 for $n_F = 1, 3$ and 9. The couplings are smaller than those in the SM. For large $\theta_H > 0.55$, λ_4 becomes negative though $V_{\rm eff}$ is bounded from below. It is seen that the relations $\lambda_3(\theta_H)$ and $\lambda_4(\theta_H)$ are also universal and independent of n_F, once $m_H = 126$ GeV is fixed.

The Higgs couplings to W, Z, quarks/leptons and their KK excited states are determined. All of the 3 point couplings of SM particles to H at the tree level are suppressed by a common factor $\cos\theta_H$ [28–31]. It is necessary to find these 3 point couplings of KK states for evaluating the 1-loop processes such as $gg \to H$ and $H \to \gamma\gamma, gg$.

Let us first consider the process $H \to \gamma\gamma$. It proceeds through one-loop diagrams. All charged particles with non-vanishing Higgs couplings contribute. The dominant contributions come from the W boson, top quark, and their KK towers. The extra fermion Ψ_F also contributes. The decay rate is given by [32–34]

$$\begin{aligned}
&\Gamma(H \to \gamma\gamma) \\
&= \frac{\alpha^2 g_w^2}{1024\pi^3}\frac{m_H^3}{m_W^2}\left|\mathcal{F}_W + \frac{4}{3}\mathcal{F}_{\rm top} + \left(2\left(Q_X^{(F)}\right)^2 + \frac{1}{2}\right)n_F\mathcal{F}_F\right|^2, \\
&\mathcal{F}_W = \sum_{n=0}^{\infty}\frac{g_{HW^{(n)}W^{(n)}}}{g_w m_W}\frac{m_W^2}{m_{W^{(n)}}^2}F_1(\tau_{W^{(n)}}), \\
&\mathcal{F}_{\rm top} = \sum_{n=0}^{\infty}\frac{y_{t^{(n)}}}{y_t^{\rm SM}}\frac{m_t}{m_{t^{(n)}}}F_{1/2}(\tau_{t^{(n)}}), \\
&\mathcal{F}_F = \sum_{n=1}^{\infty}\frac{y_{F^{(n)}}}{y_t^{\rm SM}}\frac{m_t}{m_{F^{(n)}}}F_{1/2}(\tau_{F^{(n)}}),
\end{aligned} \tag{4}$$

where $W^{(0)} = W$, $t^{(0)} = t$, $\tau_a = 4m_a^2/m_H^2$ and the functions $F_1(\tau)$ and $F_{1/2}(\tau)$ are defined in Ref. [34]. $Q_X^{(F)}$ is the $U(1)_X$ charge of Ψ_F. $y_t^{\rm SM}$ denotes the top Yukawa coupling in the SM. Note that $F_1(\tau) \to 7$ and $F_{1/2}(\tau) \to -\frac{4}{3}$ for $\tau \to \infty$. The extra fermion multiplet Ψ_F contains particles with electric charges $(Q_X^{(F)} \pm \frac{1}{2})e$. It will be seen below that the contribution $\mathcal{F}_F$ is small for $\theta_H < 0.5$. The $HW^{(n)}W^{(n)\dagger}$ coupling $g_{HW^{(n)}W^{(n)}}$ and the Yukawa couplings $y_{t^{(n)}}$ and $y_{F^{(n)}}$ are unambiguously determined in the gauge-Higgs unification. The infinite sums in (4) turn out finite. The expression for $\mathcal{F}_W$ corresponds to the amplitude in the unitary gauge. It has been shown in Ref. [35] that the correct amplitude is reproduced in the unitary gauge in the SM.

In the gauge-Higgs unification the $HW^{(n)}W^{(n)\dagger}$ and Yukawa couplings result from the $\mathrm{tr}\, F_{\mu 5}F^{\mu 5}$ term and $\overline{\Psi}\Gamma^5 A_5\Psi$ terms in the action, where the vector potential A_5 contains the 4D Higgs field. To good approximation $g_{HWW} \sim g_{HWW}^{\rm SM}\cos\theta_H = g_w m_W\cos\theta_H$ and $y_t \sim y_t^{\rm SM}\cos\theta_H$.

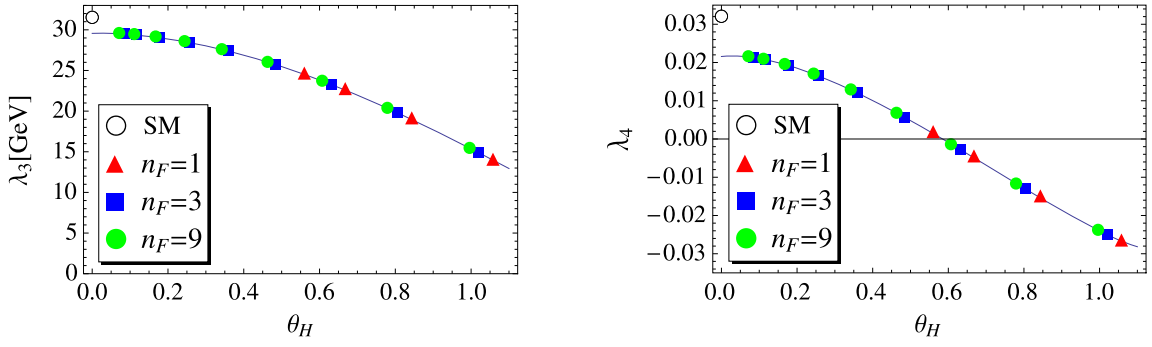

Fig. 3. The cubic coupling λ_3 and quartic coupling λ_4 of the Higgs boson are plotted against θ_H for $n_F = 1, 3$ and 9. The universal relations between (λ_3, λ_4) and θ_H, independent of n_F, are seen. The fitting curves for λ_3 and λ_4 are given by $\lambda_3 = 5.28 + 21.1\cos\theta_H + 3.20\cos 2\theta_H$ and $\lambda_4 = 0.0256 - 0.0537\cos\theta_H + 0.0495\cos 2\theta_H$, respectively. The SM values are $\lambda_3 = 31.5$ GeV and $\lambda_4 = 0.0320$ [6].

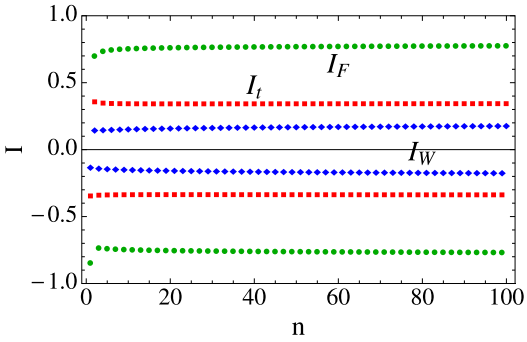

Fig. 4. The ratios $I_{W^{(n)}} = g_{HW^{(n)}W^{(n)}}/g_w m_{W^{(n)}} \cos\theta_H$ in (5), $I_{t^{(n)}} = y_{t^{(n)}}/y_t^{\rm SM}\cos\theta_H$ in (6) and $I_{F^{(n)}} = y_{F^{(n)}}/y_t^{\rm SM}\sin\frac{1}{2}\theta_H$ in (7) are plotted for $n_F = 3$ and $\theta_H = 0.360$ ($z_L = 10^8$) in the range $1 \leqslant n \leqslant 100$. (□: the top quark tower, ◇: the W tower, ○: the Ψ_F tower) $I_{W^{(0)}} = 1.004$ and $I_{t^{(0)}} = 1.012$. The sign of $g_{HW^{(n)}W^{(n)}}$, $y_{t^{(n)}}$ and $y_{F^{(n)}}$ alternates as n increases. $I_{W^{(1)}}, I_{t^{(1)}}, I_{F^{(1)}} < 0$.

One finds that

$$I_{W^{(n)}} = \frac{g_{HW^{(n)}W^{(n)}}}{g_w m_{W^{(n)}}\cos\theta_H} = -\sqrt{kL(z_L^2-1)}\frac{\sin\theta_H}{N_{W^{(n)}}}\frac{C(1;\lambda_{W^{(n)}})}{S(1;\lambda_{W^{(n)}})},$$

$$N_{W^{(n)}} = \int_1^{z_L}\frac{dz}{z}\Big\{\big(1+\cos^2\theta_H\big)C(z;\lambda_{W^{(n)}})^2 + \sin^2\theta_H\hat{S}(z;\lambda_{W^{(n)}})^2\Big\},$$

$$C(z;\lambda) = \frac{\pi}{2}\lambda z z_L F_{1,0}(\lambda z,\lambda z_L),$$

$$S(z;\lambda) = -\frac{\pi}{2}\lambda z F_{1,1}(\lambda z,\lambda z_L), \qquad \hat{S}(z;\lambda) = \frac{C(1;\lambda)}{S(1;\lambda)}S(z;\lambda). \quad (5)$$

We note that $S(1;\lambda_{W^{(n)}}) = 0$ at $\theta_H = 0$. The values $I_{W^{(n)}}$ are plotted in Fig. 4 for $n_F = 3$ and $\theta_H = 0.360$ ($z_L = 10^8$). One sees that the sign of $I_{W^{(n)}}$ alternates as n increases, and its magnitude is almost constant; $I_{W^{(n)}} \sim (-1)^n\{0.14 + 0.0025\ln n + 0.0011(\ln n)^2\}$ in the range $50 < n < 200$. Note that $|g_{HW^{(n)}W^{(n)}}|$ itself increases with $m_{W^{(n)}}$, in sharp contrast to the behavior in the UED models [8].

Similar behavior is observed for the Yukawa couplings of the top tower. One finds that

$$I_{t^{(n)}} = \frac{y_{t^{(n)}}}{y_t^{\rm SM}\cos\theta_H} = -\frac{g_w}{2y_t^{\rm SM}}\sqrt{kL(z_L^2-1)}\frac{\sin\theta_H}{N_{t^{(n)}}}\frac{C_L(1;\lambda_{t^{(n)}},c_t)}{S_L(1;\lambda_{t^{(n)}},c_t)},$$

$$N_{t^{(n)}} = \int_1^{z_L} dz\Big\{\big(1+\cos^2\theta_H + 2r_t\big)C_L(z;\lambda_{t^{(n)}},c_t)^2 + \sin^2\theta_H\hat{S}_L(z;\lambda_{t^{(n)}},c_t)^2\Big\},$$

$$C_L(z;\lambda,c) = \frac{\pi}{2}\lambda\sqrt{zz_L}F_{c+(1/2),c-(1/2)}(\lambda z,\lambda z_L),$$

$$\hat{S}_L(z;\lambda,c) = \frac{C_L(1;\lambda,c)}{S_L(1;\lambda,c)}S_L(z;\lambda,c). \quad (6)$$

The values $I_{t^{(n)}}$ are plotted in Fig. 4. The value of $I_{t^{(n)}}$ alternates in sign as n increases, and the magnitude of $y_{t^{(n)}}$ are almost constant for large n.

The behavior of the $y_{F^{(n)}}$ of the extra fermion is slightly different. In contrast to quarks and leptons, the lowest mode $F^{(1)}$ in the KK tower of Ψ_F is massive at $\theta_H = 0$; its mass is approximately given by $m_{F^{(1)}}(\theta_H) \propto \cos\frac{1}{2}\theta_H$. Its Yukawa coupling is, therefore, expected to be $y_{F^{(1)}} \propto \sin\frac{1}{2}\theta_H$, becoming small for small θ_H. Indeed one finds

$$I_{F^{(n)}} = \frac{y_{F^{(n)}}}{y_t^{\rm SM}\sin\frac{1}{2}\theta_H} = -\frac{g_w}{4y_t^{\rm SM}}\sqrt{kL(z_L^2-1)}\frac{\cos\frac{1}{2}\theta_H}{N_{F^{(n)}}}\frac{C_R(1;\lambda_{F^{(n)}},c_F)}{S_R(1;\lambda_{F^{(n)}},c_F)},$$

$$N_{F^{(n)}} = \int_1^{z_L} dz\Big\{\sin^2\frac{\theta_H}{2}C_R(z;\lambda_{F^{(n)}},c_F)^2 + \cos^2\frac{\theta_H}{2}\hat{S}_R(z;\lambda_{F^{(n)}},c_F)^2\Big\},$$

$$\hat{S}_R(z;\lambda,c) = \frac{C_R(1;\lambda,c)}{S_R(1;\lambda,c)}S_R(z;\lambda,c). \quad (7)$$

$I_{F^{(n)}}$ is plotted in Fig. 4. Again the value of $y_{F^{(n)}}$ alternates in sign as n increases. For large n, $y_{F^{(n)}}/y_t^{\rm SM} \sim (-1)^n 0.14$ for $(n_F, z_L) = (3, 10^8)$.

With all these Higgs couplings at hand, one can evaluate the rate $\Gamma(H\to\gamma\gamma)$ in (4). As all KK masses increase as $m_n \sim \frac{1}{2}nm_{\rm KK}$ for large n and $F_1, F_{1/2}$ approach constant, the infinite sums rapidly converge as $\sum(-1)^n n^{-1}$ or $\sum(-1)^n n^{-1}(\ln n)^q$ ($q = 1, 2, \ldots$). We have found that the sums saturate with about 50 terms. The behavior of the alternating sign in the Higgs couplings of KK states has been previously noticed in Refs. [36] and [37]. Let $\mathcal{F}_{W\,\rm only}$ ($\mathcal{F}_{\rm top\,only}$) be the contribution of $W = W^{(0)}$ ($t = t^{(0)}$) to $\mathcal{F}_W$ ($\mathcal{F}_{\rm top}$) in (4). For $n_F = 3$ and $z_L = 10^8$ (10^5), which yields $\theta_H = 0.360$ (0.117), one finds that $\mathcal{F}_{W\,\rm only} = 7.873$ (8.330), $\mathcal{F}_{\rm top\,only} = -1.305$ (-1.372), $\mathcal{F}_W/\mathcal{F}_{W\,\rm only} = 0.998$ (0.9996), $\mathcal{F}_{\rm top}/\mathcal{F}_{\rm top\,only} = 0.990$ (0.998) and $\mathcal{F}_F/\mathcal{F}_{\rm top\,only} = -0.033$ (-0.0034).

Let us suppose $Q_X^{(F)} = 0$. In this case we obtain $\mathcal{F}_W + \frac{4}{3}\mathcal{F}_{\rm top} + \frac{3}{2}\mathcal{F}_F = 6.199$ (6.508). Its ratio to $\mathcal{F}_{W\,\rm only} + \frac{4}{3}\mathcal{F}_{\rm top\,only}$ is 1.011 (1.001). In other words, the contributions from KK states and Ψ_F amount to only 1% (0.1%). The dominant effect for the decay rates comes from the $\cos\theta_H$ suppression factor in the amplitudes. Compared to the value in the SM, $\Gamma[H\to\gamma\gamma]$ is suppressed by 10% (1%) for $\theta_H = 0.360$ (0.117). The decay rate to two gluons is [38–40]

$$\Gamma(H\to gg) = \frac{\alpha_s^2 g_w^2 m_H^3}{128\pi^3 m_W^2}|\mathcal{F}_{\rm top}|^2, \quad (8)$$

if Ψ_F is a color singlet. If Ψ_F is a color triplet, $\mathcal{F}_{\rm top}$ is replaced by $\mathcal{F}_{\rm top} + \frac{2}{3}n_F\mathcal{F}_F$ in the above formula. The correction due to KK excited states is small.

In the gauge-Higgs unification all decay rates for $H\to WW$, $ZZ, c\bar{c}, b\bar{b}, \tau\bar{\tau}$ are suppressed by a common factor $\cos^2\theta_H$ at the tree level. We have found that loop corrections due to KK excited states are very small. Consequently the correction to the branching fraction of $H\to\gamma\gamma$ turns out very small, about 2% (0.2%) in the gauge-Higgs unification for $\theta_H = 0.360$ (0.117). The observed event rate for $H\to\gamma\gamma$, for instance, is determined by the product of the Higgs production rate and the branching fraction, $\sigma_H^{\rm prod}\cdot B(H\to\gamma\gamma)$. The production rate is suppressed, compared to the SM, by $\cos^2\theta_H$, but the branching fractions remain nearly the same as in the SM. The gauge-Higgs unification predicts that the signal strength relative to the SM is $\sim\cos^2\theta_H$. For $\theta_H = 0.1$ (0.3), it is about 0.99 (0.91). This is in sharp contrast to other models. In the UED models the contributions of KK states to $\mathcal{F}_{\rm top}$ add up in the same sign and may become sizable [8]. In the gauge-Higgs unification the contributions alternate in sign in the amplitudes, resulting in the destructive interference and giving very small correction.

The rate $\Gamma(H\to\gamma\gamma)$ in Eq. (4) can be enhanced through the factor $2(Q_X^{(F)})^2 + \frac{1}{2}$ for sufficiently large $Q_X^{(F)}$. For example, for $Q_X^{(F)} = 4$ and $n_F = 3$, we obtain the enhancement by a factor 2.22 (1.13) compared with the SM.

The fact $m_H \sim 126$ GeV leads to important consequences in the gauge-Higgs unification. We have found the universal relations among $m_{\rm KK}, \lambda_3, \lambda_4$ and θ_H, which are independent of how many

extra fermions are introduced. The low energy data, the S parameter constraint, and the tree-level unitarity constraint indicate small $\theta_H < 0.3$. The KK mass scale $m_{\rm KK}$ is predicted to be $3 \sim 7$ TeV for $\theta_H = 0.1 \sim 0.3$. The existence of new charged heavy particles can affect the production and decay rates of the Higgs boson through loop diagrams. There are many proposals of models which employ such a mechanism to predict the enhancement of the $H \to \gamma\gamma$ mode over other decay channels [8–16]. In the gauge-Higgs unification there are new charged heavy particles, namely KK excited states of W and top quark. However, we have shown that their couplings to the Higgs boson alternate in sign in each KK tower so that the correction to the decay and production rates becomes very small. The gauge-Higgs unification gives phenomenology at low energies very close to that of the SM so long as $Q_X^{(F)}$ is moderately small.

Nevertheless new rich structure is predicted to emerge. We have seen above that the cubic and quartic self-couplings of the Higgs boson significantly deviate from the SM. The most clear signal for the gauge-Higgs unification would be the production of the first KK states of the Z boson and photon at LHC. Their masses are predicted, for $\theta_H = 0.117$ (0.360), to be $m_{Z^{(1)}} = 5.910$ (2.414) TeV and $m_{\gamma^{(1)}} = 5.913$ (2.421) TeV. The current data [41–44] indicate $m_{Z^{(1)}} > 2.5$ TeV. We have checked that there is a universal relation between θ_H and $m_{Z^{(1)}}$, independent of n_F. The data therefore imply that $\theta_H < 0.35$. Another robust signal would be the production of a pair of the first KK state of the extra fermion, $F^{(1)}\bar{F}^{(1)}$, which become stable. So far no new exotic stable charged fermion has been observed at LHC [45]. Its current limit puts a constraint $m_{F^{(1)}} > 0.5$ TeV. The value of $m_{F^{(1)}}$ depends on both θ_H and n_F so that no universal relation between $m_{F^{(1)}}$ and θ_H is found. $m_{F^{(1)}}$ becomes smaller as n_F increases with θ_H fixed. $m_{F^{(1)}} > 0.5$ TeV implies $\theta_H < 0.45$ for $n_F = 3$. We will come back to these issues with more details separately.

計画研究 B03 班

課題名「 テラスケールの物理から超弦理論への展開 」

研究組織

(1)研究代表者
渡利　泰山（WATARI, Taizan）
東京大学 ・カブリ数物連携宇宙研究機構・特任准教授
研究者番号：40451819

(4) 研究協力者：　科研費補助事業期間を通して、常時４－５人で推移した。
（多少の入れ替わりあり）

大河内　豊（OOKOUCHI,Yutaka）
九州大学・基幹教育院 自然科学理論系部門 ・准教授
研究者番号　40599990

高柳　匡（TAKAYANAGI,Tadashi）
京都大学, 基礎物理学研究所, 教授
研究者番号　10432353

Yu-Chieh Chung
現所属・不明
研究者番号　40624135

John Kehayias,
Vanderbilt 大学・物理天文学科・特任研究員
研究者番号　30624142

西尾 亮一 (NISHIO, Ryoichi)
SmartNews, Inc.・社員

研究者番号　なし

Dong-Min Gang,
東京大学・カブリ数物連携宇宙研究機構・特任研究員
研究者番号　50748853

Matthias Weissenbacher
東京大学・カブリ数物連携宇宙研究機構・特任研究員
研究者番号　80775677

交付決定額

計画研究 B03 班に配分された交付額を表 1 に示す。

表 1. 交付決定額（配分額）　（金額単位：円）

年度	直接経費	間接経費	合計
平成 23 年度	5,400,000	1,620,000	7,020,000
平成 24 年度	6,800,000	2,040,000	8,840,000
平成 25 年度	6,900,000	2,070,000	8,970,000
平成 26 年度	6,500,000	1,950,000	8,450,000
平成 27 年度	6,500,000	1,950,000	8,450,000
総計	32,100,000	9,630,000	41,730,000

研究成果

１．研究開始当初の背景

素粒子物理のフロンティアを前進させることができるのは究極的には実験である。その中でも加速器実験は重要な位置を占める。一方で、加速器実験でエネルギーの一段高い世界に踏み込んでいくには、非常に長い時間を要する。ゆえに、実験から直接的に分かることだけでなく、その意味するところを十二分に引き出す理論的試みが重要な意味を持つことになる。

そのような理論的試みの中で、実験にもっとも近いところに寄り添うアプローチは、現象論とか模型構築とか呼ばれている。そのアプローチの基本言語は、低エネルギー有効局所場の理論である。そして、このアプローチの限界は２つある。１つは、局所場の理論が許す自由度があまりに大きく、標準模型を超える模型を構築するにあたって、理論的に許される自由度が大きすぎるのである。そしてもう一つは、加速器実験で解析できる事象が、場の理論の摂動的取扱が可能なものに限られていることである。クォークやグルーオンなどの大角度高エネルギー散乱は摂動計算扱えるが、終状態としてハドロンを含むような過程は、摂動計算では扱えない。

超弦理論は、低エネルギー有効局所場の理論を超える理論的枠組みである。であるから、上記の２つの低エネルギー有効局所場の理論の限界を弦理論を用いて乗り越えようとするアプローチが試みられてきた。

(1) 模型構築のアプローチの限界を超えようとする試みとして、超弦理論のコンパクト化が１９８０年代半ばから研究されてきた。しかし、９０年代半ばに起きた超弦理論の理解の飛躍的進歩により、８０年代からの蓄積は大幅なバージョンアップが必要になった。そのバージョンアップが００年代半ばに始まり、理論的基礎での不明な部分が大方片付いたのが、当該科研費補助事業の「研究開始当時」の状況である。

しかし、超弦理論のコンパクト化の現象論のための理論的基礎の理解が固まることと、それを用いて低エネルギーの物理に有用な洞察をもたらすことの間にはまだ相当の距離があった。

(2) 加速器実験での事象の解析を局所場の理論の摂動計算に依拠する、という限界を超えようとする試みとしては、AdS/CFT 対応の応用の研究がなされてきた。

９０年代末から００年代にかけては、AdS 空間上の重力理論を用いて、ハドロンの質量や結合定数、形状因子を計算する手法が開発された。これは、AdS/CFT 対応のハドロン物理への応用において基礎中の基礎になる事項である。

一方、質量や形状因子は、ハドロンの静的、もしくはそれに準ずる低エネルギー領域での性質である。ハドロンの純高エネルギー散乱では、パートンの描像がよい近似になることが知られており、また、散乱の重心系エネルギーが大きいけれども運動量移行が小さい場合(Regge 領域と呼ばれる)には、ハドロン描像とパートン描像の中間・折衷的な性質をもった理論が必要であることが知られている。ゆえに、さらなる理論開発が必要なのである。

２００２年の Polchinski Strassler, および ２００６年の Brower Polchinski Strassler Tan (BPST) の論文は、この方面において突破口を開くものであった。AdS/CFT の枠組みの中でどのようにパートンを扱うべきか、そして Regge 領域の散乱を取り出すには、超弦理論のどのような近似計算を行うべきか、の指針を明らかにしたのである。ただし、06 年の BPST 論文は、２つのハドロンの間の弾性散乱のみを扱う理論的枠組みの提示にとどまった。多種多彩なハドロンの高エネルギー散乱現象を理解するための理論的枠組みとして使えるようになるには、まだ相当の理論の開発が必要、というのが、「研究開始当時」の状況である。

２．研究の目的

新学術領域「テラスケール」の B03 班では、上記 (1), (2) の試みを追及していくことを目的とした。

３．研究の方法

(1) 当該科研費補助事業の開始時点で懸案であったのは、「コンパクト化に導入可能な位相的フラックスを、特異点を持つ多様体においてどう記述するか」という技術的問題である。位相的フラックスは低エネルギー有効理論の物質場の世代数も決定するし、コンパクト化多様体の形状も決定する、ひいては低エネルギー有効理論の結合定数を決定する、というものであるから、まずはここを攻略せねばならない。我々は、05 年の Aspinwall Kallosh 論文、11 年の Esole Yau 論文を徹底的に読み込むことから開始した。

そこから得られた理解を基に、次は、03 年の Ashok Douglas, 04 年の Denef Douglas 論文にお

ける弦理論の解の統計分析を拡張一般化し、統計分析の手法を F-理論コンパクト化にも適用できるようにした。

これらの段階を乗り越えたうえで、F-理論のフラックスコンパクト化で得られる低エネルギー有効理論の統計を調べ、その結果を、ゲージ群、世代数、結合定数など低エネルギーで観測可能な物理量の関数求めるところまで持ち込んだ。結果は次の項で記す。

この超弦理論の真空の統計分布を調べることが可能になることによって、模型構築のアプローチにおいて通常用いられる「自然さ」という考え方に対して、科学的基礎づけを与えることが可能になる。超対称統一理論におけるフレーバー構造の起源についても、この統計に基づいた洞察を超弦理論から引き出せるようになる。

(2) まずは、02 年 Polchinski Strassler 論文、そして 06 年 BPST 論文を精読し消化するところから我々は研究を開始した。

この両論文のあいまいな個所、論理の不備などに修正を加える一方で、我々は この手法を深部仮想的コンプトン散乱過程と呼ばれる高エネルギーハドロン散乱過程に適用した。必要は発明の母である。具体的な物理過程を対象とすることにより、理論的枠組みのどこが拡張再構築を必要としているかが明らかになるので、一石二鳥の狙いである。

深部仮想的コンプトン散乱過程の記述は、摂動計算と一般化されたパートン分布関数(GPD)と呼ばれる 3 変数非摂動関数の組み合わせによってなされるのだが、弦理論(AdS/CFT)に基づいた手法の強みは、[理論的枠組みがきちんと整備拡張された場合に]この非摂動関数の部分について定性的な予言を出すことができることである。この非摂動関数部分は、摂動計算の過程で複雑な畳み込み積分に使われるため、実験データから直接フィットするわけにはいかない。フィットの前に、理論に基づく媒介変数表示を与える必要があるので、この弦理論に基づくアプローチは、その面での進歩をもたらしうる。

4．研究成果

(1) まずは、フラックスコンパクト化による多様体の形状の安定化機構は、本質的に代数幾何におけるネーター・レフシェッツ問題と等価であるという観察に基づき、まずは F-理論の K3xK3 コンパクト化のフラックス存在下での安定解を調べた。K3 多様体の場合にはネーター・レフシェッツ問題を具体的に手で取り扱うことができる。一方でこの同じ設定に対して、Douglas Ashok Denef の統計的手法を F-理論用に一般化した解析を行うことにより、ネーター・レフシェッツ問

題を扱う手法と、統計的手法が同じ結果を与えることを確認した。かくして、汎用性が高い（と目される）Douglas らの手法を、F-理論の一般的なコンパクト化にも用いてよいことが示された。

なお、この過程で、ヘテロ弦理論と F-理論の間の 8 次元での双対性対応が、離散モジュラー群のとり方まで含めて成立していることを(ついでに)厳密に示した。

Douglas らの統計的手法を F-理論の一般のコンパクト化に用いる場合、4 次コホモロジー群を縦成分、横成分、その他成分に分割し、それぞれの成分の次元を求める必要があることも明らかにした。我々は、この各成分の次元を求める数学公式をも導いた。これにより、低エネルギー有効理論の物理量に対して、F-理論のフラックスコンパクト化解の数がどのような統計分布をを示すかを計算できるようになった。

一般的な結果として、次のことが分かった。
まず、有効理論の物質場の世代数に関しては、ガウス分布であり、分散は O(1)程度。これは、現実世界の 3 世代という値と大きな乖離はない。次に、ゲージ群のとり方に関しては、
乱暴に言って、統一理論のようなゲージ群を持つ解は、全くゲージ群がない解に比べて、１０のマイナス１０００乗程度、もしくはもっと、という信じがたい小さな比率であることが分かった。

宇宙定数の値が現在の宇宙での値ほどに小さい確率は、１０のマイナス１００乗程度、という問題がよく知られているが、この問題の発見のインパクトはその上を行くものである。この結果のインパクトから、MIT の研究者は多様体の 4 次コホモロジーの横成分の次元の計算を多くの例について調べ、３０万次元ほどの大きさの横成分があるものを発見した。このことは、上記の比率が、10 のマイナス１０００乗などでは全く済まないことを示している。

この大きな問題をわきにおけば(人間原理という解がないわけではないので)、この統計分布を用いて、現実世界のフレーバー構造の起源のいくつかの仮説について、優劣の判定をつけることができる。ある仮説については、
１万分の１の真空で成り立つのに対し、別の仮説は、１０のマイナス 1 万乗の比率の真空でしか成り立たないということを示した。

(2)02 年 Polchinski Strassler 論文および 06 年 BPST 論文を精読し、改良を加えた。その結果、パートン分布関数を 2 変数関数に拡張したもの（縦方向運動量 x とローレンツ不変運動量移行 t)について、クロスオーバー転移が存在することを指摘した。

また、06 年 BPST 論文の弾性散乱用に開発された手法を一般化して、2 体から 2 体への散乱な

がら、始状態と終状態で質量が違いうる場合にも適用できるように拡張した。この結果、深部仮想コンプトン散乱にこの AdS/CFT を用いた手法が適用可能になった。

その手法を用いて、3 変数(x, t そしてよじれ具合 eta)に依存する非摂動関数、一般化されたパートン分布関数を求めて、そのいろいろな性質を導いた。

Abstract: Four-form flux in F-theory compactifications not only stabilizes moduli, but gives rise to ensembles of string vacua, providing a scientific basis for a stringy notion of naturalness. Of particular interest in this context is the ability to keep track of algebraic information (such as the gauge group) associated with individual vacua while dealing with statistics. In the present work, we aim to clarify conceptual issues and sharpen methods for this purpose, using compactification on K3 × K3 as a test case. Our first approach exploits the connection between the stabilization of complex structure moduli and the Noether-Lefschetz problem. Compactification data for F-theory, however, involve not only a four-fold (with a given complex structure) Y_4 and a flux on it, but also an elliptic fibration morphism $Y_4 \longrightarrow B_3$, which makes this problem complicated. The heterotic-F-theory duality indicates that elliptic fibration morphisms should be identified modulo isomorphism. Based on this principle, we explain how to count F-theory vacua on K3 × K3 while keeping the gauge group information. Mathematical results reviewed/developed in our companion paper are exploited heavily. With applications to more general four-folds in mind, we also clarify how to use Ashok-Denef-Douglas' theory of the distribution of flux vacua in order to deal with statistics of sub-ensembles tagged by a given set of algebraic/topological information. As a side remark, we extend the heterotic/F-theory duality dictionary on flux quanta and elaborate on its connection to the semistable degeneration of a K3 surface.

Keywords: Flux compactifications, F-Theory, Superstring Vacua

1 Introduction

Flux compactifications of type IIB string theory / F-theory can generate large supersymmetric masses for moduli, so that the moduli particles decay well before the period of big-bang nucleosynthesis. In addition to this phenomenological advantage, the discretum of vacua in this class of compactifications provides an ensemble of vacua (or landscape), which gives rise to a scientific/stringy basis for a notion of naturalness [1, 2]. Certainly the (geometric phase) Calabi-Yau compactifications of type IIB / F-theory are not more than a small subset of all possible vacua in string theory. However, one can still think of some use in such a restricted ensemble of vacua because supersymmetric extensions of the Standard Model and grand unification can be naturally accommodated in this framework.

Given a topological configuration of three-form fluxes in type IIB string theory compactified on a Calabi-Yau threefold M_3, the dilaton and complex structure moduli of M_3 are stabilized and their vacuum expectation values (vevs) are determined. By this mechanism, however, not only the moduli vevs (= the coupling constants of the low-energy effective theories), but also a configuration of D7-branes (= (a part of) the gauge group of the effective theories) is determined.

Low-energy effective theories in particle physics are usually crudely classified by such information as gauge groups, matter representations, types of non-vanishing interactions and matter multiplicity, and then the effective theories sharing this information are distinguished by the values of coupling constants. In order to fit this natural framework of thought, ensembles of string flux vacua should also be crudely classified by algebraic and topological information. After this, statistics should be presented in the form of distributions over the moduli space of compactifications sharing the same set of algebraic and topological information. With the statistics of flux vacua presented in this way, we begin to be able to ask such naturalness-related questions as the ratio of the number of vacua having various algebraic and/or topological data or the distribution of various coupling constants (moduli parameters) in a class of theories having a give set of algebraic/topological data. This article aims at taking one step further in this program. The distribution of gauge groups in effective four-dimensional theories derived from string compactifications has been studied from several perspectives in the literature, see [3–6] for examples.

Stabilization / determination of D7-brane configurations can be understood purely in type IIB language in terms of calibration conditions [7, 8]. Another option is to use F-theory, where the 7-brane configuration, dilaton vev and complex structure moduli of M_3 are all treated as part of the complex structure moduli of a Calabi-Yau fourfold Y_4. In F-theory language, there are two ways to understand the mechanism of determination of the moduli vevs. One is to specify the four-form flux on an elliptic fibred Calabi-Yau fourfold Y topologically,[1]

$$[G^{(4)}] \in H^4(Y;\mathbb{Z})\,. \tag{1.1}$$

[1]The four-form flux should be in the Abelian group $\left[H^4(Y;\mathbb{Z}) + \frac{1}{2}[c_2(TY)]\right] \cap H^{2,2}(Y;\mathbb{R})$ [9], with a possibly half-integral shift $(1/2)[c_2(TY)]$. When Y is a smooth Weierstrass model, however, $c_2(TY)$ is always even, and the four-form flux takes its value in (1.3) [10, 11]. In the present case, where we work with K3 × K3, $c_2(TY)$ is manifestly even and no such issue arises. Hence we ignore this point from now on.

JHEP04(2014)050

The Gukov-Vafa-Witten superpotential

$$W_{\rm GVW} \propto \int_Y \Omega_Y \wedge G^{(4)} \tag{1.2}$$

gives rise to an F-term scalar potential that depends on the complex structure moduli of Y. The minimization of this potential determines the vevs of those moduli. Once the moduli vevs arrive at the minimum of the potential (and if the cosmological constant happens to vanish), the four-form flux $G^{(4)}$ is guaranteed to only have a $(2,2)$ component in the Hodge decomposition under the complex structure corresponding to the vevs [12, 13]. In the presence of the four-form flux, the moduli fields slide down the potential to find a vacuum complex structure, so that $[G^{(4)}]$ only has the $(2,2)$ component. If we are to allow large vacuum expectation values of $W_{\rm GVW}$ $[G^{(4)}]$ may also have $(4,0)$ and $(0,4)$ components.

An alternative way to characterize the vacuum choice of the complex structure of Y is available by focussing on the finitely generated Abelian group

$$H^4(Y;\mathbb{Z}) \cap H^{2,2}(Y;\mathbb{R}) \qquad \left(\text{or } H^4(Y;\mathbb{Z}) \cap H^{2,2}(Y;\mathbb{R}) \oplus [H^{4,0}(Y;\mathbb{C}) + \text{h.c}]\right) . \tag{1.3}$$

The rank of this Abelian group remains constant almost everywhere on the moduli space of the complex structure of Y, but it jumps at special loci. In mathematics, this problem — at which loci in the moduli space the rank of this Abelian group jumps, and how it changes there — is known as the Noether-Lefschetz problem. Once we find a point in the Noether-Lefschetz locus and insert four-form flux in the enhanced part of the Abelian group (1.3), we can no longer go away continuously from the Noether-Lefschetz loci in the moduli space while keeping the flux purely of type $(2,2)$. The higher the codimension of a Noether-Lefschetz locus is in the complex structure moduli space, the more moduli are given masses and stabilized. Therefore, the problem of determination of vacuum complex structure is equivalent to the Noether-Lefschetz problem (e.g., [14]).[2]

This article begins, in sections 2.2, 4.1, 4.3 and 5.2 in particular, with exploiting this equivalence[3] to see how the Noether-Lefschetz problem in F-theory determines statistics of such things as gauge group, discrete symmetry and moduli vevs. We focus our attention on $K3 \times K3$ compactifications of F-theory, as in [15, 16, 18, 21–25]. This compactification cannot be considered realistic enough for an immediate use in particle physics (e.g. there are no matter curves), but a sufficient complexity is involved in this toy model of landscape to make it suitable for the purpose of clarifying various concepts as well as sharpening technical tools.

In the process of deriving statistics, one cannot avoid asking about the modular group (e.g., [17]). In other words, we have to understand when a pair of seemingly different compactification data actually correspond to the same vacuum in physics. In F-theory we have to introduce some equivalence relation among the space of elliptic fibrations that are

[2] We can also draw an analogy with the attractor mechanism [14], although the analogy is particularly good in the case with $G_1 \neq 0$ and $G_0 = 0$ in (2.15), (2.16).

[3] This is an obvious continuation of a program initiated a decade earlier. This idea is already evident in pioneering works such as [14–18], to name a few, and has also been reflected in recent articles such as [19, 20].

JHEP04(2014)050

admitted by Y_4, so that the quotient space corresponds to the set of physically distinct vacua. In section 3.2, we use the duality between heterotic string theory and F-theory, and find that the modulo-isomorphism classification of elliptic fibrations should be adopted. This observation yields two problems. One is purely mathematical: how can we work out the modulo-isomorphism classification of elliptic fibration for a given Y_4? A companion paper by the present authors [26] is dedicated to this problem, with a Calabi-Yau fourfold Y_4 replaced by a K3 surface, and the results in [26] are reviewed mainly in section 4.1 in this article. The other problem is how to use such results in mathematics to carry out vacuum counting in physics. We take on this issue in section 4.2.

Sample statistics, which give us some feeling of what string landscapes can do to answer statistical/naturalness questions in particle physics, are obtained in sections 4.3 and 5.2.

At the same time, though, the study running up to section 5.2 in this article along with [26] also hints that it may not be easy to pursue the Noether-Lefschetz problem approach for Calabi-Yau fourfolds which are not as simple as K3 × K3 or K3-fibration over some complex surface. One may of course always use the strategy of computing periods, as done e.g. in [27] in the present context. Of course, this approach has its own technical challenges.

The theory of [2, 28, 29] is a promising direction to go beyond a case-by-case study for different choices of fourfolds Y. Therefore, the second theme begins to dominate in section 5.4 toward the end of this article. Since articles as [29] and [17] seemed to have had applications in Type IIB orientifold compactifications in mind primarily, we clarify how to use the Ashok-Denef-Douglas theory to study statistics of flux vacua in F-theory, with the total ensemble resolved into sub-ensembles according to their algebraic and/or topological data such as gauge groups and matter multiplicity. The presentation in [17] sits in the middle between our discussion up to section 5.2 and that of [28, 29], and makes it easier to understand how the conceptual issues discussed in the sections up to 5.3 fit into the Ashok-Denef-Douglas theory. Although the presentation in section 5.4 and appendix C uses $K3 \times K3$ compactification as an example, we tried to phrase it in a way ready for generalization at least to cases with K3-fibred Calabi-Yau fourfolds, and possibly to general F-theory compactifications.

There is also the third theme behind sections 4.3.2, 5.3 and appendix B in this article. In the duality between heterotic string theory and F-theory, the dictionary of flux data has been mostly phrased by using the stable degeneration limit of [30, 31]. This was for good reasons, because [32–34] focused on fluxes in F-theory that are directly responsible for the chirality of non-Abelian (GUT gauge group) charged matter fields on the matter curves. There is an extra algebraic curve in the singular fibre over the matter curve in the F-theory geometry, and a flux can be introduced in this algebraic cycle [33, 34]. For more general flux configurations, however, it is not a priori clear to what extent we can use the $dP_9 \cup dP_9$ limit in the duality dictionary, because $dP_9 \cup dP_9$ is quite different from a K3 surface when it comes to whether two-cycles are algebraic or not. There is the work of [20], indicating that U(1) flux associated with an elliptically fibred geometry with an extra section stabilizes some complex structure moduli. Furthermore, the spectral cover description of vector bundles in heterotic string theory [30] did not rule out twisting

JHEP04(2014)050

information γ which is more general than (5.26) for special choices of complex structure. Section 5.3 and the appendix B provide a comprehensive understanding of this material, generalizing the duality dictionary of the flux data in the literature without relying on the $dP_9 \cup dP_9$ limit. Appendix B also makes a trial attempt of studying how much information of such fluxes can be captured by the $dP_9 \cup dP_9$ limit.

A similar theme has already been studied extensively in the series of papers [35–40]. It will be interesting to clarify the relation between the logical construction given there and the presentation in this article, but this task is beyond the scope of this present article.

All $K3$ surfaces which appear as solutions in this article have Picard number 20, which fixes the rank of the total gauge group to be 18 (this is the 'geometric' gauge group, which can still be further broken by fluxes). Whenever the non-abelian part of the gauge group has rank less than 18, there are U(1) factors which are geometrically realized as extra sections of the elliptic fibration. The explicit construction of extra section has been an active research program in recent years. As discussed in [20, 41, 42], sections can be realized by demanding appropriate factorization conditions in the Weierstrass model. A study of fluxes in (a resolution of) the scenario of [41] appeared in [43]. As already discussed in [41], extra sections can equivalently be obtained by realizing the elliptic fibre as a hypersurface in ambient spaces with more than a single toric divisor. This strategy is systematically exploited in [44–47]. Using toric techniques, in particular the classification of tops, models with I_5 fibres and extra sections were constructed in [48–51]. Given a specific embedding of the fibre, one can also use a similar approach as [52], i.e. use Tate's algorithm, to find all possible degenerations leading to a prescribed gauge group [53]. F-theory compactifications with U(1) symmetries also give rise to an interesting interplay between geometry and anomalies of the effective field theory, see [54–57] for some recent works in this direction.

We regret that we use some mathematical jargon and notations, which are non-standard in the physics literature, without explanations. Sections 2–4 of the mathematical companion paper of the present article [26] should contain the necessary background.

2 Four-form flux in M/F-theory on K3 × K3

2.1 Review of known results

Compactification of F-theory on $Y = \mathrm{K3} \times \mathrm{K3}$ has been studied from various perspectives in the literature. To start off, we begin this section with a review of a result in [18].[4] Their results are immediate for M-theory compactification down to 2+1-dimensions, but it is clear that we can build a study of F-theory compactification down to 3+1-dimensions by adding extra structure and imposing conditions on top of the discussion for M-theory [18].

When the Calabi-Yau fourfold Y is a product of two K3 surfaces, S_1 and S_2, the complex structure moduli space of Y, $\mathcal{M}_{\mathrm{cpx}}(Y)$, is the product of the complex structure moduli space of S_1 and S_2, $\mathcal{M}_{\mathrm{cpx}}(S_1) \times \mathcal{M}_{\mathrm{cpx}}(S_2)$. A discussion of the modular group is postponed to later sections. Over the moduli space of $[h^{3,1}(Y) = h^{1,1}(S_1) + h^{1,1}(S_2) = 40]$

[4] See also sections 2.2, 5.1 and 5.2 in this article, where the material reviewed in this section is extended.

JHEP04(2014)050

dimensions, the Hodge decomposition of $H^4(Y;\mathbb{C})$ varies, because the decompositions of $H^2(S_1;\mathbb{C})$ and $H^2(S_2;\mathbb{C})$ vary on the moduli spaces of the two K3 surfaces.[5]

$$H^{2,2}(Y;\mathbb{R}) = H^{1,1}(S_1;\mathbb{R}) \otimes H^{1,1}(S_2;\mathbb{R}) + [H^{2,0}(S_1;\mathbb{C}) \otimes H^{0,2}(S_2;\mathbb{C}) + \text{h.c.}]\,, \quad (2.1)$$

$$[H^{4,0}(Y;\mathbb{C}) + \text{h.c.}] = [H^{2,0}(S_1;\mathbb{C}) \otimes H^{2,0}(S_2;\mathbb{C}) + \text{h.c.}]\,, \quad (2.2)$$

where $[V + \text{h.c.}]$ for a complex vector space V with $\dim_{\mathbb{C}} V = 1$ denotes the corresponding 2-dimensional vector space over $\mathbb{R}$. The Hodge components $[H^{4,0}(Y;\mathbb{C}) + \text{h.c}]$ are also included here for now, partly because the four-form flux with non-vanishing $(4,0)$ and $(0,4)$ components still preserves AdS supersymmetry. The overlap between $H^2(S_1;\mathbb{Z}) \otimes H^2(S_2;\mathbb{Z}) \subset H^4(Y;\mathbb{Z})$ and $H^{2,2} \oplus [H^{4,0} + \text{h.c.}]$ has the maximal rank, 404, when

$$\text{rank}\left[H^2(S_1;\mathbb{Z}) \cap H^{1,1}(S_1;\mathbb{R})\right] = 20, \qquad \text{rank}\left[H^2(S_2;\mathbb{Z}) \cap H^{1,1}(S_2;\mathbb{R})\right] = 20\,. \quad (2.3)$$

The loci satisfying these conditions have complex codimension 40 in the moduli space $\mathcal{M}_{\text{cpx}}(S_1) \times \mathcal{M}_{\text{cpx}}(S_2)$, and hence are isolated points. Once plenty of fluxes are introduced in this rank 404 free Abelian group, all the complex structure moduli are stabilized.

The Abelian group

$$S_X = \left[H^{1,1}(X;\mathbb{R}) \cap H^2(X;\mathbb{Z})\right] \subset H^2(X;\mathbb{Z}) \quad (2.4)$$

for a K3 surface X is called Neron-Severi lattice (or group), and the rank of S_X — denoted by ρ_X or $\rho(X)$ — is called the Picard number of X. S_X is empty for X with a generic complex structure, but its rank can be as large as 20, which is possible only in points of $\mathcal{M}_{\text{cpx}}(X)$. K3 surfaces with $\rho_X = 20$ are called *attractive K3 surfaces* in [58, 59].[6] Thus, the ensemble of flux vacua of M-theory/F-theory compactifications on $Y = \text{K3} \times \text{K3}$ are mapped into a subset of $\mathcal{M}_{\text{cpx}}(S_1) \times \mathcal{M}_{\text{cpx}}(S_2)$ where both S_1 and S_2 are attractive K3 surfaces.

It is convenient for the classification of K3 surfaces with large Picard number to use the transcendental lattice. For a K3 surface X, it is defined as the orthogonal complement of S_X under the intersection form in $H^2(X;\mathbb{Z})$:

$$T_X := \left[(S_X)^\perp \subset H^2(X;\mathbb{Z})\right]. \quad (2.5)$$

[5] The $H^4(S_1;\mathbb{Z}) \otimes H^0(S_2;\mathbb{Z}) \oplus H^4(S_1;\mathbb{Z}) \otimes H^4(S_2;\mathbb{Z})$ components in $H^4(Y;\mathbb{Z})$ (and their $\mathbb{R}$-coefficient versions) are ignored here, because fluxes in these components do not preserve the $\text{SO}(3,1)$ symmetry in the application to F-theory compactifications. This extra assumption is made implicitly everywhere in this article.

[6] In the mathematics literature, a K3 surface with $\rho_X = 20$ is sometimes called a *singular K3 surface*, although the word "singular" only means "very special" in this case, and does not imply that the surface has a singularity. Ref. [58, 59] introduced the term *attractive K3 surface* for K3 surfaces satisfying the same condition, which allows us to avoid confusing terminology. This terminology is a natural choice: just like the complex structure of Calabi-Yau threefolds for type IIB compactifications is attracted towards special loci in $\mathcal{M}_{\text{cpx}}$ near the horizon of a BPS black hole in 4D $\mathcal{N} = 2$ effective theory of IIB/CY_3 in the attractor mechanism [60], the complex structure of fourfold for F-theory/M-theory should be driven towards special loci in $\mathcal{M}_{\text{cpx}}$ in a cosmological evolution in the presence of (G_1-type) flux due to the F-term potential from (1.2). In both cases, special loci are characterized by the condition that some topological flux falls into some particular Hodge component. [58, 59]. In this article, we follow [58, 59] and use the word attractive K3 surface.

JHEP04(2014)050

For a K3 surface with Picard number ρ_X, $\mathrm{rank}(T_X) = 22 - \rho_X$. K3 surfaces with a given transcendental lattice form a $(20-\rho_X)$-dimensional subspace of $\mathcal{M}_{\mathrm{cpx}}(\mathrm{K3})$, and in particular, attractive K3 surfaces are in one-to-one correspondence[7] with rank-2 transcendental lattices (modulo orientation-preserving basis change).

For an attractive K3 surface X, its rank-2 transcendental lattice has to be even and positive definite. This is equivalent to the condition that, for a set of generators $\{p, q\}$ of T_X, the intersection from is given by[8]

$$\begin{bmatrix} (p,p) & (p,q) \\ (q,p) & (q,q) \end{bmatrix} = \begin{bmatrix} 2a & b \\ b & 2c \end{bmatrix}, \tag{2.7}$$

where a, b, c are all integers, $Q := 4ac - b^2$ is positive, and $a, c > 0$. The 2-dimensional vector space $T_X \otimes \mathbb{C}$ over $\mathbb{C}$ (resp. $T_X \otimes \mathbb{R}$ over $\mathbb{R}$) agrees precisely with the vector space $H^{2,0}(X;\mathbb{C}) \oplus H^{0,2}(X;\mathbb{C})$ (resp. $[H^{2,0}(X;\mathbb{C}) + \text{h.c.}]$), and the complex vector subspace $H^{2,0}(X;\mathbb{C}) \subset T_X \otimes \mathbb{C}$ is identified with $\mathbb{C} \cdot \Omega_X \subset T_X \otimes \mathbb{C}$, where

$$T_X \otimes \mathbb{C} \ni \Omega_X := p + \tau q, \qquad \tau := \frac{-b + i\sqrt{Q}}{2c}. \tag{2.8}$$

With orientation-preserving basis changes of T_X, one can always choose the integers a, b, c such that

$$0 \le |b| \le c \le a \qquad (\text{but} \quad 0 \le b \quad \text{if } c = a) \qquad \text{and } Q > 0\,. \tag{2.9}$$

An attractive K3 surface characterized by integers a, b, c in the way explained above is denoted by $X_{[a\ b\ c]}$ in this article.

For a pair of attractive K3 surfaces S_1 and S_2, let $\{q_1, p_1\}$ and $\{q_2, p_2\}$ be the oriented basis of T_{S_1} and T_{S_2}, respectively. The intersection form in this basis is denoted by

$$\begin{bmatrix} (p_1,p_1) & (p_1,q_1) \\ (q_1,p_1) & (q_1,q_1) \end{bmatrix} = \begin{bmatrix} 2a & b \\ b & 2c \end{bmatrix}, \qquad \begin{bmatrix} (p_2,p_2) & (p_2,q_2) \\ (q_2,p_2) & (q_2,q_2) \end{bmatrix} = \begin{bmatrix} 2d & e \\ e & 2f \end{bmatrix}, \tag{2.10}$$

where a, b, c, d, e and f are all integers. The positive definiteness implies that

$$0 \le |b| \le c \le a, \qquad (\text{but } 0 \le b \text{ if } c = a), \qquad Q_1 := 4ac - b^2 > 0, \tag{2.11}$$

$$0 \le |e| \le f \le d, \qquad (\text{but } 0 \le e \text{ if } f = d), \qquad Q_2 := 4df - c^2 > 0, \tag{2.12}$$

[7] A pair of K3 surfaces X and X' are regarded equivalent iff there is a holomorphic bijection between them.

[8] A set of generators $\{q, p\}$ of T_X with the ordering between q and q specified is called an *oriented basis* of an attractive K3 surface X, if $\mathrm{Im}[\langle \Omega_X, q\rangle / \langle \Omega_X, p\rangle] > 0$. Choosing $\mathrm{Im}(\tau) > 0$ as in (2.8), $\{q, p\}$ is indeed an oriented basis. We follow the convention of [18], and present and parametrize the intersection form of T_X as in (2.7) in this article. But it looks more common in math literatures (such as [61]) and also in [58, 59] to parametrize the intersection form in this way:

$$\begin{bmatrix} (q,q) & (q,p) \\ (p,q) & (p,p) \end{bmatrix} = \begin{bmatrix} 2a & b \\ b & 2c \end{bmatrix}. \tag{2.6}$$

Thus, $[a\ b\ c]$ here (and in [18]) correspond to $[c\ b\ a]$ in [61].

JHEP04(2014)050

where all $a, \cdots, f$ are integers. The holomorphic (2,0)-forms on the K3 surfaces $S_1 = X_{[a\ b\ c]}$ and $S_2 = X_{[d\ e\ f]}$ can then be written as

$$\Omega_{S_1} = p_1 + \tau_1 q_1, \quad \tau_1 = \frac{-b + i\sqrt{Q_1}}{2c}, \qquad \Omega_{S_2} = p_2 + \tau_2 q_2, \quad \tau_2 = \frac{-e + i\sqrt{Q_2}}{2f}\,. \tag{2.13}$$

Note that $\tau_1 \in \mathbb{Q}[\sqrt{Q_1}]$ and $\tau_2 \in \mathbb{Q}[\sqrt{Q_2}]$. Both $\mathbb{Q}[\sqrt{Q_1}]$ and $\mathbb{Q}[\sqrt{Q_2}]$ are degree 2 ($\mathcal{D} = 2$) algebraic extensions of $\mathbb{Q}$ (see refs. [58, 59]).

In physics applications, we would rather like to impose one more condition. The M2/D3-brane tadpole cancellation is equivalent to

$$\frac{1}{2}\int_Y (G \wedge G) + N_{M2/D3} = \frac{\chi(Y)}{24} = 24\,, \tag{2.14}$$

where $N_{M2/D3}$ is the number of M2/D3-branes minus anti-M2/D3-branes (that are point like) in Y. When we exclude anti M2/D3-branes on Y, $N_{M2/D3} \geq 0$, and thus not all the pairs of attractive K3 surfaces in $\mathcal{M}_{\rm cpx}(S_1) \times \mathcal{M}_{\rm cpx}(S_2)$ qualify for the landscape of flux vacua of M-theory compactified on $Y = \text{K3} \times \text{K3}$.

Aspinwall and Kallosh carried out an explicit study of which pairs of attractive K3 surfaces can satisfy the condition (2.14), within a couple of constraints that make the analysis easier [18]. In order to state one of the constraints introduced in [18], we need the following definition. Let us focus on a pair of attractive K3 surfaces S_1 and S_2. Any $G^{(4)}$ in (1.3) on $Y = S_1 \times S_2$ can be decomposed, under the Hodge structure of Y, into $[G] = [G_1] + [G_0]$, where

$$[G_0] \in \left[H^{1,1}(S_1;\mathbb{R}) \otimes H^{1,1}(S_2;\mathbb{R})\right] = S_{S_1} \otimes S_{S_2} \otimes \mathbb{R}, \tag{2.15}$$

$$[G_1] \in \left[H^{2,0}(S_1;\mathbb{C}) \otimes H^{0,2}(S_2;\mathbb{C}) + \text{h.c.}\right], \tag{2.16}$$

$$\left(\text{or} \quad \in \left[H^{2,0}(S_1;\mathbb{C}) + \text{h.c.}\right] \otimes \left[H^{2,0}(S_2;\mathbb{C}) + \text{h.c.}\right] = T_{S_1} \otimes T_{S_2} \otimes \mathbb{R}\right)\,. \tag{2.17}$$

The explicit study in ref. [18] assumes that

$$[G_0] = 0, \tag{2.18}$$

and[9] $[G_1] \neq 0$ is that of (2.16) rather than (2.17), so that $G^{(4)} = G_1$ is purely of $(2,2)$ type in the Hodge structure of $Y = S_1 \times S_2$, and the vev of $W_{\rm GVW}$ vanishes. Another assumption is to set

$$N_{M2/D3} = 0\,, \tag{2.19}$$

so that

$$\frac{1}{2}[G_1] \cdot [G_1] = 24\,. \tag{2.20}$$

Under these constraints, $[G_1]$ has to be an integral element of $T_{S_1} \otimes T_{S_2}$:

$$[G_1] \in [H^{2,0}(S_1;\mathbb{C}) \otimes H^{0,2}(S_2;\mathbb{C}) + \text{h.c.}] \cap (T_{S_1} \otimes T_{S_2}). \tag{2.21}$$

[9] If the $[G_1]$ component were to vanish, then there would be no interaction in the effective theory violating $\mathcal{N} = 2$ supersymmetry in 3+1 dimensions [15, 22]. Moduli mass terms purely from the $[G_0]$ component are consistent with $\mathcal{N} = 2$ supersymmetry.

[2 2 2]	[1 1 1]	$2 \times \gamma^{(6)}$

Table 1. Table 1 of ref. [18] is reproduced here (with minor modifications) for the convenience of the reader. Intersection forms (2.10) of T_{S_1} and T_{S_2} are simply denoted by [a b c] and [d e f] in this table. All the possible choices of $\gamma \in \mathbb{C}$ are listed; $\gamma^{(6)} := \{\pm 2i/\sqrt{3}, \pm 1 \pm i/\sqrt{3}\} = 2i/\sqrt{3} \times \{e^{2\pi i k/6} | k = 0, 1, 2, 3, 4, 5\}$, $\gamma^{(4)} := \{\pm 1, \pm i\} = \{e^{2\pi i k/4} | k = 0, 1, 2, 3\}$.

It is not always guaranteed for any pair of attractive K3 surfaces S_1 and S_2 that there can be $[G_1] \neq 0$. The Abelian group on the right hand side of (2.21) can be empty. Writing down $[G_1]$ as

$$[G_1] = \mathrm{Re}\left(\gamma \Omega_{S_1} \wedge \overline{\Omega}_{S_2}\right) \tag{2.22}$$

for some $\gamma \in \mathbb{C}$ and expanding this in the integral basis $\{p_1 \otimes p_2,\ q_1 \otimes p_2,\ p_1 \otimes q_2,\ q_1 \otimes q_2\}$ of $T_{S_1} \otimes T_{S_2}$, Aspinwall and Kallosh found that (2.21) is non-empty if and only if

$$^{\exists} m \in \mathbb{Z} \quad \text{s.t.} \quad Q_1 Q_2 = m^2 \,. \tag{2.23}$$

This implies that the two algebraic number fields $\mathbb{Q}[\sqrt{Q_1}]$ and $\mathbb{Q}[\sqrt{Q_2}]$ are the same. All the period integrals of the holomorphic (4,0) form $\Omega_Y = \Omega_{S_1} \wedge \Omega_{S_2}$ take values in the common degree-2 ($\mathcal{D} = 2$) algebraic extension field $\mathbb{Q}[\sqrt{Q_1}]$ of $\mathbb{Q}$ (cf. [17]).

Imposing the condition (2.20) on $[G_1]$ in (2.21), [18] worked out the complete list of pairs of attractive K3 surfaces where there exists a flux $G^{(4)}$ satisfying (2.18), (2.21), (2.20). The result are 13 pairs of attractive K3 surfaces [18], which are listed in table 1 along with all possible values of $\gamma \in \mathbb{C}$.

Two remarks are in order here. First note that for a supersymmetric compactification of M-theory on $Y = S_1 \times S_2$ with a four-form flux $G^{(4)} = G_1$, we could think of a compactification on $\overline{Y} = \overline{S_1} \times \overline{S}_2$ obtained by simply declaring that the holomorphic local coordinates on Y are anti-holomorphic coordinates on $\overline{Y}$, keeping the underlying real-8-dimensional manifold the same. The flux $[G_1] \in H^4(Y; \mathbb{Z})$ remains the same. This new compactification, however, should not be regarded as a vacuum physically different from the original one, only the role of the superpotential and its hermitian conjugate, and that of chiral multiplets and anti-chiral multiplets in the low-energy effective theory, are exchanged. The physics remains the same.

The transcendental lattice of the K3 surface $S_1' = \overline{S}_1$ can be regarded as $T_{S_1'} \cong \mathrm{Span}_{\mathbb{Z}}\{p_1', q_1'\} := \mathrm{Span}_{\mathbb{Z}}\{p_1, -q_1\}$, where the symmetric pairing is described by [a' b' c'] =

JHEP04(2014)050

[a -b c]. The holomorphic $(2,0)$-form is given by[10]

$$\Omega_{S_1'} = p_1' + \tau_1' q_1' := p_1 + \bar{\tau}_1 q_1 = \overline{\Omega}_{S_1}. \tag{2.24}$$

Thus, the four-form flux $G_1 = \mathrm{Re}[\gamma \Omega_{S_1} \wedge \overline{\Omega}_{S_2}]$ is rewritten in terms of $S_1' \times S_2' = \overline{S}_1 \times \overline{S}_2$ as $G_1 = \mathrm{Re}[\gamma^* \Omega_{S_1'} \wedge \overline{\Omega}_{S_2'}]$. Thus, $Y = S_1 \times S_2$ compactification with [a b c], [d e f] and γ and another compactification with [a -b c] and [d -e f] and γ^* are completely equivalent, and should not be regarded as different compactifications (or different vacua). For this reason, only one of each such pairs is shown in table 1.

Secondly, as for M-theory compactification, $Y = S_1 \times S_2$ with $G_1 = \mathrm{Re}(\gamma \Omega_{S_1} \wedge \overline{\Omega}_{S_2})$ and $Y = S_2 \times S_1$ with $G_1 = \mathrm{Re}(\gamma^* \Omega_{S_2} \wedge \overline{\Omega}_{S_1})$ should also be regarded equivalent. Thus, table 1 only shows cases where $a \geq d$, and furthermore, in cases with $a = d$, we impose $c \geq f$.

2.2 Extending the list

Before proceeding to the next section, it is worthwhile to extend the list so that the condition (2.20) is relaxed to

$$\frac{1}{2}[G_1] \cdot [G_1] \leq 24. \tag{2.25}$$

Certainly for any compactification of M-theory over $Y = S_1 \times S_2$ with a four-form flux $[G_1]$ in (2.21) satisfying the inequality above, at least we can introduce an appropriate number of M2-branes to satisfy the tadpole condition (2.14). One might even be able to find a flux $[G_0] \in (S_{S_1} \otimes S_{S_2})$ to satisfy (2.14). See section 5 for more about the case with $[G_0] \neq 0$, however.

Straightforward analysis allows us to extend table 1, so that it contains all pairs of attractive K3 surfaces S_1 and S_2 and a choice of $\gamma \in \mathbb{C}$ satisfying (2.18), (2.21) and (2.25), rather than (2.18), (2.21) and (2.20). The result of our analysis is presented in table 2.

Table 2. This table reproduces all the 13 cases with the total flux of G_1 type being 24 in [18]. The first 5/6 of this table covers the cases with $be \geq 0$; see comments at the end of section 2.1. The last 1/6 of this table is the list of cases with $(be) < 0$; this table only shows cases with $b < 0$ (so $e > 0$), in order to reduce the redundant information associated with $S_2 \longleftrightarrow S_1$ and $\gamma \longleftrightarrow \gamma^*$. See section 4.2 for the meaning of the last two columns.

Out of the 66 entries in table 2, some pairs of K3 surfaces appear more than once. In these cases, there are different possible choices of γ which give rise to different contributions to the tadpole that are less than 24. For the pairs $S_1 \times S_2 = X_{[1\ 0\ 1]} \times X_{[1\ 0\ 1]}$ and $X_{[1\ 1\ 1]} \times X_{[1\ 1\ 1]}$, all the possible values of $\gamma \in \mathbb{C}$ (and the corresponding $[G_1] \cdot [G_1]/2$ contribution to the M2/D3 tadpole) are shown in figure 1. They form a lattice within $\mathbb{C}$, and so do $[G_1]$ in (2.21) [58, 59]. In fact, one can show that that the possible values for γ form a lattice for any pair of K3 surfaces satisfying (2.23). The upper bound (2.25), however, allows only finitely many choices of $G^{(4)} = G_1$ for a given pair of attractive K3 surfaces satisfying (2.23).

JHEP04(2014)050

(a) for $X_{[1\ 0\ 1]} \times X_{[1\ 0\ 1]}$ (b) for $X_{[1\ 1\ 1]} \times X_{[1\ 1\ 1]}$

Figure 1. Possible values of $\gamma \in \mathbb{C}$ appearing in table 2 for $X_{[1\ 0\ 1]} \times X_{[1\ 0\ 1]}$ and $X_{[1\ 1\ 1]} \times X_{[1\ 1\ 1]}$, respectively. In (a), black, red, green and blue points (from inside to outside) correspond to $[G_1] \cdot [G_1]/2 = 4, 8, 16$ and 20, respectively, while in (b), the black, red, green and blue points give rise to the contributions $3, 9, 12$ and 21, respectively.

3 F-theory classification of elliptic fibrations on a K3 surface

The study reviewed in the previous section implies that a pair of K3 surfaces S_1 and S_2 corresponding to a pair of transcendental lattices $T_{S_1} = \begin{bmatrix} 2a & b \\ b & 2c \end{bmatrix}$ and $T_{S_2} = \begin{bmatrix} 2d & e \\ e & 2f \end{bmatrix}$ in tables 1 and 2 is realized in the landscape of flux compactifications of M-theory on $Y = S_1 \times S_2$ down to 2+1-dimensions, with all the 40 complex structure moduli stabilised. In order to translate this result to the landscape of F-theory compactifications to 3+1-dimensions, however, we have to impose a couple of extra conditions [18].

One of the conditions to be imposed, of course, is that either one of the K3 surfaces S_1 or S_2 admits an elliptic fibration with a section (in its vacuum complex structure), and the vev of the Kähler moduli should be such that the volume of the elliptic fibre vanishes. Let X be this elliptic fibred K3 surface,[11] and the other one of S_1 and S_2 be denoted by S;

$$Y = X \times S, \qquad \pi_X : X \to \mathbb{P}^1, \qquad \sigma : \mathbb{P}^1 \to X. \tag{3.1}$$

The authors of [18] pointed out that S_1 (resp. S_2) can be identified with a K3 surface of the form $X = T^4/\mathbb{Z}_2$, if and only if all of a, b and c (resp. d, e and f) in table 1 are even (the same rule applies also to table 2), based on a known fact on Kummer surfaces (see [61–63]). Projecting down to $T^2/\mathbb{Z}_2 \simeq \mathbb{P}^1$, we obtain an elliptic fibration with four singular fibres of type I_0^* (namely, $D_4 = \mathrm{SO}(8)$ gauge groups on 7-branes); this is the F-theory/Type IIB orientifold model in [64].

This class of F-theory vacua, which admits a type IIB orientifold interpretation without any approximation or ambiguity, is only a subset of all possible vacua of F-theory, however. In fact, it is known that any K3 surface with $\rho \geq 13$ admits an elliptic fibration with a section (Lemma 12.22 of [65]). Hence all the K3 surfaces in tables 1 and 2 admit an elliptic fibration with a section, so that they all have an interpretation in terms of F-theory if the

[11] In this article, we always imply by "elliptic fibration" that it is accompanied by a section.

JHEP04(2014)050

vev of the Kähler moduli is chosen appropriately. It should be noted, however, that there can be more than one elliptic fibration morphism $\pi_X : X \longrightarrow \mathbb{P}^1$ for a given K3 surface X, and furthermore, the type of singular fibres (type = collection of some of I_n, I_n^*, II, III, IV*, III* and II*) will in general be different for each of the fibrations. We are thus facing at least two questions:

- How do we find out the list of all possible elliptic fibrations, when the transcendental lattice $T_X \subset H^2(X;\mathbb{Z})$ of a K3 surface X is given?
- Suppose that there are two elliptic fibrations $\pi_X : X \longrightarrow \mathbb{P}^1$ and $\pi'_X : X \longrightarrow \mathbb{P}^1$ available; how do we find out whether the two fibrations correspond to the same vacuum in physics or not?

The former question is purely mathematical in nature, while the latter is a question in physics. Our companion paper [26] is dedicated to a study of the first question, while the latter question is addressed in this section. The primary conclusion in this section is (3.23) and the discussion that follows immediately after.[12] We begin by reviewing Torelli theorem for K3 surface in section 3.1, as it plays a crucial role in our discussion in section 3.2.

3.1 On the Torelli theorem for K3 surfaces

In this we discuss the relation between the moduli space of complex structures of K3 surfaces and periods of the holomorphic $(2,0)$ form. Statements of this type are generally referred to as 'Torelli theorems'. For K3 surfaces, there exist several powerful versions, which are closely related to each other, yet shed light on the subject from slightly different angles. Those Torelli theorems combined allow many questions on K3 moduli to be reformulated in terms of lattice theory. The following review on Torelli theorems for K3 surfaces is designed to serve as preparation for section 3.2. This review together with section 2 of [26] is designed to be self-contained, all the jargon and notation without definition or explanation in this section should be explained in section 2 of [26]. See also [63, 66] for a concise mathematical exposition.

We begin with defining such words as "(moduli space of) marked K3 surface" and "period domain", and proceed to explain the period map. A *marked K3 surface* is a K3 surface X for which we have fixed a set of generators for $H^2(X;\mathbb{Z})$, i.e. we consider a pair (X,φ) which consists of the K3 surface X and an isometry between lattices $\varphi : H_2(X;\mathbb{Z}) \longrightarrow \Lambda_{\rm K3}$, where

$$\Lambda_{\rm K3} = U \oplus U \oplus U \oplus E_8 \oplus E_8 \,. \tag{3.2}$$

The map φ is called the *marking*. Note that we use conventions in which the A–D–E lattices have a negative definite inner product, as is natural in the present context.

Two marked K3 surfaces (X,φ) and (X',φ') are said to be *equivalent*, if and only if there is an isomorphism $f : X \to X'$ such that $\varphi' \cdot f_* = \varphi$ as an isometry from $H_2(X;\mathbb{Z})$

[12] It is an option to skip this section and proceed to the next section, if one is happy to accept this statement.

JHEP04(2014)050

to $\Lambda_{\rm K3}$. Each point of the *moduli space of marked K3 surface* N corresponds to such an equivalence class of marked K3 surfaces.

The *period domain* D, on the other hand, is a subspace of $\mathbb{P}[\Lambda_{\rm K3}\otimes\mathbb{C}]$ given by

$$D := \{[\omega]\in\mathbb{P}[\Lambda_{\rm K3}\otimes\mathbb{C}] \mid \omega\cdot\omega = 0,\ \omega\cdot\overline{\omega} > 0\ \}\subset\mathbb{P}[\Lambda_{\rm K3}\otimes\mathbb{C}]\,. \tag{3.3}$$

The global structure of D is given by

$$D\cong O(\Lambda_{\rm K3}\otimes\mathbb{R})/{\rm SO}(2)\times O(1,19) = {\rm Gr}^{\rm po}(2;\Lambda_{\rm K3}\otimes\mathbb{R})\,, \tag{3.4}$$

where the superscript "po" stands for "positive and oriented", in the sense that we consider the Grassmannian of oriented 2-dimensional subspaces in $\Lambda_{\rm K3}\otimes\mathbb{R}$ with signature $(2,0)$.[13]

Using the holomorphic $(2,0)$-form $\Omega_X\in H_2(X;\mathbb{C})$ and the intersection form on $H_2(X;\mathbb{C})$, we may map a point in the moduli space of marked K3 surface N to a point in the period domain D:

$$\mathcal{P}: N\ni[(X,\varphi)]\longmapsto\varphi([\Omega_X])\in D\subset\mathbb{P}[\Lambda_{\rm K3}\otimes\mathbb{C}]\,. \tag{3.5}$$

$\mathcal{P}$ is called the *period map*. Here, $[\Omega_X]$ stands for both the complex line $\mathbb{C}\Omega_X\subset H_2(X;\mathbb{C})$ as well as its image in $\mathbb{P}[H_2(X;\mathbb{C})]$; the same notation has already been used in (3.3).

The classic **local Torelli theorem** for K3 surface states that the period map is locally an isomorphism between N and D. For any point in N and its image under the period map in D, we can always take an appropriate open set in N and D so that the period map becomes an isomorphism between the two open sets. Thus, locally in the moduli space(s), K3 surfaces are uniquely determined by their periods.

In the following, we will turn to global aspects of the moduli spaces N and D, and the period map $\mathcal{P}$ between them. While it turns out that complex deformations can be used to introduce local coordinates on N, and to give it the structure of a complex manifold, the moduli space N fails to be Hausdorff. The way the period maps glue globally is expressed by the

> **Global Torelli Theorem, version 1** (see e.g. [66]): the moduli space of marked K3 surfaces N consists of two connected components N^o and $N^{o'}$, and the period map $\mathcal{P}$ maps each one of them surjectively, and also generically injectively to the period domain D.

To elaborate more on this, note first that the group of all the isometries of the lattice $\Lambda_{\rm K3}$ — ${\rm Isom}(\Lambda_{\rm K3})$ — acts naturally on D (from the left), and it also acts on N through the marking; $g\in{\rm Isom}(\Lambda_{\rm K3})$ maps $[(X,\varphi)]\in N$ to $[(X,g\cdot\varphi)]\in N$. The action of this symmetry group on N and D commutes with the period map $\mathcal{P}: N\longrightarrow D$. This isometry group has a structure ${\rm Isom}(\Lambda_{\rm K3})\cong\{\pm{\rm id.}\}\times{\rm Isom}^+(\Lambda_{\rm K3})$. The ${\rm Isom}^+(\Lambda_{\rm K3})$ subgroup is such that the orientation of the 3-dimensional positive definite subspace of $\Lambda_{\rm K3}\otimes\mathbb{R}$ is preserved.

[13] By forgetting the orientation, a twofold cover $D = {\rm Gr}^{\rm po}(2;\Lambda_{\rm K3}\otimes\mathbb{R})\to{\rm Gr}^{\rm p}(2;\Lambda_{\rm K3}\otimes\mathbb{R})$ can be constructed; ${\rm Gr}^{\rm p}(2;\Lambda_{\rm K3}\otimes\mathbb{R})\cong O(\Lambda_{\rm K3}\otimes\mathbb{R})/O(2)\times O(1,19)$.

JHEP04(2014)050

A pair of elements $[(X,\varphi)]$ and $[(X,-\varphi)]$ are different points in N because automorphisms of X cannot induce $(-\mathrm{id.})$ on $H_2(X;\mathbb{C})$. The period map $\mathcal{P}: N \longrightarrow D$ sends these two elements to the same point in D, $[\varphi(\Omega_X)] = [-\varphi(\Omega_X)] \in \mathbb{P}[\Lambda_{\mathrm{K3}} \otimes \mathbb{C}]$. In the Torelli theorem above, such a pair of points in N corresponds to two inverse images[14] of a given point in D; one is in N^o, and the other is in the other connected component N'^o. The action of $(-\mathrm{id.}) \in \mathrm{Isom}(\Lambda_{\mathrm{K3}})$ maps these two elements in N to each other, and hence the subgroup $\{\pm\mathrm{id.}\}$ of $\mathrm{Isom}(\Lambda_{\mathrm{K3}})$ acts trivially on D, while it exchanges the two connected components of N.

Next we discuss the classical form of the global Torelli theorem. First, the homomorphism $\mathrm{Aut}(X) \longrightarrow \mathrm{Isom}(H_2(X;\mathbb{Z}))$ is injective (Prop. 2 of section 2 in [62]), where $\mathrm{Aut}(X)$ is the group of automorphisms of a K3 surface X, and $\mathrm{Isom}(H_2(X;\mathbb{Z}))$ is the isometry group of $H_2(X;\mathbb{Z})$ endowed with a symmetric pairing from intersection number. Note that this means that there cannot be any non-trivial automorphism which acts as the identity on $H_2(X;\mathbb{Z})$. Furthermore,

> **Global Torelli Theorem, version 2**: (Prop. of section 7 and Thm. 1 of section 6 in [62]) the image of $\mathrm{Aut}(X)$ under the injective homomorphism is $\mathrm{Isom}(H_2(X;\mathbb{Z}))^{(\text{Hodge eff})}$, the group of isometries that are both Hodge and effective. This means that for a given $\varphi \in \mathrm{Isom}(H_2(X;\mathbb{Z}))^{(\text{Hodge eff})}$, there exists a unique automorphism $f \in \mathrm{Aut}(X)$ such that $\varphi = f_*$. Furthermore, the subgroup $\mathrm{Isom}(H_2(X;\mathbb{Z}))^{(\text{Hodge eff.})} \cong \mathrm{Aut}(X)$ sits inside the group of Hodge isometries, which have the form
>
> $$\mathrm{Isom}\,(H_2(X;\mathbb{Z}))^{(\text{Hodge})} \cong \{\pm\mathrm{id.}\} \times \left[W^{(2)}(S_X) \rtimes \mathrm{Aut}(X)\right]. \qquad (3.6)$$
>
> For K3 surfaces X and X' there is an isomorphism of surfaces $f: X \longrightarrow X'$ if and only if there is a Hodge and effective isometry $\varphi: H_2(X;\mathbb{Z}) \longrightarrow H_2(X';\mathbb{Z})$. In this case, $f_* = \varphi$.

See the mathematics literature (such as [62]) or [26] for the definition of Hodge and effective isometries. $W^{(2)}(S_X)$ is the group generated by reflections associated with algebraic curves of self-intersection (-2) in the Neron-Severi lattice S_X. Section 2.2 of [26] explains the structure of the group (3.6) in more detail. Another version of the theorem, which is equivalent to version 2, is also useful:

> **Global Torelli Theorem, version 3** (e.g., Chapt. 10 of [66]): For a pair of K3 surface X and X', there is an automorphism $f: X \longrightarrow X'$, if and only if there is a Hodge isometry $\varphi: H_2(X;\mathbb{Z}) \longrightarrow H_2(X';\mathbb{Z})$. Furthermore, in this case, $\varphi^{-1}\cdot f_* \in \mathrm{Isom}(H_2(X;\mathbb{Z}))^{(\text{Hodge})}$. When it is known that φ maps Pos^+_X to $\mathrm{Pos}^+_{X'}$, then $\varphi^{-1}\cdot f_* \in \mathrm{Isom}^+(H_2(X;\mathbb{Z}))^{(\text{Hodge})}$, the index 2 subgroup of $\mathrm{Isom}(H_2(X;\mathbb{Z}))^{(\text{Hodge})}$ obtained by dropping $\{\pm\mathrm{id.}\}$ from (3.6).

[14] In this version of the Torelli theorem, we included a statement that there are just *two* and not more than two connected components in the moduli space of marked K3 surfaces N. This statement comes from the fact that the full $\mathrm{Isom}^+(H_2(X;\mathbb{Z}))$ subgroup of $\mathrm{Isom}(H_2(X;\mathbb{Z}))$ is realized as the monodromy group on $H_2(X;\mathbb{Z})$ for a given K3 surface X through continuous complex structure deformations [67–69]. See [66] Chapt.10 for more detailed list of references.

JHEP04(2014)050

Having seen these three versions of the Torelli theorem, we may now use the perspective of version 3 of the global Torelli theorem to elucidate the meaning of the expression 'generically injective' used in version 1. Suppose that the period map $\mathcal{P} : N^o \longrightarrow D$ restricted to one of the two connected components maps two points $[(X, \varphi)]$ and $[(X', \varphi')]$ in N^o to one and the same point $[\omega] \in D$. That is, both $[(X, \varphi)]$ and $[(X', \varphi')]$ are contained in $\mathcal{P}^{-1}([\omega]) \cap N^o$. It then follows from version 3 of the global Torelli theorem that there exists an isomorphism of surfaces $f : X \longrightarrow X'$, because $\varphi'^{-1} \cdot \varphi : H_2(X; \mathbb{Z}) \longrightarrow \Lambda_{\mathrm{K3}} \longrightarrow H_2(X'; \mathbb{Z})$ is a Hodge isometry. This means that a marked K3 surface $(X, \varphi' \cdot f)$ is equivalent to the marked K3 surface $[(X', \varphi')]$ in N^o. Thus, if $\mathcal{P} : [(X_0, \varphi_0)] \longmapsto [\omega_0] = \varphi_0([\Omega_X])$, then all elements of $\mathcal{P}^{-1}([\omega_0]) \cap N^o$ can be written in the form of $[(X_0, \varphi)]$ with some marking φ.

Deviation from the injectiveness of the period map $\mathcal{P}|_{N^o}$ therefore corresponds to the variety of marking φ allowed for $\mathcal{P}^{-1}([\omega_0]) \cap N^o$. The remaining variety for φ can also be read out from the version 3 of the global Torelli theorem. Since $[(X, \varphi)]$ belongs to the same connected component as $[(X, \varphi_0)]$, $\varphi_0^{-1} \cdot \varphi \in W^{(2)}(S_X) \rtimes \mathrm{Aut}(X)$, and conversely, any φ satisfying this condition gives rise to $[(X, \varphi)] \in \mathcal{P}^{-1}([\omega_0]) \cap N^o$. Therefore, reminding ourselves of the definition of the equivalence relation between (X, φ) and (X, φ_0) in the moduli space N, we see that

$$\mathcal{P}^{-1}([\omega_0]) \cap N^o = \left\{ [(X, \varphi)] \;\middle|\; \varphi \in \varphi_0 \cdot \left[W^{(2)}(S_X) \rtimes \mathrm{Aut}(X) \right] / \mathrm{Aut}(X) \right\}. \tag{3.7}$$

For a general (non algebraic) complex K3 surface X, the Neron-Severi lattice S_X is trivial, $\rho_X = 0$, so that $W^{(2)}(S_X)$ is the trivial group. In this case, there is only one element $[(X, \varphi)] \in N^o$ that is mapped to a given point $[\omega] \in D$, that is, the period map $\mathcal{P} : N^o \longrightarrow D$ is injective there. Since only a measure-zero subspace of N is occupied by algebraic K3 surfaces, the period map is indeed generically injective. For an algebraic K3 surface X, however, the group $W^{(2)}(S_X)$ can be non-trivial, and there can be multiple points in the inverse image of the period map, as in (3.7). Since our interest in this article is primarily in K3 surfaces X with large Picard number, $\rho_X = \mathrm{rank}(S_X)$, this non-injective behaviour of the period map is of particular importance.

Although we have seen above that any two points in N that are mapped to the same point in D are represented by a common K3 surface X, there are more points in N that share the same K3 surface X. To see this, remember that the $\mathrm{Isom}^+(\Lambda_{\mathrm{K3}})$ subgroup of $\mathrm{Isom}(\Lambda_{\mathrm{K3}})$ acts on individual connected components of N, that is, N^o and $N^{o'}$, as well as on the period domain D. If there is an isometry $g \in \mathrm{Isom}^+(\Lambda_{\mathrm{K3}})$ mapping $[\omega] \in D$ to $[\omega'] \in D$, then it also maps $\mathcal{P}^{-1}([\omega]) \cap N^o$ to $\mathcal{P}^{-1}([\omega']) \cap N^o$. For any element in these inverse images, $[(X, \varphi)] \in \mathcal{P}^{-1}([\omega]) \cap N^o$ and $[(X', \varphi')] \in \mathcal{P}^{-1}([\omega']) \cap N^o$, $\varphi'^{-1} \cdot g \cdot \varphi : H_2(X; \mathbb{Z}) \longrightarrow H_2(X'; \mathbb{Z})$ is a Hodge isometry, and hence the version 3 of the global Torelli theorem implies that there is an isomorphism of surfaces $f : X \longrightarrow X'$. Thus, for all the points $[\omega] \in D$ in a given orbit of $\mathrm{Isom}(\Lambda_{\mathrm{K3}})$, all the points in N mapped to this orbit can be represented by a common K3 surface X and some markings. Conversely, if two points $[X, \varphi]$ and $[(X, \varphi')]$ in N share the same K3 surface, then $\varphi' \cdot \varphi^{-1}$ is an isometry of Λ_{K3} mapping the image of $[(X, \varphi)]$ to that of $[(X, \varphi')]$. Therefore, the $\mathrm{Isom}(\Lambda_{\mathrm{K3}})$-orbit decomposition of the period domain,

JHEP04(2014)050

$\mathrm{Isom}^+(\Lambda_{\mathrm{K3}})\backslash D$ is equivalent to the classification of K3 surfaces modulo isomorphism of surfaces.

Finally, let us take a closer look at how the $\mathrm{Isom}(\Lambda_{\mathrm{K3}})$ symmetry group acts on the moduli space N or N^o. Its action on D is quite simple, but its action on N^o has a more interesting structure, and we will need that in section 3.2. When an element $g \in \mathrm{Isom}^+(\Lambda_{\mathrm{K3}})$ maps $[\omega] \in D$ to another element $[\omega'] \neq [\omega]$, the fibres of those two points under the period map can be described by $\{[(X,\varphi)] \mid \varphi \in \varphi_0 \cdot [W^{(2)}(S_X) \rtimes \mathrm{Aut}(X)]/\mathrm{Aut}(X)\}$ and $\{[(X,\varphi')] \mid \varphi' \in \varphi_0' \cdot [W^{(2)}(S_X) \rtimes \mathrm{Aut}(X)]/\mathrm{Aut}(X)\}$ for some φ_0 and φ_0', respectively.[15] The action of g establishes a one-to-one correspondence between the two fibres by setting $\varphi' = g \cdot \varphi$.

The stabilizer subgroup of $[\omega] \in D$ in $\mathrm{Isom}^+(\Lambda_{\mathrm{K3}})$ is

$$G_{[\omega]} = \varphi_0 \cdot \left[W^{(2)}(S_X) \rtimes \mathrm{Aut}(X)\right] \cdot \varphi_0^{-1} \subset \mathrm{Isom}^+(\Lambda_{\mathrm{K3}}). \tag{3.8}$$

This stabiliser group acts naturally on the inverse image of $[\omega]$, given in (3.7).

3.2 When are two elliptic fibrations considered "different" in F-theory?

In the description of complex structure moduli of K3 surfaces, one can think of several different moduli spaces in mathematics, such as N (or N^o) (the moduli space of marked K3 surfaces), D (the period domain) and $\mathrm{Isom}^+(\Lambda_{\mathrm{K3}})\backslash D$ (the moduli space of K3 surfaces modulo automorphism). These different moduli spaces contain different information and are mutually related in the way we have reviewed above. When we refer to "the moduli space" in string theory applications, however, we want it to parametrize vacua (hopefully with less redundancy in the parametrization, and at least with information on the redundancy), and use it as the target space of a non-linear sigma model to describe light degrees of freedom.

It is considered that, in M-theory compactification on $Y = S_1 \times S_2$ with both S_1 and S_2 being K3 surfaces, the moduli space (in the absence of four-form flux) is given by[16]

$$\left[\mathrm{Isom}^+(\Lambda_{\mathrm{K3}}^{(S_1)}) \times \mathrm{Isom}^+(\Lambda_{\mathrm{K3}}^{(S_2)})\right] \backslash \left[D^{(S_1)} \times D^{(S_2)}\right] . \tag{3.9}$$

It makes perfect sense to take a quotient by the symmetry group $\mathrm{Isom}^+(\Lambda_{\mathrm{K3}})$, because two marked K3 surfaces $[(X,\varphi)]$ and $[(X,\varphi')]$ in N^o which differ only in the markings φ and φ' should not be considered as different compactifications in 11-dimensional supergravity.[17]

[15] Here, $\varphi_0' \notin \varphi_0 \cdot [W^{(2)}(S_X) \rtimes \mathrm{Aut}(X)]$.

[16] We postpone a slightly more refined argument for the choice of the quotient group to section 4.2.2, for M-theory moduli space as well as for F-theory. The essence of the argument in this section remains valid after section 4.2.2.

[17] Homogeneous coordinates can be introduced to the period domain D by taking a basis $\{\Sigma_I\}_{I=1,\cdots,22}$ in the lattice Λ_{K3}. The period integrals $\Pi_I := \int_{\Sigma_I} \omega$ can be used as the coordinates. With these coordinates, the Kähler potential (obtained by dimensional reduction) is given by

$$K \propto -\ln\left[\int_Y (\Omega_{S_1} \wedge \Omega_{S_2}) \wedge (\overline{\Omega}_{S_1} \wedge \overline{\Omega}_{S_2})\right] = -\ln\left[\Pi_I^{(S_1)} C^{IJ} \overline{\Pi}_J^{(S_1)}\right] - \ln\left[\Pi_I^{(S_2)} C^{IJ} \overline{\Pi}_J^{(S_2)}\right] , \tag{3.10}$$

where C^{IJ} is the inverse of the intersection form of Λ_{K3} in the basis $\{\Sigma_I\}_{I=1,\cdots,22}$. The action of the $\mathrm{Isom}^+(\Lambda_{\mathrm{K3}}^{(S_1)}) \times \mathrm{Isom}^+(\Lambda_{\mathrm{K3}}^{(S_2)})$ group on the $\Pi_I^{(S_{1,2})}$ leaves the Kähler potential unchanged, because it preserves the intersection form.

JHEP04(2014)050

Since F-theory compactification on an elliptic-fibred Calabi-Yau fourfold is regarded as a special case of M-theory compactification on a Calabi-Yau fourfold, this moduli space can be regarded as a reliable place to start for F-theory as well.

The moduli space of F-theory compactification on a K3 surface X (where we require that there is an elliptic fibration $\pi_X : X \longrightarrow \mathbb{P}^1$ and a section $\sigma : \mathbb{P}^1 \longrightarrow X$) without any flux is given by

$$\mathcal{M}^{\rm cpx}_{F;\rm K3} := \left[\mathrm{Isom}^+(\Lambda_{\rm K3})\right] \setminus \left\{(\phi_U, [\omega]) \mid [\omega]|_{\phi_U(U)} = 0\right\} / \left\{\pm \mathrm{id}._U\right\} , \tag{3.11}$$

where $[\omega] \in D$ as before, and $\phi_U : U \hookrightarrow \Lambda_{\rm K3}$ is an embedding of the hyperbolic plane lattice U. It is a popular way to make sure that there is an elliptic fibration by specifying a sublattice (which is isomorphic to U) generated by algebraic cycles corresponding to the elliptic fibre and the section (e.g. [26, 70]). A remaining subtlety can arise in the choice of the quotient group. The group $\mathrm{Isom}^+(\Lambda_{\rm K3})$ acts on D and embeddings of U (while preserving $[\omega]|_{\phi_U(U)} = 0$), while $\{\pm \mathrm{id}._U\}$ is a subgroup of $\mathrm{Isom}(U) \cong \mathbb{Z}_2 \times \mathbb{Z}_2$ (see section 2 of [26]), and acts on embeddings $\phi_U : U \hookrightarrow \Lambda_{\rm K3}$ from the right by changing ϕ_U to $\pm\phi_U$. We will see shortly that this is the right choice of the quotient group. Once this statement is accepted, then it wouldn't be difficult to accept the following: the moduli space of F-theory compactification on $Y = X \times S$ (where X has an elliptic fibration as before) is given by

$$\mathcal{M}^{\rm cpx}_{F;\rm K3} \times \left(\mathrm{Isom}^+(\Lambda^{(S)}_{\rm K3}) \backslash D^{(S)}\right) . \tag{3.12}$$

Now, in order to justify the statement (3.11), we need to understand the space $\mathcal{M}^{\rm cpx}_{F;\rm K3}$ better. It is often a good strategy in understanding a space M to construct a map $f : M \longrightarrow B$ to some simple space B, and study how the "fibres" $f^{-1}(b) \subset M$ change with $b \in B$. First consider a projection

$$\mathrm{fgt}_{[\omega]} : \mathcal{M}^{\rm cpx}_{F;\rm K3} \longrightarrow \mathrm{Isom}^+(\Lambda_{\rm K3}) \backslash \left\{\phi_U : U \hookrightarrow \Lambda_{\rm K3}\right\} / \left\{\pm \mathrm{id}._U\right\} \tag{3.13}$$

by throwing away the information of $[\omega]$ from $\mathcal{M}^{\rm cpx}_{F;\rm K3}$. The base of this forgetful map, "B", consists of only one point: due to the uniqueness (modulo isometry) of even unimodular lattices of signature $(n, n+16)$, there always exists an isometry $\varphi \in \mathrm{Isom}^+(\Lambda_{\rm K3})$ such that either $\phi'_U = \varphi \cdot \phi_U$ or $-\phi'_U = \varphi \cdot \phi_U$ holds for any two embeddings ϕ_U and ϕ'_U of the hyperbolic plane lattice U. Thus, the whole set $\mathcal{M}^{\rm cpx}_{F;\rm K3}$ can be studied by looking at the fibre over just one point in the base; that is, we can take an arbitrary embedding $\phi_{U0} : U \hookrightarrow \Lambda_{\rm K3}$, and just study the fibre $\mathrm{fgt}^{-1}_{[\omega]}([\phi_{U0}])$. The fibre over this one point is

$$\mathrm{Isom}(U^{\oplus 2} \oplus E_8^{\oplus 2}) \backslash \left\{[\omega] \in D_{U^\perp}\right\} , \tag{3.14}$$

$$D_{U^\perp} := \left\{[\omega] \in \mathbb{P}[(\phi_{U0}(U))^\perp \subset \Lambda_{\rm K3}] \mid \omega \cdot \omega = 0,\ \omega \cdot \overline{\omega} > 0\right\} . \tag{3.15}$$

Therefore, the set $\mathcal{M}^{\rm cpx}_{F;\rm K3}$ is equivalent to (3.14), the global structure of which is

$$\mathrm{Isom}(U^{\oplus 2} \oplus E_8^{\oplus 2}) \backslash \mathrm{Gr}^{\rm po}(2; (U^{\oplus 2} \oplus E_8^{\oplus 2}) \otimes \mathbb{R}) \cong \mathrm{Isom}(U^{\oplus 2} \oplus E_8^{\oplus 2}) \backslash \mathrm{O}(2, 18; \mathbb{R}) / \mathrm{SO}(2) \times \mathrm{O}(18) . \tag{3.16}$$

JHEP04(2014)050

This is a double cover over what we know as the moduli space of heterotic string compactifications on T^2 [71] (see e.g., also section 5 of [72]),

$$\mathrm{Isom}(U^{\oplus 2}\oplus E_8^{\oplus 2})\backslash \mathrm{Gr}^{\mathrm{p}}(2;(U^{\oplus 2}\oplus E_8^{\oplus 2})\otimes\mathbb{R}) \cong \mathrm{Isom}(U^{\oplus 2}\oplus E_8^{\oplus 2})\backslash \mathrm{O}(2,18;\mathbb{R})/\mathrm{O}(2)\times\mathrm{O}(18). \tag{3.17}$$

This argument almost proves[18] that we can take $\mathcal{M}^{\mathrm{cpx}}_{F;\mathrm{K3}}$ in (3.11) as the classification scheme of F-theory vacua when an elliptic fibred K3 surface is involved as part of the compactification data.

We understand that the remaining subtlety — double cover — corresponds, in F-theory language, to a pair of (elliptic fibred) K3 surfaces X and $X' = \overline{X}$ where $H^{2,0}(X;\mathbb{C})$ and $H^{0,2}(X;\mathbb{C})$ in the Hodge decomposition of $H^2(X;\mathbb{C})$ are identified with $H^{0,2}(X';\mathbb{C})$ and $H^{2,0}(X';\mathbb{C})$. X and X' are a mutually complex conjugate pair. The difference between them is only in declaring a complex coordinate as holomorphic or anti-holomorphic, and that should not make a difference in physics in 7+1-dimensions. Thus, even in F-theory, the moduli space of K3 compactification to 7+1-dimensions should be (3.17), rather than (3.16). As we proceed to consider compactifications of F-theory on $Y = X \times S$ along with a four-form flux on Y, it *does* make a difference in low-energy physics in 3+1-dimensions to take complex conjugation of X, while keeping the complex structure of S and the flux. We therefore take (3.12) as the classification scheme for K3 × K3 compactification of F-theory for now; the $\mathbb{Z}_2$ quotient associated with unphysical holomorphic-anti-holomorphic distinction will be implemented in section 4.2 after introducing fluxes.

Let us now start from $\mathcal{M}^{\mathrm{cpx}}_{F;\mathrm{K3}}$ in (3.11) again, and derive a useful way to look at it in order to address the second one of the two questions raised at the beginning of this section. Consider a projection

$$\mathrm{fgt}_{\phi_U} : \mathcal{M}^{\mathrm{cpx}}_{F;\mathrm{K3}} \longrightarrow \mathrm{Isom}^+(\Lambda_{\mathrm{K3}})\backslash D\,, \tag{3.18}$$

This time, we throw away the information on the embedding ϕ_U from $\mathcal{M}^{\mathrm{cpx}}_{F;\mathrm{K3}}$. As we have seen in section 3.1, the "base" space of this projection, $\mathrm{Isom}^+(\Lambda_{\mathrm{K3}})\backslash D$, corresponds to the classification of K3 surfaces modulo surface isomorphism. Thus, by studying the "fibre" of this projection, we can find the variety of F-theory vacua that (the surface-isomorphism class of) a K3 surface admits.

We begin this study by looking at the fibration structure of the following projection map instead:

$$\mathrm{fgt}_{\phi_U} : \left\{(\phi_U,[\omega])\,|\,[\omega]\in D,\ [\omega]|_{\phi_U(U)}=0\right\}/\{\pm\mathrm{id}_U\} \longrightarrow \{[\omega]\,|\,[\omega]\in D\} = D\,. \tag{3.19}$$

Before and after the projection, we are not taking a quotient by the symmetry group $\mathrm{Isom}^+(\Lambda_{\mathrm{K3}})$ action here, which makes the problem easier to get started. For a given $[\omega]\in D$, and for any ϕ_U satisfying the condition $[\omega]|_{\phi_U(U)}=0$, ϕ_U embeds the hyperbolic plane lattice U into $S_{[\omega]} := \left[[\omega]^\perp \subset \Lambda_{\mathrm{K3}}\right]$. That is,

$$\mathrm{fgt}^{-1}_{\phi_U}([\omega]) = \left\{\phi_U : U \hookrightarrow S_{[\omega]}\right\}/\{\pm\mathrm{id}_U\}\,. \tag{3.20}$$

[18] Without microscopic foundation of F-theory, it is hard to make any precise statement about F-theory physics directly. Here, this problem is overcome by relying on heterotic-F-theory duality.

JHEP04(2014)050

This means geometrically that for any one of the inverse images $[(X_{[\omega]}, \varphi_{[\omega]})] \in \mathcal{P}^{-1}([\omega]) \cap N^o$ under the period map, an embedding of the hyperbolic plane lattice into the Neron-Severi lattice of the K3 surface $X_{[\omega]}$, $S_{X_{[\omega]}}$, is defined:

$$\varphi_{[\omega]}^{-1} \cdot \phi_U : \ U \hookrightarrow S_{X_{[\omega]}} \subset H^2(X_{[\omega]}; \mathbb{Z}) \,. \tag{3.21}$$

The inverse image $\mathcal{P}^{-1}([\omega]) \cap N^o$ of any given element $[\omega] \in D$ is described in (3.7); we can choose an appropriate φ in (3.7) so that either $\varphi^{-1} \cdot \phi_U$ or $\varphi^{-1} \cdot (-\phi_U)$ defines a *canonical embedding* of hyperbolic plane lattice into $S_{X_{[\omega]}}$. This is a sufficient condition to construct an elliptic fibration $\pi_X : X \longrightarrow \mathbb{P}^1$ along with a zero section $\sigma : \mathbb{P}^1 \longrightarrow X$, see section 3.1 of [26] for a more detailed explanation. Each element ϕ_U in $\mathrm{fgt}_{\phi_U}^{-1}([\omega])$ in (3.20) therefore defines an elliptic fibration on X.

Let us now go back to the study of the fibre of the projection (3.18), bringing back the quotient by $\mathrm{Isom}^+(\Lambda_{\mathrm{K3}})$. First of all, when an element $g \in \mathrm{Isom}^+(\Lambda_{\mathrm{K3}})$ maps $[\omega] \in D$ to $[\omega'] := g \cdot [\omega] \neq [\omega]$, taking a quotient does not change the fibre of the projection map. It only establishes a one-to-one identification between the elements in the fibre $\mathrm{fgt}_{\phi_U}^{-1}([\omega])$ and $\mathrm{fgt}_{\phi_U}^{-1}([\omega'])$. The stabilizer subgroup $G_{[\omega]}$ of $\mathrm{Isom}^+(\Lambda_{\mathrm{K3}})$ for $[\omega] \in D$, however, can be non-trivial, as we have seen in (3.8). We have to take a quotient of (3.20) by the stabilizer group $G_{[\omega]}$ in order to obtain the fibre of the projection map in (3.18) at $[[\omega]] \in \mathrm{Isom}^+(\Lambda_{\mathrm{K3}}) \backslash D$. Therefore, we conclude that

$$\begin{aligned}
\mathrm{fgt}_{\phi_U}^{-1}([[\omega]]) &= \left[W^{(2)}(S_{[\omega]}) \rtimes \varphi_0(\mathrm{Aut}(X_{[\omega]}))\right] \backslash \left\{\phi_U : U \hookrightarrow S_{[\omega]} \subset \Lambda_{\mathrm{K3}}\right\} / \{\pm \mathrm{id}_U\} \qquad (3.22) \\
&= \left[W^{(2)}(S_{X_{[\omega]}}) \rtimes \mathrm{Aut}(X_{[\omega]})\right] \backslash \left\{\varphi_0^{-1} \cdot \phi_U : U \hookrightarrow S_{X_{[\omega]}} \subset H^2(X_{[\omega]}; \mathbb{Z})\right\} / \{\pm \mathrm{id}_U\} \\
&= \left[W^{(2)}(S_{X_{[\omega]}}) \rtimes \mathrm{Isom}(S_{X_{[\omega]}})^{(\text{Amp Hodge})}\right] \backslash \left\{\varphi_0^{-1} \cdot \phi_U : U \hookrightarrow S_{X_{[\omega]}}\right\} / \{\pm \mathrm{id}_U\} \\
&= \mathcal{J}_1(X_{[\omega]}) \,. \qquad (3.23)
\end{aligned}$$

As we have explained in section 3 of [26], this $\mathcal{J}_1(X_{[\omega]})$ corresponds to the classification of elliptic fibrations (π_X, σ) for a K3 surface X ($\pi_X : X \longrightarrow \mathbb{P}^1$ along with $\sigma : \mathbb{P}^1 \longrightarrow X$ so that $\pi_X \cdot \sigma = \mathrm{id}_{\mathbb{P}^1}$) modulo $\mathrm{Aut}(X) \times \mathrm{Aut}(\mathbb{P}^1) = \mathrm{Aut}(X) \times PGL(2; \mathbb{C})$. Therefore, the projection map fgt_{ϕ_U} in (3.18) enables us to apprehend the moduli space (vacuum classification scheme) of F-theory compactifications on K3 surface $\mathcal{M}_{F;\mathrm{K3}}^{\mathrm{cpx}}$ as a fibration over $\mathrm{Isom}^+(\Lambda_{\mathrm{K3}}) \backslash D$ (i.e., complex structure moduli space of K3 surface modulo surface isomorphism), with the fibre given by the $\mathcal{J}_1$ classification (i.e., modulo automorphism) of elliptic fibrations.

4 A miniature landscape: F-theory on K3 × K3 with $G_0 = 0$

4.1 $\mathcal{J}_1(X)$ and $\mathcal{J}_2(X)$ classification

When we classify low-energy effective theories, we normally group together theories with the same gauge groups and matter representations first, and then pay attention to the values of various coupling constants. Although two elliptic fibrations (π_X, σ) and (π'_X, σ') for a K3 surface X are not regarded as the same vacuum (or the same low-energy effective

JHEP04(2014)050

theory) in the absence of an appropriate automorphism in $\mathrm{Aut}(X)\times PGL(2;\mathbb{C})$, they might still have the same gauge groups and matter presentations.

Corresponding to the coarse classification in terms of gauge groups and matter representations is the $\mathcal{J}_2(X)$ classification of elliptic fibrations on a K3 surface X. This is close to the classification of singular fibre types, but slightly different and more suited for physicists' needs. As reviewed in detail in [26],

$$\begin{aligned}\mathcal{J}_1(X) &= \left[W^{(2)}(S_X)\rtimes \mathrm{Isom}(S_X)^{(\text{Amp Hodge})}\right]\setminus\{U\hookrightarrow S_X\}/\{\pm\mathrm{id}_U\}\,,\\ \mathcal{J}_2(X) &= \left[W^{(2)}(S_X)\rtimes \mathrm{Isom}(S_X)^{(\text{Amp})}\right]\setminus\{U\hookrightarrow S_X\}/\{\pm\mathrm{id}_U\}\,.\end{aligned}\tag{4.1}$$

Here, the group $\mathrm{Isom}(S_X)^{(\text{Amp Hodge})}$ is a subgroup of $\mathrm{Isom}(S_X)^{(\text{Amp})}$, and hence the $\mathcal{J}_2(X)$ classification is obviously more coarse than the $\mathcal{J}_1(X)$ classification.[19] The $\mathcal{J}_2(X)$ classification is equivalent to the classification of frame lattices of elliptic fibrations modulo isometry. For an elliptic fibration $\pi : X \longrightarrow \mathbb{P}^1$ with a fibre class $[F]\in S_X$, the frame lattice is given by

$$W_{\text{frame}} = \left[[F]^\perp\subset S_X\right]/\langle[F]\rangle\,.\tag{4.2}$$

Readers are referred to [26] for more mathematical aspects of this discussion. The frame lattice W_{frame} (modulo isometry) contains all the information of 7-brane gauge groups and representations of charged matters. Individual equivalence classes in $\mathcal{J}_2(X)$ are referred to as *types*, and those in $\mathcal{J}_1(X)$ as *isomorphism classes*.

There is a systematic procedure to study the $\mathcal{J}_2(X)$ classification for a given K3 surface X with large Picard number ρ_X (see [73] or section 4 of [26]). The $\mathcal{J}_2(X)$ classification of elliptic fibrations has already been studied for some K3 surfaces (i.e., for some particular choices of complex structures of K3 surface). For most generic Kummer surfaces[20] $X = \mathrm{Km}(A)$, for example, there are 25 different types in the $\mathcal{J}_2(X)$ classification [74]. Roughly speaking, this means that the compactifications of F-theory on $Y = X\times S$ with $X = \mathrm{Km}(A)$ admits 25 different choices of 7-brane gauge groups and matter representations. A slightly more special class (2-parameter family) of Kummer surfaces, $X = \mathrm{Km}(E\times F)$, admits 11 different types of elliptic fibrations in the $\mathcal{J}_2(X)$ classification. Reference [73] worked out the $\mathcal{J}_2(X)$ classification for four attractive K3 surfaces, $X_{[1\ 0\ 1]}$, $X_{[1\ 1\ 1]}$, $X_{[2\ 0\ 2]}$ and $X_{[2\ 2\ 2]}$ among others, and found that there are $\mathcal{O}(10\sim 100)$ inequivalent types of elliptic fibrations in the $\mathcal{J}_2(X)$ classification (table 3 in this article contains detailed information of the $\mathcal{J}_2(X)$ classification of $X_{[1\ 1\ 1]}$). We also worked out the $\mathcal{J}_2(X)$ classification partially for another attractive K3 surface $X_{[3\ 0\ 2]}$ (see section4.4 of [26]) and found that there are at least 54 inequivalent types in $\mathcal{J}_2(X)$. Based on such an experience, it may not be too far off the mark to guess that the attractive K3 surfaces in table 2 have $\mathcal{O}(10\sim 100)$ inequivalent types of elliptic fibrations in the $\mathcal{J}_2(X)$ classification.[21]

[19] The quotient group $[W^{(2)}(S_X)\rtimes\mathrm{Isom}(S_X)^{(\text{Amp})}]$ for the $\mathcal{J}_2(X)$ classification is equivalent to $\mathrm{Isom}^+(S_X)$ (an index 2 subgroup of the entire isometry group of the Neron-Severi lattice).

[20] The Picard number of this family is $\rho_X = 17$, so that there are 3 complex structure parameters.

[21] A brute force calculation (or automatized/computerized calculation) following the procedure reviewed in section4 of [26] should be able to verify or correct this statement, but this task is beyond the scope of this article and [26].

JHEP04(2014)050

Let us now focus on a given type of elliptic fibration in $\mathcal{J}_2(X)$ (i.e., we focus on a particular choice of 7-brane gauge group and matter representation) for some K3 surface X. There can be more than one isomorphism class of elliptic fibrations in the $\mathcal{J}_1(X)$ classification (fine classification) that corresponds to the same type. The number of such mutually non-isomorphic elliptic fibrations is referred to as the "number of isomorphism classes", or simply "multiplicity" of that type in this article. Reference [75] worked out the multiplicity for each one of the types in $\mathcal{J}_2(X)$ for $X = \mathrm{Km}(E \times F)$. There is no theory known (at least to the authors) that computes multiplicities for any K3 surface, and the authors of this article made an attempt at generalizing the study of [75] so the multiplicities are estimated, if not computed, for a broader class of K3 surfaces with large Picard number. The primary goal of section 5 of [26] is to develop a theory for this purpose.

One of the solid results obtained in [26] is that the multiplicities are at most 16 for any type and for any one of the 34 attractive K3 surfaces that appear in table 2. For individual attractive K3 surfaces (or for individual types of elliptic fibrations of a given attractive K3 surface), stronger upper bounds on the multiplicity are obtained. For example, the multiplicity is at most 2 for all types of 20 out of the 34 attractive K3 surfaces in table 2, and furthermore, the multiplicity is 1 — any two elliptic fibrations of a given type must be mutually isomorphic — for 10 attractive K3 surfaces among them.[22] See Corollary D in [26] for more information.

There are two remarks to be made: first, it is not guaranteed that $\mathrm{Isom}(S_X)^{(\text{Amp Hodge})}$ is always a normal subgroup of $\mathrm{Isom}(S_X)^{(\text{Amp})}$. If it is, then the map from $\mathcal{J}_1(X)$ to $\mathcal{J}_2(X)$ is regarded as the quotient map under the action of the quotient group $\mathrm{Isom}(S_X)^{(\text{Amp Hodge})}\backslash\mathrm{Isom}(S_X)^{(\text{Amp})}$. The multiplicity of a given type is the number of elements of the orbit under this group. When the quotient group is not a normal subgroup, however, mutually non-isomorphic elliptic fibres do not necessarily form an orbit of a group action.

There seems to be a correlation between the multiplicity of a given type and the Picard number, at least among the examples that have been looked at in [26]. The multiplicities for various types range in $\mathcal{O}(10)$–$\mathcal{O}(100)$ for a 3-parameter family of K3 surfaces $X = \mathrm{Km}(A)$ (where $\rho_X = 17$), while they range in a few-10 for a 2-parameter family of K3 surfaces $X = \mathrm{Km}(E \times F)$ (where $\rho_X = 18$), and the multiplicities often become a few or even less for many attractive K3 surfaces ($\rho_X = 20$) appearing in table 2. This is far from a rigorous mathematical statement, and in particular, it is conceivable that the physics-motivated condition (2.25) has extracted biased samples from all the attractive K3 surfaces. For a study of supersymmetric landscapes, however, it is mandatory to set upper bounds like (2.25) on the flux quanta. The 34 attractive K3 surfaces are then our sample of interest (see also section 5 for a related discussion), and this bias is not a problem at all.

4.1.1 Frame lattice, Mordell-Weil group and U(1) charges

Before proceeding to section 4.2, we take a moment to give a detailed account of how physics information is read out from the frame lattice (4.2). This is largely a well-known

[22] They are $X_{[1\ 0\ 1]}$, $X_{[1\ 1\ 1]}$, $X_{[2\ 0\ 1]}$, $X_{[2\ 1\ 1]}$, $X_{[3\ 0\ 1]}$, $X_{[3\ 1\ 1]}$, $X_{[4\ 0\ 1]}$, $X_{[5\ 1\ 1]}$, $X_{[6\ 1\ 1]}$ and $X_{[3\ 1\ 2]}$.

JHEP04(2014)050

subject, and this section is primarily meant to be a review or reading guide for section 4 of [26]. The details of the following presentation are not directly relevant to the rest of this article. However, this section also contains a generalization of the discussion in [76] in a way applicable to K3 surfaces away from the stable degeneration limit.

The Cartan (maximal torus) part of 7-brane gauge fields in F-theory originates from the three-form field of 11-dimensional supergravity. These fields correspond to fluctuations of the three-form field in the form of $A^a \wedge \omega^a$, where A^a is a vector field in the low-energy effective theory, and ω^a is chosen from

$$F^1/F^0 \cong H^1(B_3; R^1\pi_{Y*}\mathbb{Z})\,; \tag{4.3}$$

$H^2(Y;\mathbb{Z})$ for an elliptic fibred Calabi-Yau fourfold Y with $\pi_Y : Y \longrightarrow B_3$ has a filtration

$$H^2(Y;\mathbb{R}) = F^2 \supset F^1 \supset F^0 \tag{4.4}$$

and

$$F^2/F^1 \cong H^0(B_3; R^2\pi_{Y*}\mathbb{R}) = H^0(B_3;\mathbb{R}), \tag{4.5}$$
$$F^1/F^0 \cong H^1(B_3; R^1\pi_{Y*}\mathbb{R}), \tag{4.6}$$
$$F^0 \cong H^2(B_3; R^0\pi_{Y*}\mathbb{R}) = H^2(B_3;\mathbb{R}). \tag{4.7}$$

This — choosing ω from F^1/F^0 — is because two-forms purely in the base, F^0, correspond to scalars (or two-forms) in the effective theory in 3+1-dimensions, and those containing two-forms in the elliptic fibre, F^2/F^1, to a part of metric in 3+1-dimensions [15]. The total rank of the 7-brane gauge group in the effective theory is therefore $h^2(Y) - h^2(B_3) - 1$ [31]. In the case of $\pi_Y : Y = \mathrm{K3} \times \mathrm{K3} \longrightarrow \mathbb{P}^1 \times \mathrm{K3}$, the rank is $44 - 23 - 1 = 20$.

In the case of $Y = X \times S$ with an elliptic K3 surface X, F^1/F^0 can simply be identified with

$$F^1/F^0 \cong H^1(\mathbb{P}^1; R^1\pi_{X*}\mathbb{R})\,. \tag{4.8}$$

The condition that ω^a be within $F^1 \subset F^2 = H^2(X;\mathbb{R})$ corresponds to $\omega^a \in [[F]^\perp \subset H^2(X;\mathbb{R})]$. One can see that $(F^1/F^0) \cong (T_X \oplus W_{\mathrm{frame}}) \otimes \mathbb{R}$, because i) $H^2(X;\mathbb{R}) = (T_X \oplus S_X) \otimes \mathbb{R}$, and ii) the generator of $F^0 \cong H^2(\mathbb{P}^1;\mathbb{R}) = \mathbb{R}$ is Poincaré dual to the fibre class $[F]$ of the elliptic K3 surface X, and iii) also because of the definition of the frame lattice (4.2). For a K3 surface X with $\rho_X = 20$, rank-2 U(1) gauge fields are associated with $T_X \otimes \mathbb{R}$, while the remaining 18 Cartan U(1)'s are related to $W_{\mathrm{frame}} \otimes \mathbb{R}$.

In the presence of four-form flux purely of G_1 type, the two U(1) vector fields associated with $T_X \otimes \mathbb{R}$ become massive by a Stückelberg mechanism. At the level of analysis in this article (where non-perturbative effects are not considered, and stabilization of Kähler moduli is also ignored), those two U(1) symmetries remain in the effective theory as global symmetries.

The frame lattice is negative definite. As we always assume that the elliptic fibration $\pi_X : X \longrightarrow \mathbb{P}^1$ has a section $\sigma : \mathbb{P}^1 \longrightarrow X$, we can identify a sublattice of S_X isomorphic to W_{frame} in the case of K3 surface X; it is characterized as

$$W_{\mathrm{frame}*} := \left[(\mathrm{Span}_{\mathbb{Z}}\{[F],[\sigma]\} \cong U)^\perp \subset S_X\right], \tag{4.9}$$

JHEP04(2014)050

the orthogonal complement of a sublattice generated by the fibre class $[F]$ and the section $[\sigma]$, and we call this sublattice $W_{\text{frame}*}$ the canonical frame lattice of a given elliptic fibration $(\pi_X, \sigma; X, \mathbb{P}^1)$.

The non-Abelian part of the gauge group in F-theory is associated with the (Poincaré dual of the) irreducible (-2) curves in the singular fibres of X that do not meet the zero section $[\sigma]$. They are contained in $W_{\text{frame}*}$ and are linearly independent. The sublattice generated by these (-2)-curves is contained in

$$W_{\text{root}} := \text{Span}_{\mathbb{Z}} \left\{ D \in W_{\text{frame}*} \mid D^2 = -2 \right\} , \tag{4.10}$$

the sublattice generated by norm-(-2) elements of the canonical frame lattice. But this W_{root} — called the root lattice of $W_{\text{frame}*}$ — is also known to be the same as the sublattice generated by the (-2)-curves (not meeting the section) in the singular fibres of X.[23] Therefore, once an elliptic fibration is specified in the form of an embedding of the lattice U into S_X, the non-Abelian part of the gauge group can be read out by calculating the W_{root} lattice from W_{frame} without dealing with defining equations (or the fibration map) of the K3 surface.

When the rank of the frame lattice $W_{\text{frame}*} \cong W_{\text{frame}}$ is larger than W_{root}, there is a massless U(1) vector field in the effective theory (if there is only G_1 component of the flux). Since "W-bosons" in the non-Abelian gauge groups should not be charged under such a U(1) symmetry, the two-form ω^a for such a U(1) vector field should be in the sublattice

$$W_{\text{U}(1)} := \left[W_{\text{root}}^{\perp} \subset W_{\text{frame}} \right] . \tag{4.11}$$

This is equivalent to an object known as the *essential lattice* of an elliptic surface X in the mathematics literature [65, 77], and may also be denoted by $L(X)$. Let $\{\omega^a\}$ be an independent set of generators of $W_{\text{U}(1)} = L(X)$. The massless U(1) vector fields in the effective theory are obtained from

$$C^{(3)} = \sum_{a=1}^{\rho_X - 2 - \text{rk}(W_{\text{root}})} A^a \omega^a , \tag{4.12}$$

where $\rho_X - 2 = \text{rk}(W_{\text{frame}*})$.[24] Theorem 1.3 in [77] states that the relation between the Mordell-Weil group $MW(X)$ and W_{frame} of an elliptically fibred surface is as follows:

$$\text{MW}(X) \cong \text{NS}(X)/[U \oplus W_{\text{root}}] \cong W_{\text{frame}}/W_{\text{root}} . \tag{4.13}$$

Thus, the rank of Mordell-Weil lattice is the same as $\text{rank}(W_{\text{U}(1)})$, the number of massless U(1) vector fields in the effective theory (when $G_1 \neq 0$, and $G_0 = 0$), and serves the

[23] To see this, suppose that D is a generator of W_{root}, i.e., $D \in W$ and $D^2 = -2$. Then either D or $-D$ corresponds to a class containing an effective divisor (curve) due to the Riemann-Roch theorem (Lemma 2.2 in section 1 of [62]), and secondly, it should be mapped down to a point in the base space $\mathbb{P}^1$ of the elliptic fibration, because the effective divisor in $W_{\text{frame}*}$ does not intersect with the fibre class. Therefore, it has to be contained in some singular fibres. The W_{root} lattice is attributed purely to singular fibres, not to any other sort of non-trivial sections of the elliptic fibration.

[24] The ω^a are not necessarily Poincaré dual to effective curves. This does not pose a problem as we only have to carry out a dimensional reduction to obtain their physics properties.

JHEP04(2014)050

purpose of counting degrees of freedom [31]. It should be remembered, though, that the U(1) vector fields are directly associated with two-forms in F^1, and hence in $W_{\rm frame}$, in physics. The connection with the Mordell-Weil group is only through an extra theorem in mathematics [65, 77].[25] To go beyond the degree-of-freedom counting in [31], and extract more physics information, $W_{\rm U(1)}$ lattice is the right object to deal with, as will be clear in the following discussion.

A preceding attempt of extracting more physics data, matter representations in F-theory compactifications on K3 surfaces in particular, has been made in [76]. The discussion in [76] leaves room for further sophistication in that

- only the stable degeneration limit of K3 surface was considered and, instead of a K3 surface, rational elliptic surfaces ($X = {\rm dP}_9$) were used for the analysis. This means that that $H^2(X;\mathbb{Z}) = S_X$, and the transcendental lattice is trivial. That is now different for a K3 surface.

- The primary interest in [76] was to keep track of matter representations under the non-Abelian part of the gauge group. But one may also be interested in classifying matter representations using not just non-Abelian charges but also massless (as well as global) U(1) charges. As we will see in section 4.3, it is not rare among attractive K3 surfaces that $W_{\rm U(1)}$ is non-empty.

Thus, a revised version of the discussion in [76] is provided in the following, using the lattice-theory language that has already been explaining in this section.

Obviously we can think of (not necessarily light) matter fields originating from "somehow quantizing" an M2-brane wrapped on a cycle in $U^{\oplus 2} \oplus E_8^{\oplus 2} \cong [U_*^\perp \subset H_2(X;\mathbb{Z})]$. Their representations under the massless gauge group associated with two-forms $W_{\rm gauge} := W_{\rm root} \oplus W_{\rm U(1)}$ (resp. under the symmetry group associated with $W_{\rm gauge} \oplus T_X$) should be specified by their weights, elements in the dual space $W^*_{\rm gauge} := {\rm Hom}(W_{\rm gauge}, \mathbb{Z})$ (resp. $W^*_{\rm gauge} \oplus T^*_X$). Any quantized states arising from an M2-brane wrapped on a two-cycle in $[U_*^\perp \subset H_2(X;\mathbb{Z})] \cong U^{\oplus 2} \oplus E_8^{\oplus 2}$ are in the same weight, and the weight is determined by the pairing between the divisors in $W_{\rm gauge}$ (resp. $W_{\rm gauge} \oplus T_X$) and the two-cycle. The collection of weights realized in this way forms a sublattice of the weight lattice $W^*_{\rm gauge}$ (resp. $W^*_{\rm gauge} \oplus T^*_X$). Let $G_{\rm matter}$ (resp. $\widetilde{G}_{\rm matter}$) be the image of this sublattice in the quotient space $G_{W_{\rm gauge}} = W^*_{\rm gauge}/W_{\rm gauge}$ (resp. $(W^*_{\rm gauge}/W_{\rm gauge}) \times G_{T_X}$). $G_{\rm matter}$ (resp. $\widetilde{G}_{\rm matter}$) is referred to as the N-ality of a given effective theory. Remembering that the unimodular lattice $U^{\oplus 2} \oplus E_8^{\oplus 2}$ is an overlattice of $W_{\rm frame*} \oplus T_X$, and that $W_{\rm gauge} \subset W_{\rm frame*} \subset W^*_{\rm frame*} \subset W_{\rm gauge}$, one finds an exact sequence

$$0 \longrightarrow (W_{\rm frame*}/W_{\rm gauge}) \longrightarrow \widetilde{G}_{\rm matter} \longrightarrow \Delta \longrightarrow 0\,, \tag{4.14}$$

[25] If we are to exploit this connection, the narrow Mordell-Weil lattice $MW(X)^0$ will be a more appropriate object than $MW(X)$. $MW(X)^0$ is defined as the subgroup of $MW(X)$ that consists of sections of an elliptic fibration $(\pi_X, \sigma; X, \mathbb{P}^1)$ that cross singular fibres only through the (-2) curves meeting the zero section σ, rather than through (-2) curves generating A–D–E root lattices in $W_{\rm root}$. Theorem 8.9 in [77] states that the narrow Mordell-Weil lattice is isomorphic to $W_{\rm U(1)} = L(X)$ as an Abelian group, and the height pairing of $MW(X)^0$ (positive definite) is precisely the intersection form of $L(X)$ (negative definite) times (-1).

JHEP04(2014)050

where Δ is the diagonal subgroup of $G_{S_X} \times G_{T_X} \cong G_{W_{\text{frame}*}} \times G_{T_X}$. This characterizes the N-ality of matter representations $\widetilde{G}_{\text{matter}}$ under the symmetry group. For definitions of lattice theory jargon as well as reviews on background material, see e.g., [26]. If we are to ignore the U(1) symmetry charges associated with the vector fields from T_x (which are not massless in the presence of G_1 type flux), then the N-ality is given by

$$0 \longrightarrow (W_{\text{frame}*}/W_{\text{gauge}}) \longrightarrow G_{\text{matter}} \longrightarrow [(W^*_{\text{frame}*}/W_{\text{frame}*}) \cong G_{S_X}] \longrightarrow 0\,. \tag{4.15}$$

The matter fields in $W_{\text{frame}*}/W_{\text{gauge}}$ form a subgroup in G_{matter}, which means that interactions among these fields must be closed within themselves. Techniques to calculate $W_{\text{frame}*}/W_{\text{gauge}}$ as well as $G_{S_X} \cong \Delta$ are presented in [26], section 4. Note that $W^*_{\text{frame}*} \subset W^*_{\text{gauge}}$ is now regarded as the kernel of

$$[W^*_{\text{gauge}} = \text{Ext}^0(W_{\text{gauge}}, \mathbb{Z})] \longrightarrow [\text{Ext}^1(W_{\text{frame}*}/W_{\text{gauge}}, \mathbb{Z}) = W^*_{\text{gauge}}/W^*_{\text{frame}*}]\,, \tag{4.16}$$

rather than the kernel of

$$[W^*_{\text{root}} = \text{Ext}^0(W_{\text{root}}, \mathbb{Z})] \longrightarrow [\text{Ext}^1(W_{\text{frame}*}/W_{\text{gauge}}, \mathbb{Z}) \cong \text{Tor}(MW(X))] \tag{4.17}$$

as presented in [76]. This difference from [76] is due to the generalization from the stable degeneration limit (rational elliptic surface) to K3 surfaces and the inclusion of information on Abelian charges of the matter fields. It is thus best for physics purposes to extract the information of an elliptic fibration in the form of the sublattice W_{gauge} and the quotient $W_{\text{frame}*}/W_{\text{gauge}}$. Consequently. computation results in [26] are presented in this way.

Explicit examples will help understand the abstract theory above. In this article, we only show table 3, more examples are found in [26]. For an attractive K3 surface $X = X_{[1\ 1\ 1]}$ (often denoted also by X_3), which has 6 different types of elliptic fibrations, the Mordell-Weil group has been computed for any one of these types (see table 1.1 of [73]). It is certainly well-motivated to study Mordell-Weil groups of elliptic fibrations in mathematics, to begin with, and decompose them into their free part and torsion part. However, more suitable for physicists' needs is to extract information from $W_{\text{frame}*}$ in the form of W_{gauge}, $(W_{\text{frame}*}/W_{\text{gauge}})$ and G_{matter}. The subtle differences between them should be visible in the examples in table 3.

When we employ the expansion in the form of (4.12), the gauge kinetic term of the vector fields on $S \times \mathbb{R}^{3,1}$ is given by

$$\propto -\int_{\mathbb{R}^{3,1}} d^4x \int_S d^4y \sqrt{g(y)}\; M_*^4 \left(T_R^{-1} \text{tr}_R\, [F_{mn}F^{mn}] - 2(\omega_a, \omega_b) F^a_{mn} F^b_{mn} \right)\,; \tag{4.18}$$

the normalization of the second term is set relatively to that of the first term, so that the maximal torus part of the non-Abelian components also have the same normalization[26] as

[26] When the maximal torus part of a non-Abelian A_{n-1} component is expanded as $C^{(3)} = \sum_{a=1}^{n-1} C_a A^a$, with A^a being $\mathbb{R}$-valued vector fields, then this corresponds to $\text{diag}(-A^1, A^1 - A^2, \cdots, A^{n-2} - A^{n-1}, A^{n-1})$ in the fundamental (n-dimensional) representation of SU(n), since an M2-brane wrapped on C_b — usually assigned to the $(b, b+1)$ entry of the $n \times n$ matrix representation — should have a covariant derivative involving $A^{b-1} - 2A^b + A^{b+1}$. Then $T_n^{-1}\, \text{tr}_n\, [(\text{diag}(-F^1, F^1 - F^2, \cdots, F^{n-1}))^2] = 4[(F^1)^2 + \cdots + (F^{n-1})^2] - 4[F^1F^2 + \cdots + F^{n-2}F^{n-1}] = -2(C_a, C_b) F^a_{mn} F^b_{mn}$.

Table 3. The N-ality $G_{\text{matter}} \subset G_{W_{\text{gauge}}}$ of the six different types of elliptic fibrations in $\mathcal{J}_2(X)$ for an attractive K3 surface $X = X_3$. In this table, one can confirm that i) $(W_{\text{frame}}/W_{\text{gauge}}) \subset G_{\text{matter}} \subset G_{W_{\text{gauge}}}$, ii) $MW \cong W_{\text{frame}*}/W_{\text{root}} \longrightarrow (W_{\text{frame}*}/W_{\text{gauge}})$ is a quotient, and iii) the quotient of $(W_{\text{frame}*}/W_{\text{gauge}}) \hookrightarrow G_{\text{matter}}$ is always $G_{T_X} \cong \mathbb{Z}_3$ of the attractive K3 surface X_3. In the 3rd and 4th entries, the generators of the rank-1 lattice (-6) are denoted by $2\cdot\mathbf{56}$, because the generator is that of the weight $2\cdot\mathbf{56}$ in E_7^*, when this rank-1 lattice is regarded as $[E_6^\perp \subset E_7]$.

the Abelian components given by the intersection form on the K3 surface X. $T_R^{-1}\,\mathrm{tr}_R[\cdots]$ is the ordinary convention adopted for non-Abelian gauge theories. The gauge coupling constant[27] of the massless U(1) vector fields is given by the opposite of the intersection form on the essential lattice $L(X) = W_{\mathrm{U}(1)}$, $-(\omega_a,\omega_b) = -\int_X \omega_a \wedge \omega_b$, which is equivalent to the (positive definite) height pairing of the narrow Mordell-Weil lattice $MW(X)^0$.

4.2 Moduli space of F-theory with flux

4.2.1 Subspace of K3 moduli space with a given Picard number

The discussion in sections 2.1 and 2.2 centres on (pairs of) attractive ($\rho = 20$) K3 surfaces, while that of sections 3 and 4.1 is applicable for K3 surfaces with any Picard number ρ. Thus all the statements in sections 3 and 4.1 are applicable to the special cases treated in sections 2.1 and 2.2. As a warming up for the discussion in section 4.2.2 and later, however, let us first elaborate a little more about the relation between the characterization of attractive K3 surfaces in terms of (2.7), (2.8), (2.9) and the complex structure moduli space $\mathrm{Isom}^+(\Lambda_{\mathrm{K3}})\backslash D$. This is only to repeat material presented in [18, 58, 59, 78], apart from the purpose of setting up notations that we need later.

[27] Note that this kinetic term most likely corresponds to the one renormalized at the Kaluza-Klein scale, since this is obtained from a simple dimensional reduction (truncation) of 11-dimensional supergravity on a flat spacetime, whose infrared physics (especially when it comes to renormalization) is quite different from what we are really interested in.

JHEP04(2014)050

Let us first define a pair of sublattices $(T_{[\omega]}, S_{[\omega]})$ for $[\omega] \in D$ as

$$S_{[\omega]} := \left[\omega^\perp \subset \Lambda_{\rm K3}\right], \qquad T_{[\omega]} := \left[S_{[\omega]}^\perp \subset \Lambda_{\rm K3}\right]. \tag{4.19}$$

These two sublattices are mutually orthogonal complements in $\Lambda_{\rm K3}$ (which also means that they are primitive sublattices of $\Lambda_{\rm K3}$). Thus, one can define a map

$$D \ni [\omega] \mapsto (T_{[\omega]}, S_{[\omega]}) \in \{(T,S)|\text{ mutually orthog. sublattices of } \Lambda_{\rm K3}\} =: \mathcal{C}\,. \tag{4.20}$$

$\mathcal{C}$ is further decomposed into $\mathcal{C}_\rho$ with $\rho = 0, 1, \cdots, 20$ where $T_{[\omega]}$ and $S_{[\omega]}$ have signature $(2, 20-\rho)$ and $(1, \rho-1)$, respectively, and others which we are not interested in.[28] D is also decomposed into D_ρ with $\rho = 0, \cdots, 20$, where D_ρ is the fibres over $\mathcal{C}_\rho$. Each irreducible component of the fibres is of complex dimension $20-\rho$. The group $\mathrm{Isom}^+(\Lambda_{\rm K3})$ acts also on the $\mathcal{C}_\rho$, and the action on D_ρ and $\mathcal{C}_\rho$ commutes with the map introduced above.

The Theorem 2.10 of [78] states that there is a map that is both injective and surjective between $\mathrm{Isom}^+(\Lambda_{\rm K3})\backslash\mathcal{C}_\rho$ and the classification of even lattice T of signature $(2, 20-\rho)$ modulo isometry, if $\rho \geq 12$ (which comes from a condition $\mathrm{rank}(T) \leq \mathrm{rank}(S) - 2$). In the case of $\rho = 20$, $\mathrm{Isom}^+(\Lambda_{\rm K3})\backslash D_{\rho=20} \longrightarrow \mathrm{Isom}^+(\Lambda_{\rm K3})\backslash\mathcal{C}_{\rho=20}$ (or, equivalently, $D_{\rho=20} \longrightarrow \mathcal{C}_{\rho=20}$) is surjective[29] and the fibre consists of 2 elements; they correspond to the two different choices of an orientation in $T_{[\omega]} \otimes \mathbb{R}$ that turns it into a complex line $[\omega] \in \Lambda_{\rm K3} \otimes \mathbb{C}$. Thus, the scan over even lattices of signature $(2,0)$ with orientation in the basis — the scanning in [18] and in sections 2.1 and 2.2 — is in one-to-one correspondence with $\mathrm{Isom}^+(\Lambda_{\rm K3})\backslash D_{\rho=20}$ [18]. Therefore, the entries in table 2 are regarded as a subset of

$$\left[\mathrm{Isom}^+(\Lambda_{\rm K3}^{(X)})\backslash D_{\rho=20}^{(X)}\right] \times \left[\mathrm{Isom}^+(\Lambda_{\rm K3}^{(S)})\backslash D_{\rho=20}^{(S)}\right], \tag{4.21}$$

specified by the condition (2.25).

4.2.2 Moduli space in the presence of flux

Moduli spaces such as (3.9), (3.11), (3.12) arise from compactifications of M/F-theory without flux. Let us now move on formulate the moduli spaces for compactifications including fluxes, paying close attention to the choice of the quotient group which should tell us when a pair of vacua should be regarded the same in physics and when as distinct.

To get started, let us return to M-theory compactification on $Y = S_1 \times S_2$ down to 2+1-dimensions. Remembering that the moduli space was (3.9) because we take a quotient by $\mathrm{Isom}^+(\Lambda_{\rm K3}^{(S_1)}) \times \mathrm{Isom}^+(\Lambda_{\rm K3}^{(S_2)})$ in order to reduce the unphysical difference in the choice of marking, we claim that the complex structure moduli space[30] of compactifications on

[28] Either $T_{[\omega]}$ or $S_{[\omega]}$ contains all three positive directions in such cases. They are not in the image of D, however.

[29] The original proof of surjectivity of the map from $\mathrm{Isom}^+(\Lambda_{\rm K3})\backslash D_{\rho=20}$ to the set of even lattices of signature $(2,0)$ with orientation in [61] was to show that, for any even $(2,0)$ lattice with orientation, $T^{\rm or}$, a K3 surface can be constructed whose transcendental lattice with an oriented basis becomes the even $(2,0)$ lattice $T^{\rm or}$.

[30] There is nothing wrong to introduce the flux $G^{(4)}$ also in $H^4(S_1;\mathbb{Z}) \otimes H^0(S_2;\mathbb{Z}) \oplus H^0(S_1;\mathbb{Z}) \otimes H^4(S_2;\mathbb{Z})$ in M-theory compactifications down to 2+1-dimensions, where we do not have to preserve $\mathrm{SO}(3,1)$ Lorentz symmetry. Strictly speaking, $H^{2,2}(Y;\mathbb{R})$ in this equation should be replaced by its image under the marking. We do not try to be precise beyond our need.

JHEP04(2014)050

$Y = S_1 \times S_2$ in the presence of 4-from flux should be given by the quotient space of

$$\left\{ \left([\omega_1], [\omega_2], G^{(4)} \right) \;\middle|\; [\omega_i] \in D^{(S_i)},\ [G^{(4)}] \in \left(\Lambda_{\rm K3}^{(S_1)} \otimes \Lambda_{\rm K3}^{(S_2)} \right) \cap H^{2,2}(Y;\mathbb{R}) \right\} \tag{4.22}$$

by[31,32]

$$\Gamma = \mathbb{Z}_2 \langle \text{c.c.} \rangle \times \mathbb{Z}_2 \langle \text{exch}_{12} \rangle \ltimes \left[\text{Isom}^+(\Lambda_{\rm K3}^{(S_1)}) \times \text{Isom}^+(\Lambda_{\rm K3}^{(S_2)}) \right] , \tag{4.23}$$

where exch_{12} exchanges S_1 and S_2, and c.c. denotes complex conjugation of the entire $Y = S_1 \times S_2$. As stated at the end of section 2.1, a pair of descriptions related by $\mathbb{Z}_2 \langle \text{c.c.} \rangle \times \mathbb{Z}_2 \langle \text{exch}_{12} \rangle$ should not be regarded distinct vacua in physics.

This moduli space has a number of disconnected components corresponding to topological choices of the four-form flux. For non-trivial fluxes, some moduli have masses, and such connected components of the moduli space have reduced dimensions. Thus, this moduli space should be that of effective theories below the mass scale of stabilized moduli,[33] and can be used at least for the purpose of parametrizing/counting vacua.[34]

It is instructive to use the landscape of vacua already shown in table 2, where $G_0 = 0$, to see what the isolated (completely stabilized) components of this moduli is like. Already the table serves as the list of quotient of $D_{\rho=20}^{(S_1)} \times D_{\rho=20}^{(S_2)}$ by the group (4.23). The rest is to work out the number of different choices of fluxes $G^{(4)} = G_1$ (or equivalently the number of different choices of γ) modulo the action of the residual symmetry in the group (4.23). Written in the second to last column of table 2 is the number of different γ modulo the residual symmetry in $\mathbb{Z}_2 \langle \text{c.c.} \rangle \times \mathbb{Z}_2 \langle \text{exch}_{12} \rangle$. Assuming further that all of the $\text{Isom}(T_{S_1})^{(\text{Hodge})} \times \text{Isom}(T_{S_2})^{(\text{Hodge})} \cong \mathbb{Z}_{m_1} \times \mathbb{Z}_{m_2}$ $(m_{1,2} = 2, 4, 6)$ symmetries of the transcendental lattices T_{S_1} and T_{S_2} can be lifted to isometries of the entire lattice $\Lambda_{\rm K3}$, however,[35] all the γ's are equivalent for all the entries, except in two entries marked by $*$ in the table, where there are two inequivalent values of γ. Thus, we conclude — under this assumption — that the landscape of M-theory compactification on $Y = S_1 \times S_2$ with a four-form flux purely of type G_1 and completely stabilized complex structure moduli consists $1 \times 64 + 2 \times 2 = 68$ vacua.

Let us now turn to F-theory and try to figure out the moduli space for F-theory compactifications on elliptically fibred $X \times S$, with a four-form flux preserving $\text{SO}(3,1)$ symmetry. From the experience so far, it is natural to consider that the moduli space is

[31] Note that $\mathbb{Z}_2 \langle \text{exch}_{12} \rangle$ in the modular group Γ also acts on the Kähler moduli.

[32] To be more precise, we only know that the true modular group should contain this Γ in (4.23) as a subgroup. To draw an analogy, $T^2 \times T^2 \times \cdots$ compactifications of type II string theory has a larger duality group than just $\text{SL}(2;\mathbb{Z}) \times \text{SL}(2;\mathbb{Z}) \times \cdots$. The same comment applies also to the choice of modular group (4.26) for F-theory.

[33] In the case of type IIB/F-theory compactifications, the mass scale is typically $M_{\rm KK}^3/M_{\rm str}^2$ [13].

[34] In order to use this as the target space of a non-linear sigma model below the mass scale of the stabilized moduli, one has to study corrections to the metric (Kähler potential) on moduli space. Note that the classification of matter representations in section 4.1.1 includes information on stringy states, and hence is not a classification of effective field theories below the scale of moduli masses. Note also that the restricted moduli space $\mathcal{M}_*$ to be introduced in section 5.4 should be regarded more as a mathematical (rather than physical) object on which the $\rho_{\rm ind}$ distribution is presented.

[35] This assumption is satisfied, if $p_S : \text{Isom}(S_{S_{1,2}}) \longrightarrow \text{Isom}(q_{1,2})$ is surjective. It is known that this is the case for some K3 surfaces with large Picard number. See [26] for more information.

JHEP04(2014)050

given by

$$\Gamma\backslash\left\{\left([\omega_X],[\omega_S],G^{(4)},\phi_U\right)\;\middle|\;\; G^{(4)}\in L,\;\right\}/\{\pm\mathrm{id}._U\}\,, \tag{4.24}$$

where $([\omega_X],[\omega_S])\in D^{(X)}\times D^{(S)}$, $\phi_U : U\hookrightarrow\left[[\omega_X]^\perp\subset\Lambda_{\mathrm{K3}}\right]$, and the four-form flux $G^{(4)}$ is in

$$\begin{aligned} L:=\Big(\Big[\phi_U(U)^\perp\subset\Lambda^{(X)}_{\mathrm{K3}}\Big]\otimes\Lambda^{(S)}_{\mathrm{K3}}\Big)\cap\\ \big[\varphi_{[\omega_X]}(H^{2,0}(X_{[\omega_X]};\mathbb{C}))\otimes\varphi_{[\omega_S]}(H^{0,2}(S_{[\omega_S]};\mathbb{C}))+\mathrm{h.c.}\\ +\varphi_{[\omega_X]}(H^{1,1}(X_{[\omega_X]};\mathbb{R}))\otimes\varphi_{[\omega_S]}(H^{1,1}(S_{[\omega_S]};\mathbb{R}))\big]\;, \end{aligned} \tag{4.25}$$

where $(X_{[\omega_X]},\varphi_{[\omega_X]})$ and $(S_{[\omega_S]},\varphi_{[\omega_S]})$ are either one of two inverse images of $[\omega_X]$ and $[\omega_S]$, respectively, under the period map. When only flux of G_1 type is introduced, the last line in L is dropped. The quotient group is given by

$$\Gamma=\mathbb{Z}_2\left\langle\text{c.c.}\right\rangle\times\mathrm{Isom}^+(\Lambda^{(X)}_{\mathrm{K3}})\times\mathrm{Isom}^+(\Lambda^{(S)}_{\mathrm{K3}})\,. \tag{4.26}$$

The $\mathbb{Z}_2\left\langle\mathrm{exch}_{12}\right\rangle$ is gone at this point, because we have already set up a convention that it is X, rather than S, whose vev of the volume of elliptic fibre goes to zero. If we are to focus on vacua with $\rho_X=\rho_S=20$, then simply the condition that $([\omega_X],[\omega_S])\in D^{(X)}\times D^{(S)}$ is replaced by $([\omega_X],[\omega_S])\in D^{(X)}_{\rho=20}\times D^{(S)}_{\rho=20}$.

4.2.3 How to carry out the vacuum counting for F-theory on K3×K3 in practice

As long as we consider compactifications on $Y=\mathrm{K3}\times\mathrm{K3}=X\times S$, with the elliptic fibration implemented as $\pi_X : X\longrightarrow\mathbb{P}^1$, all the 7-branes are in the form $\{\text{point}\}\times S$; in particular, there are no matter curves. Thus, all algebraic information (such as gauge groups and matter representations) of low-energy effective theories is captured by the frame lattice $W_{\mathrm{frame}}(X)$ and T_X. This means that

$$\amalg_{[a\;b\;c]}\;\;\mathcal{J}_2(X_{[a\;b\;c]}) \tag{4.27}$$

serves as the classification of effective theories by their algebraic information.[36] Here, $[a\;b\;c]$ runs over the thirty-four choices of the three integers characterizing the transcendental lattice of either S_1 or S_2 in table 2.

Let us take $X_{[1\;0\;1]}$ (also denoted by X_4 in the mathematics literature) as the first example. There are 13 different types of elliptic fibrations for this K3 surface [73], i.e., $\#[\mathcal{J}_2(X_{[1\;0\;1]})]=13$. When this K3 surface $X_{[1\;0\;1]}$ is to be used for the X of $Y=X\times S$ in (3.1), one can use table 2 to see that the other K3 surface S can be $X_{[6\;0\;6]}$ or $X_{[3\;0\;3]}$ (when $N_{D3}=0$), $X_{[5\;0\;5]}$ or $X_{[1\;0\;1]}$ (when $N_{D3}=4$), $X_{[4\;0\;4]}$, $X_{[4\;0\;1]}$, $X_{[2\;0\;2]}$ and $X_{[1\;0\;1]}$ (when $N_{D3}=8$), $X_{[3\;0\;3]}$ (when $N_{D3}=12$), $X_{[2\;0\;2]}$, $X_{[1\;0\;1]}$ (when $N_{D3}=16$) and finally $X_{[1\;0\;1]}$ (when $N_{D3}=20$). There are 12 options for the choice of (S,N_{D3}). For any one of

[36] It may be possible that the difference between a pair of non-equivalent embedding of $T_X\oplus W_{\mathrm{frame}}\oplus U$ into $H_2(X;\mathbb{Z})$ is absorbed by rescaling of U(1) charges, only to result in different gauge coupling constants (gauge kinetic terms). We are not paying attention at this level of detail in this article, however.

JHEP04(2014)050

these 12 choices of $(Y = X_{[1\ 0\ 1]} \times S, N_{D3})$, the stabilizer subgroup of Γ (i.e., the residual modular group) is

$$\mathbb{Z}_2 \langle \text{c.c.} \rangle \times \left[W^{(2)}(S_X) \rtimes \text{Aut}(X) \right] \times \left[W^{(2)}(S_S) \rtimes \text{Aut}(S) \right] , \tag{4.28}$$

which acts on the possible choices of elliptic fibrations $(\phi_U : U \hookrightarrow S_X)$ and flux of G_1 type (γ in table 2). This is quite a complicated problem to work out. If we are to first exploit this remaining symmetry in Γ in (4.26) to eliminate a redundant description of elliptic fibrations, we can use the Corollary D of [26]), which states that any one of the 13 types of elliptic fibrations of $X_{[1\ 0\ 1]}$ consists of a unique isomorphism class. There is no extra multiplicity coming from the difference between the $\mathcal{J}_1(X)$ and the $\mathcal{J}_2(X)$ classifications. The $\mathbb{Z}_2 \langle \text{c.c.} \rangle$ action in Γ is not necessary in eliminating redundant descriptions of elliptic fibrations on $X_{[1\ 0\ 1]}$, and we can exploit this to see that the number of inequivalent choices of the flux $G^{(4)} = G_1$ is not more than the numbers presented in the last column of table 2. Furthermore, in the cases $S = X_{[1\ 0\ 1]}$ or $X_{[2\ 0\ 2]}$, we can also see that the combined choice of flux and elliptic fibration is unique under the action of the whole group Γ because $\text{Isom}(T_S)^{(\text{Hodge})} \cong \mathbb{Z}_4$ and the generator of this group can be extended[37] to an isometry of $H_2(S;\mathbb{Z})$ for $S = X_{[1\ 0\ 1]}$ and $X_{[2\ 0\ 2]}$. For other S, the number of non-equivalent choices of flux and elliptic fibration combined cannot be determined without more information. We thus conclude that for any one of the 13 types of elliptic fibrations in $\mathcal{J}_2(X_{[1\ 0\ 1]})$, the total number of inequivalent choices of $(S, N_{D3}, \gamma, \phi_U)$, and hence the number of inequivalent choices of vacua, is somewhere in between 12 and 23.

The attractive K3 surface $X_{[2\ 1\ 1]}$ is another example for which there is a unique isomorphism class in each type of elliptic fibration (see Corollary D of [26] or footnote 22 in this article). Thus, for theories in the classification of $\mathcal{J}_2(X_{[2\ 1\ 1]})$ in (4.27), the counting of inequivalent vacua arises only from the choice of fluxes (γ), not in the isomorphism classes of elliptic fibrations. Thus, for any type of elliptic fibration in $\mathcal{J}_2(X_{[2\ 1\ 1]})$, the number of inequivalent vacua lies somewhere in between 9 and 18. These statistics originate from (S, N_{D3}) being $(X_{[4\ 2\ 2]}, 10)$, $(X_{[2\ 1\ 1]}, 10)$, $(X_{[2\ 1\ 1]}, 17)$, $(X_{[6\ -3\ 3]}, 3)$, $(X_{[4\ -2\ 2]}, 10)$, $(X_{[2\ -1\ 1]}, 10)$, $(X_{[2\ -1\ 1]}, 17)$ in table 2. Note that we have exploited $\mathbb{Z}_2 \langle \text{c.c.} \rangle$ to set $X = X_{[2\ 1\ 1]}$ rather than $X_{[2\ -1\ 1]}$.

As an example of attractive K3 surfaces where there can be multiple isomorphism classes of elliptic fibrations of the same type, let us first consider $X = X_{[2\ 2\ 2]}$. This K3 surface admits 30 different types of elliptic fibrations, $\#\left[\mathcal{J}_2(X_{[2\ 2\ 2]})\right] = 30$ [73]. The number of isomorphism classes of each type can be either one or two, and it turns out (Example J of [26]) that there is a unique isomorphism class in at least 15 out of the 30 different types. The number of remaining inequivalent choices of flux $G_1 \propto \gamma$ can be estimated as above, and it falls within 7–22, using the information in the last column of table 2. Thus, in conclusion, at least 15 classes of effective theories in $\mathcal{J}_2(X_{[2\ 0\ 2]})$ consist of 7–22 inequivalent vacua individually, and there may be 2× (7–22) inequivalent effective theories of a given algebraic information corresponding to any one of the remaining 15 types in $\mathcal{J}_2(X_{[2\ 0\ 2]})$.

[37] This is because $p_S : \text{Isom}(S_S) \longrightarrow \text{Isom}(q)$ is known to be surjective for $S = X_{[1\ 0\ 1]}$ and $X_{[2\ 0\ 2]}$.

JHEP04(2014)050

Finally, let us take a look at the cases $X = X_{[6\ 0\ 6]}$ and $X = X_{[6\ 6\ 6]}$. For these two attractive K3 surfaces, there is only one possible choice of (S, N_{D3}); $(S, N_{D3}) = (X_{[1\ 0\ 1]}, 0)$ and $(X_{[1\ 1\ 1]}, 6)$, respectively. All the choices of the flux $G_1 \propto \gamma$ turn out to be equivalent under the residual $W^{(2)}(S_S) \rtimes \mathrm{Aut}(S) \subset \mathrm{Isom}^+(\Lambda_{\mathrm{K3}}^{(S)})$ symmetry in Γ, because of the surjectiveness of $p_S : \mathrm{Isom}^+(S_S) \longrightarrow \mathrm{Isom}(q)$ for $S = X_{[1\ 0\ 1]}$ and $X_{[1\ 1\ 1]}$. The number of distinct isomorphism classes of elliptic fibrations is not more than 16 and 12 for $X = X_{[6\ 0\ 6]}$ and $X = X_{[6\ 6\ 6]}$, respectively, for any types in $\mathcal{J}_2(X)$ (Corollary D of [26]). Thus, for these two attractive K3 surfaces chosen as X, the number of inequivalent vacua is bounded from above by 16 and 12, respectively.

4.3 Sample statistics

The example-based study in section 4.2.3 indicates that each class of theories in (4.27) consists of $\mathcal{O}(10)$ vacua inequivalent under the modular group Γ in (4.26). Although the study only covers five attractive K3 surfaces $X_{[a\ b\ c]}$ out of thirty-four, small as well as large a, c are covered in the five examples. We expect that an estimate of the vacuum counting would not be different so much for the other twenty-nine attractive K3 surfaces.

This fact — the numbers of vacua in individual classes of effective theories in (4.27) are much the same — allows us to take a short-cut approach in studying statistical distributions of more inclusive classifications of effective theories. By more inclusive classifications, we mean classifications of low-energy effective theories coarser than in (4.27). One might be interested, for example, in the number of effective theories that contain a certain gauge group G (such as $\mathrm{SU}(3)_C \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$, SU(5) or SO(10)), and compare the numbers for various choices of G. When we ask this question, we have to include all the vacua from (4.27) containing the specified gauge group, regardless of the gauge groups in the hidden sector. Given the fact that the number of vacua in each class of theories in (4.27) are much the same, we can simply count the number of classes of effective theories contained in inclusive classes of theories, because more or less "the same" multiplicity $\mathcal{O}(10)$ factors out in the ratio. In this section, we take this short-cut approach in order to address three questions of interest.

4.3.1 Statistics on 7-brane gauge groups and CP violation

7-brane Gauge Groups. It is one of the most important questions we can address by using a toy/miniature supersymmetric landscape whether or not there are more vacua with an SU(5) unified gauge group than those with $\mathrm{SU}(3)_C \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ gauge group that just happens to satisfy gauge coupling unification "by accident". As is well-known, it makes sense in the context of unified theories to focus on vacua of string theory realized as compactifications for which the volume of internal space is parametrically larger than the string length. This is because in SU(5) unified gauge theories, for example, the doublet-triplet splitting problem will be too difficult to solve within string theory[38] in a form other than implementing a non-trivial line bundle (flat or non-flat) in the hypercharge direction. The Kaluza-Klein scale has to be set at the scale of gauge coupling unification then. If it

[38] Imagine implementing the missing partner mechanism in string theory, for example.

E_8+ any other	5	2	3	0	10
E_7+ any other	3	5	2	0	10
E_6+ any other	3	5	5	0	13

Table 4. This table shows the number of different types of elliptic fibrations in $X_{[1\ 0\ 1]}$, $X_{[1\ 1\ 1]}$, $X_{[2\ 0\ 2]}$ and $X_{[2\ 2\ 2]}$ that contain one of IV*, III* and II* type singular fibres, and have Mordell-Weil lattice of a given rank. One type, where $W_{\text{frame}} = E_8 \oplus E_6 \oplus D_4$ for $X_{[2\ 2\ 2]}$, is counted twice in this table.

turns out, however, that there are more vacua with the $\mathrm{SU}(3)_C \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ gauge group and accidental gauge coupling unification than those with SU(5) gauge group in the landscape obtained by assuming geometric compactification, then there must be much more $\mathrm{SU}(3)_C \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ vacua when we include string vacua with non-geometric (just CFT-based) "internal space". Therefore, it is a necessary condition that there are more SU(5) vacua than $\mathrm{SU}(3)_C \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ vacua in landscapes based on geometric compactification for the study of SU(5) unification in string compactification. It is this necessary condition that we intend to test below.

Instead of carrying out this test itself, we consider a similar (and a little easier) test in this article. Instead of studying the ratio of vacua with SU(5) × (any non-Abelian) and those with SU(3) × SU(2) × U(1) × (any non-Abelian), we study the ratio[39] of vacua with $E_n \times \mathrm{U}(1)^r \times$ (any non-Abelian) and those with $E_{n-1} \times \mathrm{U}(1)^{r+1} \times$ (any non-Abelian) $(n = 6, 7, 8)$.

The $\mathcal{J}_2(X)$ classification has been worked out completely for four attractive K3 surfaces, $X = X_{[1\ 0\ 1]}$, $X_{[1\ 1\ 1]}$, $X_{[2\ 0\ 2]}$ and $X_{[2\ 2\ 2]}$ [73]. Let us first use these statistics — a subset of (4.27) — and further use the short-cut approach we explained above to see the ratio of vacua with a $E_{6,7,8}$ gauge group on 7-branes along with how many U(1) vector fields they are accompanied. There are 112 different types of elliptic fibrations in $\mathcal{J}_2(X)$ for the four K3 surfaces combined, and 32 among them contain one of $E_{6,7,8}$ as a part of the 7-brane gauge group.[40] Using the information in table 1.1–1.4 of [73], the statistics turns out to be the following (table 4).

In addition to the four attractive K3 surfaces, the authors have partially carried out the $\mathcal{J}_2(X)$ classification for another attractive K3 surface[41] $X_{[3\ 0\ 2]}$ in [26], so that the same statistics as above can be extracted. There are 43 different types of elliptic fibrations on $X_{[3\ 0\ 2]}$ which contain either one of the IV*, III* or II* type singular fibres. The distribution of the rank of the Mordell-Weil lattice turns out be the following (table 5).

[39] It must be a reasonable assumption that such gauge groups originate from 7-branes rather than D3-branes; D3-branes (rather than fractional 3-branes) only give rise to $\mathcal{N} = 4$ super Yang-Mills theory, and furthermore, their gauge couplings are parametrically larger than those of 7-branes because of the volume of four-cycles that the 7-branes are wrapped.

[40] Here, 23/112 is the fraction of the types of elliptic fibration containing IV*, III* or II* type singular fibres in $X_{[1\ 0\ 1]}$, $X_{[1\ 1\ 1]}$, $X_{[2\ 0\ 2]}$ and $X_{[2\ 2\ 2]}$. Such a fraction for an attractive K3 surface $X_{[a\ b\ c]}$ may, however, have some correlation with whether a, c are large or small.

[41] There is no particular reason to choose this attractive K3 surface (rather than thirty-three others) from the perspective of physics.

E_6+ any other	0	8	8	3	19

Table 5. The number of different types of elliptic fibrations of $\mathcal{J}_2(X_{[3\ 0\ 2]})$ containing either one of IV*, III* or II* type singular fibres and having Mordell-Weil lattice with various ranks. Three types with $W_{\rm root} = A_2E_7E_8$, $A_1E_7E_8$ and $A_3E_6E_7$ contribute twice in this table, so that the total number is summed up to 46, rather than 43.

When we compare the numbers in the two tables (tables 4 and 5) for E_n with rank$(MW) = r$ ($E_n \times \mathrm{U}(1)^r \times$ (any non Abelian) massless gauge fields on 7-branes) and for E_{n-1} with rank$(MW) = r+1$ ($E_{n-1} \times \mathrm{U}(1)^{r+1} \times$ (any non Abelian) massless gauge fields on 7-branes), we cannot observe a clear tendency. There are as many $E_n \times \mathrm{U}(1)^r$ (i.e., more unified) vacua as $E_{n-1} \times \mathrm{U}(1)^{r+1}$ (i.e., less unified) vacua in this sample. Although we cannot hope to extract too many lessons from this study based on a miniature landscape, it may not be too outrageous to say that this statistics does not indicate that it is nonsense to study unified theories in compactifications.

CP Violation. Just like in earlier work such as [17], the miniature landscape in this section can also be used to study the fraction of vacua preserving CP symmetry. To be more specific, we study the fraction of CP preserving vacua in the class of effective theories containing $E_8 \times E_8$ gauge group from 7-branes. Such a formulation of the problem is meaningful, because we would eventually like to ask the fraction of CP-preserving/violating vacua in effective theories with the Standard Model gauge group. The choice of the gauge group — $E_8 \times E_8$ — is entirely for a technical reason. For most other choices of the gauge group, we would have to work out the $\mathcal{J}_2(X)$ classification for all the 34 attractive K3 surfaces appearing in table 2. It is known, however, (see [16, 26, 58, 59] or Footnote 49 for an explanation) that any attractive K3 surface admits an elliptic fibration whose frame lattice contains the $E_8 \oplus E_8$ lattice, so that there must be two fibres of type II^*.

In table 2, there are 66 pairs of attractive K3 surfaces $Y = S_1 \times S_2$ for M-theory compactifications. From these, one can find 98 choices of $Y = X \times S = X_{[a\ b\ c]} \times X_{[a'\ b'\ c']}$ for F-theory compactifications, where elliptic fibrations (with the vanishing volume of the fibre) are implemented in $X_{[a\ b\ c]}$. Exploiting the $\mathbb{Z}_2$ ⟨c.c.⟩ in the modular group Γ in (4.26), we can always take $b \geq 0$. We take these 98 different choices as the denominator (whole ensemble) of the statistics (see the cautionary remark at the end of this CP study).

In order to see when the low-energy effective theory possesses CP symmetry, let us write down the Gukov-Vafa-Witten superpotential (1.2), (2.22) explicitly in terms of local coordinates of the moduli space $\mathcal{M}_{K3}^{(S_1)} \times \mathcal{M}_{K3}^{(S_2)}$. Let $\Omega_{S_i}^{\rm tot}$ for $i = 1, 2$ be the total holomorphic $(2,0)$-form on the K3 surface S_i for $i = 1, 2$, including both the vacuum value and fluctuation around it:

$$\Omega_{S_i}^{\rm tot} = \langle \Omega_{S_i} \rangle + \delta\Omega_{S_i} = p_i + q_i(\tau_i + \widetilde{\Pi}_i) + C_I^{(i)} \delta\Pi_I^{(i)}, \qquad i = 1, 2\,. \tag{4.29}$$

JHEP04(2014)050

The Ω_{S_i} which appeared in section 2.1 corresponds to the vacuum value $\langle\Omega_{S_i}\rangle$ here, and $\{C_I^{(i)}\}_{I=1,\cdots,20}$ is a basis of the Neron-Severi lattice S_{S_i}. $\delta\Pi_I^{(i)}$ for $i=1,2$ and $I=1,\cdots,20$ combined are the independent local coordinates of $\mathcal{M}_{K3}^{(S_1)}\times\mathcal{M}_{K3}^{(S_2)}$, and $\widetilde{\Pi}_i$ are determined by the condition $(\Omega_{S_i}+\delta\Omega_{S_i})^2=0$. In practice,

$$\tau_1+\widetilde{\Pi}_1=\frac{-b+i\sqrt{Q_1+2c(\delta\Pi^{(1)})^2}}{2c}=\tau_1+\frac{i\sqrt{Q_1}}{2c}\left(\frac{c(\delta\Pi^{(1)})^2}{Q_1}-\frac{1}{2}\left(\frac{c(\delta\Pi^{(1)})^2}{Q_1}\right)^2+\cdots\right), \tag{4.30}$$

$$\tau_2+\widetilde{\Pi}_2=\frac{-e+i\sqrt{Q_2+2f(\delta\Pi^{(2)})^2}}{2f}=\tau_2+\frac{i\sqrt{Q_2}}{2f}\left(\frac{f(\delta\Pi^{(2)})^2}{Q_2}-\frac{1}{2}\left(\frac{f(\delta\Pi^{(2)})^2}{Q_2}\right)^2+\cdots\right), \tag{4.31}$$

where $(\delta\Pi^{(i)})^2$ is the norm of $C_I^{(i)}\delta\Pi_I^{(i)}$ under the symmetric pairing of the Neron-Severi lattices S_{S_i}. Substituting (4.29) into (1.2), (2.22), we obtain

$$W\propto\left(G_1,(\Omega_{S_1}^{\rm tot}\otimes\Omega_{S_2}^{\rm tot})\right) \tag{4.32}$$

$$\begin{aligned}&=\sqrt{Q_1Q_2}\Big[\mathrm{Re}(\gamma\tau_1\bar{\tau}_2)+\mathrm{Re}(\gamma)(\tau_1+\widetilde{\Pi}_1)(\tau_2+\widetilde{\Pi}_2)\\&\qquad-\mathrm{Re}(\gamma\bar{\tau}_2)(\tau_1+\widetilde{\Pi}_1)-\mathrm{Re}(\gamma\tau_1)(\tau_2+\widetilde{\Pi}_2)\Big],\end{aligned} \tag{4.33}$$

This potential contains mass terms of all the fluctuations,[42] as expected (moduli stabilization), and furthermore quartic and higher order interactions, as is known very well [16, 18, 22, 24].

Note first the vacuum expectation value of this superpotential vanishes. One can see this by expanding (4.33) in a power series of $(\delta\Pi^{(i)})^2$ and evaluating the zero-th order term. The vanishing vev of $W_{\rm GVW}$, however, is a straightforward consequence of choosing the four-form flux to be purely of $(2,2)$ type in the Hodge decomposition. It will be difficult to find a symmetry reason for this vanishing vev of $W_{\rm GVW}$ covering all the 66 pairs of $S_1\times S_2$ for M-theory compactification, or all the 98 choices of $X\times S$ for F-theory. It seems more appropriate to consider that the $\mathcal{D}=2$ condition (2.23) is essential, see the discussion right after (2.23) and (5.11), and also [17]. The integral structure of the flux quanta plays an essential role in determining the moduli vev through $W_{\rm GVW}$. Hence it is not appropriate to apply naive naturalness arguments of bottom up phenomenology.

In a subset of vacua where $b=e=0$ for M-theory ($b=b'=0$ for F-theory), both τ_1 and τ_2 are purely imaginary and the GVW superpotential becomes CP invariant when

[42] Chiral multiplets in the adjoint representation of the non-Abelian 7-brane gauge groups (in $W_{\rm root}$), i.e., transverse fluctuations of the 7-branes, also become massive because of this. This mass term, due to the G_1 type four-form flux, has nothing to do with the level-2 differential

$$d_2:[E_2^{0,1}=H^0(S;K_S)]\to[E_2^{2,0}=H^2(S;\mathcal{O}_S)] \tag{4.34}$$

that we encounter in the spectral sequence calculation in heterotic language [34, 79]. It is only the kernel of this d_2 that remains massless (in the absence of the G_1 type flux), but this d_2 is always trivial for the case of our interest, for reasons that are explained in [80].

JHEP04(2014)050

we choose γ to be either purely real or pure imaginary. In the first case, the two terms in the second line of (4.33) vanish, and all the terms in the superpotential have real valued coefficients. In the latter case, the two terms in the first line of (4.33) vanish, and all the remaining terms — those in the second line — have purely imaginary coefficients. With an appropriate phase redefinition of fermion fields (R-symmetry transformation), those coefficients can be made real valued. Thus, for these two case, all of the coefficients in the effective superpotential can be made real valued (by field redefinitions, if necessary), and CP symmetry is preserved. Following [17], we understand that the CP invariance in the former case is due to the compactification data $([a\ b\ c],[d\ e\ f],\gamma)$ invariant under the $\mathbb{Z}_2\,\langle$c.c.$\rangle$ subgroup of the modular group Γ, and is due, in the latter case, to the compactification data being invariant under the combination of the c.c. operation followed by a non-modular group symmetry operation (that somehow becomes an R-symmetry transformation).

Among the 66 pairs of attractive K3 surfaces in table 2, there are 20 pairs where $b = e = 0$ and γ is either purely real or purely imaginary. To turn this statistics into that of F-theory compactifications, note that among the 98 different ways of identifying the 66 pairs with $X \times S$ for F-theory, 30 different ways correspond to $b = b' = 0$ and a purely real/imaginary choice of γ. Although such precise values as 30/98 do not have much importance,[43,44] it will not be too outrageous to conclude that a non-negligible fraction of vacua possesses CP symmetry in the landscape of K3 × K3 compactifications of F-theory with all the 40 complex structure moduli stabilized by the G_1 type four-form flux. See also related discussion in section 5.

4.3.2 Stable degeneration "limit"

F-theory compactifications on $Y = \mathrm{K3}\times\mathrm{K3} = X\times S$ (without a four-form background) are dual to heterotic string compactifications on $Z = T^2\times\mathrm{K3}$ [30, 31, 52, 71, 79, 81–83]. From the heterotic string picture, one would naively expect that the Kaluza-Klein reduction of metric and B-field on T^2 gives rise to 4 massless U(1) vector fields in 7+1-dimensions, in addition to the at most rank-16 gauge group from either $E_8 \times E_8$ or SO(32). Since F-theory compactifications on an attractive K3 surface X have rank 20 gauge groups on 7-branes (two U(1)'s from T_X and rank 18 from W_{frame}), there is no mismatch in the rank of the gauge groups. It often happens in the miniature landscape we studied, however, that there are not more than four U(1) factors in the 7-brane gauge group. In tables 4

[43] It should be noted that we ignore the possibility that an attractive K3 surface may admit more than one type of elliptic fibration where $E_8 \times E_8 \subset W_{\mathrm{root}} \subset W_{\mathrm{frame}}$. In fact, one can find an example of this in section4.4 of [26]: the attractive K3 surface $X_{[3\ 0\ 2]}$ admits a pair of elliptic fibrations where W_{root} are the same, but their W_{frame} are not isometric. We also ignore multiple inequivalent choices of γ (G_1 type flux) and the number of isomorphism classes of elliptic fibrations. These factors should, in principle, be treated as a non-trivial weight on the 98 different choices in the main text. Thus, the precise value of the fraction of CP-invariant vacua does not have much importance.

[44] Complex conjugation $\mathbb{Z}_2\,\langle$c.c.$\rangle$ of the M-theory real 8-dimensional manifold is included as a part of the modular group (4.23), (4.26) in this article, while it is not in [17]. This subtle differences, however, only leads to at most a factor of 2 difference in the fraction of CP-preserving vacua. Given the other factors that we did not try to bring under control, this issue would not be particularly important from practical perspectives.

JHEP04(2014)050

and 5, for example, the rank of Mordell-Weil lattice is less than two (meaning that the number of U(1) gauge group is less than four) in a large fraction of the types of elliptic fibrations. By looking at the tables in [73], one can confirm that this phenomenon is not an artefact of requiring either one of E_6, E_7 or E_8 in the 7-brane gauge group. An appropriate interpretation of this phenomenon should be that the large fraction of attractive K3 surfaces in $\mathrm{Isom}^+(\Lambda_{\mathrm{K3}})\backslash D^{(X)}_{\rho=20}$ satisfying both the D3-tadpole condition (2.25) and the pure G_1-type assumption (2.18) does not correspond to the large $\mathrm{vol}(T^2)/\ell_s^2$ region of the heterotic string moduli space. In this case, the supergravity approximation is not valid and some of the non-Abelian 7-brane gauge groups should be understood as stringy effects in heterotic language.

Corresponding to the supergravity (large $\mathrm{vol}(T^2)/\ell_s^2$) "limit" in heterotic string theory is the stable degeneration "limit" of a K3 surface in F-theory [30, 31]. In this section, we discuss a couple of issues associated with this supergravity/stable degeneration "limit", based on the statistics in the miniature landscape. In this article, we mean by large/small "limit" of a moduli parameter xxx the region of moduli space where xxx is parametrically large/small, i.e., $\mathrm{xxx} \gg 1$ or $\mathrm{xxx} \ll 1$. However, we still assume xxx to be different from literally being ∞ or 0.

Let us begin with reminding ourselves of the following. Suppose that the elliptic fibration of a K3 surface $\pi_X : X \longrightarrow \mathbb{P}^1$ is given by the generalized Weierstrass form (or Tate form)

$$\begin{aligned} y^2 = {} & x^3 + x f_0 z^4 + g_0 z^6 \\ & + \epsilon_\eta (a^{\mathrm{v}}_{0*} z^5 + \epsilon_K^2 a^{\mathrm{v}}_{2*} x z^3 + \epsilon_K^3 a^{\mathrm{v}}_{3*} y z^2 + \epsilon_K^4 a^{\mathrm{v}}_{4*} x^2 z + \cdots) \\ & + \epsilon_\eta (a^{\mathrm{h}}_{0*} z^7 + \epsilon_K^2 a^{\mathrm{h}}_{2*} x z^5 + \epsilon_K^3 a^{\mathrm{h}}_{3*} y z^4 + \cdots) , \end{aligned} \tag{4.35}$$

where (x, y) are the coordinates of the elliptic fibre, z the inhomogeneous coordinate of the base $\mathbb{P}^1$, and f_0, g_0, a^{v}_{r*}'s ($r = 0, 2, \cdots$) and a^{h}_{r*}'s are complex numbers of order unity. In the heterotic dual, $\mathrm{vol}(T^2)/\ell_s^2$ is parametrically large when[45] $|\epsilon_\eta| \ll 1$, $|\epsilon_K| \lesssim \mathcal{O}(1)$. K3 surfaces with an elliptic fibration with small ϵ_η are said to be in the stable degeneration "limit" [30, 31].[46]

[45] The Wilson lines on T^2 are small, so the 8D field theory approximation is valid when one more condition, $|\epsilon_K| \ll 1$, is also satisfied.

[46] A family of K3 surfaces $\pi' : \mathcal{X}' \longrightarrow D$ was introduced in [31], where $D := \{t \in \mathbb{C} \mid |t| \leq 1\}$ is the unit disc, $\mathcal{X}'$ is given by $y^2 = x^3 + f_0 x z^4 + (g_0 z^6 + \epsilon_\eta a^{\mathrm{v}} z^5 + \epsilon_\eta a^{\mathrm{h}} z^7)$ defined as a subspace of (y, x, z, ϵ_η) for some complex valued parameters f_0, g_0, a^{v} and a^{h}. The morphism π' is defined by $\pi' : (y, x, z, \epsilon_\eta) \mapsto t = \epsilon_\eta$. Instead of this family of K3 surfaces, one can also consider another family $\pi : \mathcal{X} \longrightarrow D$ given by $\mathcal{X} := \{(\eta, \xi, u, v, t) \in \mathbb{C}^5 \mid \eta^2 = \xi^3 + f_0 \xi + (g_0 + a^{\mathrm{v}} u + a^{\mathrm{h}} v),\ uv = t\}$ (to be more precise, (η, ξ) and (u, t) are affine coordinates of projective space). The original family $\pi' : \mathcal{X}' \longmapsto D$ is regarded as the base change of order 2 of the second family $\pi : \mathcal{X} \longmapsto D$, $D \ni \epsilon_\eta \mapsto \epsilon_\eta^2 = t \in D$. Other coordinates are mapped by $(u, v) = (\epsilon_\eta / z, \epsilon_\eta z)$, $\eta = y/z^3$ and $\xi = x/z^2$. The second family shows a semistable degeneration, in that i) the threefold $\mathcal{X}$ is non-singular, and ii) the central fibre $X_0 := \pi^{-1}(t = 0)$ consists of two rational elliptic surfaces (a.k.a "dP_9") crossing normally along an elliptic curve at $u = v = 0$. See [84] for more information. Provided that f_0, g_0, a^{v} and a^{h} are generic, $X_t := \pi^{-1}(t)$ for any $t \in D$ has $\mathrm{II}^* + \mathrm{II}^*$-type singular fibre in the non-singular model at $(u, v) = (\infty, 0)$ and $= (0, \infty)$. The Weierstrass model version of this family has two ordinary $E_8 + E_8$ singularities.

JHEP04(2014)050

When $|\epsilon_\eta| \ll 1$, and the heterotic dual (in the supergravity approximation) corresponds to $E_8^{\rm v} \times E_8^{\rm h}$ theory with the structure group $G_{\rm str}^{\rm v} \times G_{\rm str}^{\rm h} \subset E_8^{\rm v} \times E_8^{\rm h}$, so that the unbroken symmetry group in the visible and hidden sector are $H^{\rm v} \times H^{\rm h}$, the non-$U_*$ part of the cohomology group of K3 surface X,

$$[U_*^\perp \subset H_2(X;\mathbb{Z})] \cong [U^{\oplus 2} \oplus E_8^{\oplus 2}] = {\rm II}_{2,18}\,, \tag{4.36}$$

contains $H^{\rm v} + G_{\rm str}^{\rm v} + U + U + G_{\rm str}^{\rm h} + H^{\rm h}$. The moduli spaces on both sides of the duality are identified by identifying the right-moving momenta (see appendix A for conventions on the description of T^2 compactification of heterotic string theory)

$$\mathcal{Z}^R := \sqrt{\frac{\alpha'}{2}}(k_8^R + i k_9^R) \in {\rm Hom}({\rm II}_{2,18}, \mathbb{C}) \tag{4.37}$$

in heterotic string theory with the period integral $\Omega^{\rm norm.} \in [U_*^\perp \subset \Lambda_{\rm K3}]^* \otimes \mathbb{C}$ satisfying the normalization[47]

$$(\mathcal{Z}^R, \overline{\mathcal{Z}^R}) = 2 \leftrightarrow (\Omega^{\rm norm.}, \overline{\Omega^{\rm norm.}}) = 2\,. \tag{4.38}$$

Parametrically large volume ${\rm vol}(T^2)/\ell_s^2$ with $\ell_s^2 := (2\pi)^2\alpha'$ in heterotic string theory corresponds to the behaviour

$$\mathcal{Z}^R|_{U\oplus U} \sim \frac{1}{\sqrt{2}}\left(\frac{\sqrt{\alpha'}}{R_8}, -\frac{R_8}{\sqrt{\alpha'}}, i\frac{\sqrt{\alpha'}}{R_9}, -i\frac{R_9}{\sqrt{\alpha'}}\right), \qquad \mathcal{Z}^R|_{G_{\rm str}^{\rm v}\oplus G_{\rm str}^{\rm h}} \sim \frac{\sqrt{\alpha'}}{R}\,, \tag{4.39}$$

while the period integral becomes

$$\Omega^{\rm norm.}|_{U\oplus U} \sim \frac{1}{\sqrt{2}}\left(\frac{1}{\sqrt{\ln(1/\epsilon_\eta)}}, \sqrt{\ln(1/\epsilon_\eta)}, \frac{1}{\sqrt{\ln(1/\epsilon_\eta)}}, \sqrt{\ln(1/\epsilon_\eta)}\right). \tag{4.40}$$

for small ϵ_η in F-theory. Hence the relation is ${\rm vol}(T^2)/\ell_s^2 \sim (R_8 R_9)/\alpha' \sim \ln(1/\epsilon_\eta)$ (see e.g. appendix B of [85]).[48]

Let us now study the distribution of vacua in the miniature landscape, focusing on whether the vacua are close to the stable degeneration "limit" of a K3 surface, or to the large large ${\rm vol}(T^2)/\ell_s^2$ "limit" in heterotic language. For this purpose, the volume in heterotic string theory can be defined easily and unambiguously by using the Narain moduli (see below), and we use this $[{\rm vol}(T^2)/\ell_s^2]_{\rm Het}$ as the parameter of distribution.

It is then more direct and convenient to deal with the F-theory data in terms of period integrals, rather than the defining equation(s) of K3, since we use the heterotic-F-theory

[47] For the period integral Ω, we can always take $\Omega^{\rm norm.} = \sqrt{2/(\Omega,\overline{\Omega})} \times \Omega$.

[48] In physics, it is an interesting question whether or not the $t = 0$ point should be included in the string-theory moduli space. Along a one-dimensional subspace parametrized by ϵ_η, the distance from a point with finite ϵ_η to the $\epsilon_\eta \longrightarrow 0$ limit diverges, when the metric from the Kähler potential $K = -\ln[\int \Omega \wedge \overline{\Omega}]$ is used (section 5 [72]). It is also impossible to stay within the period domain D while setting $\epsilon_\eta = 0$ (see (4.40)). Note also, however, that ϵ_η can always be absorbed by redefinition of the coordinates (y, x, z) in a special locus $a_0^{\rm h} = a_2^{\rm h} = \cdots = 0$. In this special locus, the K3 surface has a bad singularity in the fibre over the $z = \infty$ point in the base $\mathbb{P}^1$. Although this singularity can be removed by a birational transformation, the new geometry is a rational elliptic surface (where $c_1 \neq 0$), rather than a K3 surface. Physics implications of this mathematical facts should be considered separately.

JHEP04(2014)050

duality. Let us follow [16, 58, 59] and consider (for simplicity and concreteness) only the case in which the gauge groups in the visible and hidden sector E_8 both remain unbroken. For any attractive K3 surface $X = X_{[a\ b\ c]}$ with $T_X = \begin{bmatrix} 2a & b \\ b & 2c \end{bmatrix}$ there always exists such an elliptic fibration.[49] $T_X \oplus T_X[-1]$ forms a sublattice of $U \oplus U$, and $W_{\text{frame}} = E_8 \oplus E_8 \oplus T_X[-1]$. To be more explicit, let the oriented basis of T_X be $\{q, p\}$ and $T_X[-1] = \text{Span}_{\mathbb{Z}}\{Q, P\}$. Then we can embed T_X and $T_X[-1]$ primitively into $U \oplus U = \text{Span}_{\mathbb{Z}}\{v, V\} \oplus \text{Span}_{\mathbb{Z}}\{v', V'\}$ as[50]

$$(p, q, P, Q) = \left(v, V, v', V'\right) \begin{pmatrix} 1 & & -1 & \\ a & b & a & \\ & 1 & & -1 \\ & c & b & c \end{pmatrix} . \tag{4.41}$$

The period vector $\langle \Omega_X \rangle = (p + \tau_X q, \bullet)$ (with τ_X and Q_X given by τ in (2.8)) is written as

$$\langle \Omega_X \rangle \,|_{U\oplus U} = (v + (a + b\tau_X)V + \tau_X v' + c\tau_X V', \bullet) \Longrightarrow \langle \Omega_X^{\text{norm.}} \rangle = \sqrt{\frac{2c}{Q_X}}((a + b\tau_X), 1, c\tau_X, \tau_X) \tag{4.42}$$

in the component description of $[U \oplus U]^* \otimes \mathbb{C}$. This moduli data for F-theory is to be identified with

$$Z : \begin{pmatrix} n_1 \\ -w^1 \\ n_2 \\ -w^2 \end{pmatrix} \longrightarrow \frac{i}{\sqrt{2(\text{Im}\tau_H)(\text{Im}\rho_H)}}(-\tau_H, -\rho_H, 1, -\rho_H\tau_H) \begin{pmatrix} n_1 \\ -w^1 \\ n_2 \\ -w^2 \end{pmatrix} \tag{4.43}$$

modulo $\text{Isom}(U \oplus U)$. Here τ_H is the complex structure modulus of T^2 for heterotic string compactification and $\rho_H = (B + iJ)/\ell_s^2$ is the complexified Kähler modulus of T^2. With the condition (2.11), the best identification is [58, 59]

$$\tau_H \leftrightarrow \tau_X , \qquad \rho_H \leftrightarrow c\tau_X , \qquad \tau_H\rho_H \leftrightarrow -(a + b\tau_X) . \tag{4.44}$$

From this, we can read off that

$$\left[\frac{\text{vol}(T^2)}{\ell_s^2} = \text{Im}(\rho_H)\right]_{\text{Het}} = \left[\frac{\sqrt{Q_X}}{2} = \frac{\sqrt{4ac - b^2}}{2}\right]_F , \qquad |\rho_H| = \sqrt{ac} . \tag{4.45}$$

Vacua parametrically close to the stable degeneration limit (i.e., parametrically large $\text{vol}(T^2)/\ell_s^2$ for heterotic string theory) are realized when the attractive K3 surface is characterized by large ac or Q_X. There is an upper limit on the value of a and c, which comes from the D3-brane tadpole condition (2.25). For moderate choices of a, b and c, neither

[49] Indeed, we can always embed T_0 into one of the Niemeier lattices, $T_0 \hookrightarrow E_8 \subset E_8 + E_8 + E_8$, precisely in the same way T_0 is obtained, $T_0 := [T_X[-1]^\perp \subset E_8]$. The frame lattice then becomes simply $T_X[-1] + E_8 + E_8$. See [73] or section 4 of [26] for a more detailed explanation. No special condition on T_X needs to be satisfied for this fibration to exist in the $\mathcal{J}_2(X)$ classification.

[50] The symmetric pairing is given by $(v, V) = (v', V') = 1$, zero otherwise.

JHEP04(2014)050

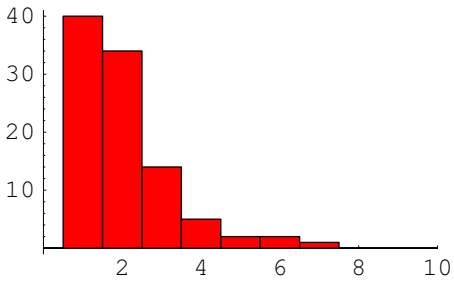

Figure 2. Distribution of $\sqrt{Q}/2 = [\mathrm{vol}(T^2)/\ell_s^2]_{\mathrm{Het}}$ in the miniature landscape (conditions (2.18), (2.25)) from F-theory on K3 × K3.

$|(a + b\tau)|$ nor $|c|$ are large, and hence the F-theory flux vacua are not attracted towards the region where the heterotic dual has a good supergravity approximation.

The distribution of $[\mathrm{vol}(T^2)/\ell_s^2]_{\mathrm{Het}}$, and hence of $\sqrt{Q_X}/2$ in F-theory, is determined and presented in figure 2, using the 98 different identifications of $S_1 \times S_2$ for M-theory in table 2 with $X \times S = X_{[a\ b\ c]} \times X_{[a'\ b'\ c']}$ for F-theory. It is clear that only a small fraction of vacua in the tail of the distribution in figure 2 are in the moduli space of K3 surfaces X in the stable degeneration "limit", or in the large $\mathrm{vol}(T^2)/\ell_s^2$ region of heterotic $E_8 \times E_8$ compactification.

This distribution can be regarded as that of an ensemble of effective theories containing $E_8 \times E_8$ 7-brane gauge groups (which are left unbroken), but it can also be regarded as that of theories with SO(32) 7-brane gauge group.[51]

For moderate choices of a, b and c, we should not expect that ϵ_K is small, either. In other words, all the period integrals in such a K3 surface either vanish or are of order unity. This means that there is no extra singular fibre located closely to a singular fibre supporting 7-brane non-Abelian gauge groups, like H^{v} and H^{h} in the visible and hidden sector. Correspondingly, the appropriate field theory local model is to take H^{v} and H^{h} as the gauge group everywhere[52] on the other K3 surface S.

Let us now turn our attention back to the defining equation (4.35) of the K3 surface. Certainly it is a better and more direct approach for a systematic search for the Noether-Lefschetz locus of Y to parametrize the moduli space by period integrals and deal with the lattices T_X, S_X etc., but it is also nice if we can figure out what kind of defining equations such vacua correspond to. Precisely the same problem has been addressed by [74, 86] for a specific class of K3 surfaces. In the following, we provide a simplified summary of their results so it fits to the context in this article.

[51] See footnote 49, and replace the lattice $L^{(\gamma)} = E_8 \oplus E_8 \oplus E_8$ with $L^{(\beta)} = E_8 \oplus D_{16}; \mathbb{Z}_2$. See [26] for more explanations.

[52] When Y is a non-trivial K3 fibration over some surface S, then there will usually be matter curves and possibly Yukawa points. That is where "singular fibres collide" and the field theory local model should be such that the rank of the gauge group is higher than that of H^{v} or H^{h} by (at least) 1 or 2, respectively [33, 87–89]. In the class of models studied in this article, however, such loci are absent because of the direct product structure $X \times S$.

JHEP04(2014)050

Consider an attractive K3 surface $X_{[2A\ 2B\ 2C]}$ (i.e., special case $a = 2A$, $b = 2B$ and $c = 2C$). Such a K3 surface corresponds to $\mathrm{Km}(E_{\rho_1} \times E_{\rho_2}) = (E_{\rho_1} \times E_{\rho_2})/\mathbb{Z}_2$ with

$$\rho_1 = \frac{-B + i\sqrt{4AC - B^2}}{2C}, \qquad \rho_2 = \frac{-B + i\sqrt{4AC - B^2}}{2} = C\rho_1\,. \tag{4.46}$$

E_{ρ_i} $(i = 1, 2)$ is an elliptic curve with the complex structure ρ_i, and we let its defining equation[53] be $y^2 = x(x-1)(x-\lambda_i)$. Kummer surfaces associated with a product type Abelian surface, which have $\rho_X = 18$, are known to have at least 11 different types of elliptic fibrations [75]. One of them (type 3 in [75]) has $2\mathrm{IV}^* + 8I_1$ type singular fibres (including two "E_6-type" fibres) in the Kodaira classification. Let us take this type of elliptic fibration as an example. Ref. [86] found that the Weierstrass model for this type of fibration (Inose's pencil) is given by

$$Y^2 = (X{+}4u^2)(X{+}4u^2(\lambda_1{+}\lambda_2))(X{+}4u^2\lambda_1\lambda_2){+}\frac{(4u^2)^3}{4}\left\{\frac{\lambda_2(\lambda_2{-}1)}{u}{+}\lambda_1(\lambda_1{-}1)u\right\}^2, \tag{4.48}$$

where u is the inhomogeneous coordinate on the base $\mathbb{P}^1$, or equivalently,

$$\tilde{Y}\left\{\tilde{Y}-(2u)^3\left(\frac{\lambda_2(\lambda_2{-}1)}{u}{+}\lambda_1(\lambda_1{-}1)u\right)\right\} = (X{+}4u^2)(X{+}4u^2(\lambda_1{+}\lambda_2))(X{+}4u^2\lambda_1\lambda_2)\,. \tag{4.49}$$

Tate's condition for a IV* fibre is satisfied at $u = 0$ and $u = \infty$. To turn this $\rho_X = 18$ K3 surface into an attractive K3 surface ($\rho_X = 20$), we only have to make a specific choice of ρ_1 and ρ_2 (and hence $\lambda_{1,2}$) in terms of integers A, B and C as in (4.46). The second equation above is already in the form of the generalized Weierstrass form (Tate form, (4.35)), apart from a shift in X that does not play an essential role.[54] The defining equation of the spectral surface can be read off from the Tate form: $a_0^{\mathrm{v}} = a_2^{\mathrm{v}} = 0$, and $a_3^{\mathrm{v}} y = 0$. Thus, in the language of the supergravity approximation of heterotic string theory, the $\rho_X = 20$ vacua of F-theory are realized due to spectral surfaces (gauge field configurations) which are far from generic and imply an intricate conspiracy among f_0, g_0, a_3^{v} and a_3^{h}. We will come back to this issue in section 5.3 and appendix B.

5 Landscapes of F-theory on K3 × K3 with $G_0 \neq 0$ flux

The study in the previous section is for a landscape with a limited choice of four-form flux; the condition (2.18) has been imposed. Consequently, the number of vacua is limited and the level of complexity of the analysis remains (barely) manageable. One can maintain full control of details, if one wishes, which enables us to understand various subtleties

[53] From the definition given in the main text, it follows that

$$\frac{2^{11}(\lambda_i^2 - \lambda_i + 1)^3}{(\lambda_i - 1)^2\lambda_i^2} = j(\rho_i) = q_i^{-1} + 744 + \mathcal{O}(q_i), \qquad q_i = \exp(2\pi i\rho_i)\,. \tag{4.47}$$

Thus, for large $\mathrm{Im}(\rho_i)$, small $|q_i|$ and large λ_i, $2^{11}\lambda_i^2 \sim e^{-2\pi i\rho_i}$.

[54] The stable degeneration "limit" corresponds to large A and C, and hence to large $\mathrm{Im}(\rho_2)$ and large $|\lambda_2|$. With the coordinate redefinition $\tilde{Y} \to \lambda_2^{9/2}\tilde{Y}'$, $X \to \lambda_2^3 X'$ and $u \to \lambda_2 u'$, one finds that $\epsilon_\eta \sim 1/\sqrt{\lambda_2}$, and hence $t = \epsilon_\eta^2 = 1/\lambda_2$.

JHEP04(2014)050

associated with multiplicity counting and the role played by the modular group. The $G_0 = 0$ assumption on the flux, however, has much to do with this advantage.

Suppose that $Y = X \times S$ for F-theory compactification is given by a pair of attractive K3 surfaces X and S, as in section 2.1. The G_0 type flux is then in $S_X \otimes S_S \otimes \mathbb{R}$ and can be written in the form

$$[G_0] = \sum_{I=1}^{18} C_I \otimes F_I \,, \tag{5.1}$$

where $\{C_I\}_{I=1,\cdots,18}$ is chosen as a basis of $W_{\rm root} \oplus W_{\rm U(1)} \subset W_{\rm frame} \subset S_X$ and $F_I \in S_S \otimes \mathbb{Q} \subset H^{1,1}(S;\mathbb{R})$. The gauge bosons corresponding to the Cartan part of the 7-brane gauge fields remain massless for a rank-rk_7 group when the $\{F_I\}$s span an $(18 - rk_7)$-dimensional subspace of $H^{1,1}(S;\mathbb{R})$. The rest of the Cartan gauge fields become massive through the Stückelberg mechanism. There will be $(18-rk_7)$ global U(1) symmetries left in the effective theory. Non-perturbative corrections break these symmetries, but they may still look like approximate symmetries if the non-perturbative corrections break them only weakly.

Therefore it is not a complete nonsense to focus on a sub-ensemble of vacua of F-theory on K3 × K3 with $G_{\rm tot} = G_1 + G_0$ flux of a given value of $(18 - rk_7)$ and to study the statistics of this sub-ensemble, as those compactifications share a common property of the resulting effective theories. In this context, the statistical results of the $G_0 = 0$ landscape in section 4.3 are also of some value. They are regarded as the statistics in the sub-ensemble characterized by the rank $rk_7 = 18$ massless gauge group on 7-branes and $\mathcal{N} = 1$ supersymmetry.

There is hence a physical motivation to study the statistics of the sub-landscape characterized by some properties of the G_0 flux, such as rk_7 (see sections 5.3 and 5.4 for more), and also to compare the numbers of vacua that have G_0 with different properties. These are the kind of problems we address in this section.

5.1 General remarks

5.1.1 Primitivity

Let us begin with a brief remark on the Kähler moduli. For supersymmetric compactifications, $G_{\rm tot} = G_1 + G_0$ not only has to be purely of Hodge type $(2,2)$, but also primitive:

$$J_Y \wedge G_{\rm tot} = J_Y \wedge G_0 = 0 \,. \tag{5.2}$$

The Kähler form J_Y on $Y = X \times S$ has the shape

$$J_Y = t_X [F_X] + J_S \,, \tag{5.3}$$

where $t_X \in \mathbb{R}_{0<}$, $[F_X]$ is the fibre class (elliptic divisor) associated with $\pi_X : X \to \mathbb{P}^1$, and J_S a Kähler form on S in the positive cone of S_S (i.e., $J_S \in S_S \otimes \mathbb{R}$, and $J_S^2 > 0$). The primitivity condition (5.2) implies that all of the F_I $(I = 1, \cdots, 18)$ are orthogonal to J_S in the inner product in $S_S \otimes \mathbb{R} \cong H^{1,1}(S;\mathbb{R})$. For a given Kähler form J_S, the G_0 type flux

JHEP04(2014)050

in $W_{\text{frame}*} \otimes [J_S^{\perp} \subset (S_S \otimes \mathbb{R})]$ always gives rise to a positive contribution — $1/2[G_0] \cdot [G_0]$ — to the D3-tadpole, since both W_{frame} and $[J_S^{\perp} \subset S_S \otimes \mathbb{R}]$ are negative definite.[55]

Because of the primitivity condition of the four-form flux, the complex structure moduli and Kähler moduli talk to each other. There are two equivalent ways to see how they "talk". One way is, to think of the Kähler moduli (t_X, J_S) as being given first, after which the F_I describing G_0 are forced to be in the subspace $[J_S^{\perp} \subset S_S \otimes \mathbb{Q}]$, as above. If the ratio of components of J_S are in $\mathbb{Q}$ — this situation is denoted by $[J_S] \in \mathbb{QP}[S_S]$ in this article — then $[J_S^{\perp} \subset S_S \otimes \mathbb{Q}]$ is of dimension [20-1=19]. If the ratio is not just in $\mathbb{Q}$, but in an extension field of $\mathbb{Q}$, then the dimension of the space for G_0 is smaller than 19. In the rest of this article, we assume that $J_S \in \mathbb{QP}[S_S]$. The other way is to think of the F_I as being given first. In this case, J_S is forced to be in the subspace of $S_S \otimes \mathbb{R}$ orthogonal to all of the F_I due to the D-term potential (e.g., [13, 22]). When the F_I span a $(18 - rk_7)$-dimensional subspace of $S_S \otimes \mathbb{Q}$, the remaining moduli space of J_S is of $(2 + rk_7)$-dimensions (in $\mathbb{R}$).[56,57] Eventually one has to think of stabilization of both complex structure moduli and Kähler moduli, so that these two perspectives are equivalent. Common to these two is the idea that the stabilization of the two groups of moduli can be dealt with separately, which is true as long as there is a separation of scales between those two stabilization mechanisms, such as in the KKLT scenario [90].

In this article, we focus on aspects of complex structure moduli stabilization in flux compactifications, using K3 × K3 as an example. This article is not committed to a particular mechanism of Kähler moduli stabilization available on K3 × K3, except that we implicitly assume this separation of scales. It is thus impossible to determine the full landscape distribution of completely discrete vacua in the product of complex structure and Kähler moduli spaces $\mathcal{M}_{\text{cpx}} \times \mathcal{M}_{\text{Kahler}}$ for K3 × K3, or projections of these distributions to $\mathcal{M}_{\text{cpx}}$, without introducing extra assumptions (on Kähler moduli stabilization). Our statements in the rest of this article are often presented in the form of distributions of flux vacua on $\mathcal{M}_{\text{cpx}}$ for a fixed choice of Kähler moduli.

5.1.2 Integrality

Let us now switch the subject, and discuss the "integrality condition" on $[G_1]$ and $[G_0]$. When both $[G_1]$ and $[G_0]$ are non-zero, each one of them does not have to be integral by itself; only the total flux $[G_{\text{tot}}] = [G_1] + [G_0]$ needs to be integral, i.e. an element of $H^4(Y; \mathbb{Z})$. Once we find that $[G_1]$ does not have to be integral — an element of $T_X \otimes T_S$ —

[55] It is not impossible to think of a case with some F_I not orthogonal to $J_S^{\perp}$. Such an F_I associated with C_I in W_{root} corresponds to non-anti-self-dual flux on a 7-brane wrapped on a K3 surface S, and is known to lead to a de-Sitter vacuum (if Kähler moduli is stabilized properly). If this negative contribution to the D3-brane tadpole — virtually the presence of an anti-D3-brane — coexists with a positive N_{D3}, we expect D3–D7 hybrid inflation to occur [91].

[56] $t_X \in \mathbb{R}_{0<}$ also remains unconstrained under the primitivity condition.

[57] As long as we keep the flux in the form of $G_0 = \sum_I C_I \otimes F_I$, a perturbation $\delta J = t_b[\sigma_X]$ of the Kähler form does not violate the primitivity condition. Thus, there is no mass given to this degree of freedom either. This mode, however, corresponds to a part of the metric, g_{33}, of the effective field theory on $\mathbb{R}^{3,1}$. Phenomenologically, we are interested in cases where the vacuum value of t_b is zero (the small elliptic fibre volume limit of M-theory), yet the fluctuation in that direction — g_{33} remains massless. Thus, there is no problem at all that the fluctuation t_b does not have a mass.

JHEP04(2014)050

on its own, the condition (2.21) is too restrictive. Contributions to the D3-brane tadpole, $[G_1]\cdot[G_1]/2$ and $[G_0]\cdot[G_0]/2$, are not necessarily integers separately either, though their sum is always integral, when $G_{\rm tot}$ is integral. This means that the search for pairs of attractive K3 surface in sections 2.1 and 2.2 needs to be carried out once again for cases with $G_0 \neq 0$. How large is the impact of this generalization?

In cases where both X and S are attractive K3 surfaces, we can decompose the 22×22-dimensional vector space $H^2(X,\mathbb{R})\times H^2(S,\mathbb{R})$ into

$$[(T_X\otimes T_S)\otimes\mathbb{R}]\ \oplus\ [(T_X\otimes S_S)\otimes\mathbb{R}]\ \oplus\ [(S_X\otimes T_S)\otimes\mathbb{R}]\ \oplus\ [(S_X\otimes S_S)\otimes\mathbb{R}]. \tag{5.4}$$

Such a decomposition is not necessarily possible with integer coefficients, not all of the elements of $H^2(X;\mathbb{Z})$ (resp. $H^2(S;\mathbb{Z})$) can be written in the form of a sum of integral elements in T_X and S_X (resp. T_S and S_S), and not all the elements in $H^2(X,\mathbb{Z})\times H^2(S,\mathbb{Z})$ can be written as a sum of integral elements in

$$[(T_X\otimes T_S)]\ \oplus\ [(T_X\otimes S_S)]\ \oplus\ [(S_X\otimes T_S)]\ \oplus\ [(S_X\otimes S_S)]. \tag{5.5}$$

The integrality of the total flux $[G]=[G_1]+[G_0]$, however, implies that for all the generators of $T_X\otimes T_S$ and $S_X\otimes S_S$, which are all integral four-cycles, the flux quanta evaluated on these cycles are integers. Hence $[G_1]$ and $[G_0]$ are contained within $(T_X\otimes T_S)^*=(T_X^*\otimes T_S^*)\subset(T_X\otimes T_S)\otimes\mathbb{Q}$ and $(S_X\otimes S_S)^*=(S_X^*\otimes S_S^*)\subset(S_X\otimes S_S)\otimes\mathbb{Q}$, respectively.[58] In particular, it follows that $[G_1]$ should be within $T_X^*\otimes T_S^*$, but may not necessarily be within $T_X\otimes T_S$.

In fact, there is a stronger necessary condition than this; although the projection of $H^2(S;\mathbb{Z})\subset T_S^*\oplus S_S^*$ to T_S^* for an attractive K3 surface is always surjective, the projection image of

$$(H^2(S_1;\mathbb{Z})\otimes H^2(S_2;\mathbb{Z}))\cap[H^{4,0}(Y;\mathbb{C})\oplus H^{2,2}(Y;\mathbb{R})\oplus H^{0,4}(Y;\mathbb{C})] \tag{5.6}$$

to $(T_{S_1}\otimes T_{S_2})^*$, for $Y=S_1\times S_2$ with a pair of attractive K3 surfaces S_1 and S_2, is not. In order to state a condition on the image of this projection, note that, for a pair of attractive K3 surfaces S_1 and S_2, the transcendental lattices, Neron-Severi lattices and their dual lattices have the following properties: as Abelian groups,

$$T_{S_i}^*/T_{S_i}\cong\mathbb{Z}_{m_i}\times\mathbb{Z}_{n_i},\qquad S_{S_i}^*/S_{S_i}\cong\mathbb{Z}_{m_i}\times\mathbb{Z}_{n_i},\qquad {}^{\exists}\gamma_i : T_{S_i}^*/T_{S_i}\cong S_{S_i}^*/S_{S_i}\qquad (i=1,2) \tag{5.7}$$

for some positive integers m_i, n_i. It then follows that

$$(T_{S_1}\otimes T_{S_2})^*/(T_{S_1}\otimes T_{S_2})\cong\mathbb{Z}_{m_1m_2}\times\mathbb{Z}_{m_1n_2}\times\mathbb{Z}_{n_1m_1}\times\mathbb{Z}_{n_1n_2}\,. \tag{5.8}$$

One can prove[59] that the image of the integral four-cycles in (5.6) has to be within the subgroup of $(T_{S_1}\otimes T_{S_2})^*$ characterized by

$$\mathrm{LCD}(m_1,m_2)\mathbb{Z}_{m_1m_2}\times\cdots\times\mathrm{LCD}(n_1,n_2)\mathbb{Z}_{n_1n_2}\subset\mathbb{Z}_{m_1m_2}\times\cdots\times\mathbb{Z}_{n_1n_2}\,. \tag{5.9}$$

[58] $T_X\otimes T_S$, $T_X\otimes S_S$, $S_X\otimes T_S$ and $S_X\otimes S_S$ form sublattices of the lattice $H^2(X;\mathbb{Z})\otimes H^2(S;\mathbb{Z})$.

[59] We are not presenting the proof here because it is just technical, and is not particularly illuminating. After all, this is not a sufficient condition. It is not guaranteed that an appropriate $G_0\in W_{\rm frame}\otimes[J_S^{\perp}\subset S_S]\otimes\mathbb{Q}$ exists and $G_1+G_0=G_{\rm tot}$ becomes integral, even when G_1 satisfies this criterion.

JHEP04(2014)050

Because of this necessary condition on $[G_1]$, one can see that $[G_1]$ still has to be an integral element of $T_X \otimes T_S$ if all the four pairs (m_1, m_2), (m_1, n_2), (n_1, m_2) and (n_1, n_2) are mutually coprime. In this case, all the possible forms of the $[G_1]$ component on a pair of attractive K3 surfaces $X \times S = S_1 \times S_2$ remain the same as in sections 2.1 and 2.2. When the four pairs of integers are not coprime, however, there are more chances for the $[G_1]$ component available in the (sublattice of) the $(T_X \otimes T_S)^*$ lattice than in the $T_X \otimes T_S$ lattice. That makes it easier to pass the D3-tadpole constraint (2.25), even for a pair of attractive K3 surfaces with relatively large values of a, c and d, f. Section 5.2 is devoted to an explicit enumerative study in order to see more of the consequences of this possibility of non-integral choice of G_1.

5.1.3 $\langle W_{\rm GVW} \rangle = 0$

When we write the $[G_1]$ component as $G_1 = \mathrm{Re}[\gamma \Omega_{S_1} \wedge \overline{\Omega}_{S_2}]$, as in [18] or in (2.22), it manifestly has only a $(2,2)$ Hodge component, without $(4,0)$ or $(0,4)$ component. However, we may also ask what is the statistical cost of requiring the absence of the $(4,0)+(0,4)$ components, or equivalently, a vanishingly small cosmological constant. For this purpose, the G_0 component is irrelevant and $[G_1] \in (T_{S_1} \otimes T_{S_2}) \otimes \mathbb{Q}$, which we can write as:

$$[G_1] = k_1(p_1 \otimes p_2) + k_2(p_1 \otimes q_2) + k_3(q_1 \otimes p_2) + k_4(q_1 \otimes q_2)\,, \tag{5.10}$$

where $k_1, k_2, k_3, k_4 \in \mathbb{Q}$ are not necessarily integers. The $(4,0)$ and $(0,4)$ Hodge components of $[G_1]$ are

$$\frac{\bar\tau_1\bar\tau_2 k_1 - \bar\tau_1 k_2 - \bar\tau_2 k_3 + k_4}{(\bar\tau_1 - \tau_1)(\bar\tau_2 - \tau_2)}\, \Omega_{S_1} \wedge \Omega_{S_2} + \frac{\tau_1\tau_2 k_1 - \tau_1 k_2 - \tau_2 k_3 + k_4}{(\bar\tau_1 - \tau_1)(\bar\tau_2 - \tau_2)}\, \overline{\Omega}_{S_1} \wedge \overline{\Omega}_{S_2}\,. \tag{5.11}$$

Thus, the absence of the $(4,0)+(0,4)$ component is equivalent to the condition that either $(\tau_1\tau_2)$, τ_1, τ_2 and 1 are not linear independent over the field $\mathbb{Q}$, or all of $k_{1,2,3,4}$ vanish (and $G_1 = 0$). For an arbitrary pair of attractive K3 surfaces S_1 and S_2, the period integrals take their values in $\mathbb{Q}[\tau_1, \tau_2]$, which is a degree $\mathcal{D} = 4$ algebraic extension field over $\mathbb{Q}$. The condition for this pair S_1 and S_2 to admit a flux with vanishing cosmological constant[60] (while $G_1 \neq 0$), however, has turned out to be that τ_2 is already contained in $\mathbb{Q}[\tau_1]$, and $\mathbb{Q}[\tau_1, \tau_2]$ is a degree $\mathcal{D} = 2$ extension field of $\mathbb{Q}$. The condition (2.23) is for $\langle W \rangle = 0$, for a general non-vanishing $[G_1]$ in $(T_X \otimes T_S) \otimes \mathbb{Q}$, rather than just for an integral $[G_1] \in (T_X \otimes T_S)$.

5.2 A landscape of vacua with a rank-16 7-brane gauge group

Just like the $G_0 = 0$ landscape in section 4.3, which is interpreted as the ensemble of vacua with rank-18 massless gauge fields on 7-branes, let us also consider the ensemble of F-theory compactifications on K3 × K3 with rank-16 massless gauge fields on 7-branes. This is realized by allowing a $G_0 \neq 0$ with only two terms non-zero in the expansion (5.1). With this study, we hope to elucidate various aspects of the landscape involving $G_0 \neq 0$. In

[60] A closely resembling phenomenon is found in section 4.2.3 of [17]. The extension degree changes from $\mathcal{D} = 4$ to $\mathcal{D} = 2$ for $W = 0$ vacua.

JHEP04(2014)050

the context of F-theory, there is not particular importance to the specific choice of having just two terms in (5.1), or equivalently $rk_7 = 16$. However, this choice makes it easier to link the present discussion to earlier results on type IIB orientifold landscapes, as discussed in section 5.4.

Suppose that $G_0 \neq 0$ flux is introduced by using some $C_{I=1}$ and $C_{I=2}$ in (5.1), where $C_{I=1,2}$ are elements of the frame lattice $W_{\rm frame}(X_{[a\ b\ c]})$ of some attractive K3 surface $X_{[a\ b\ c]}$. Then the gauge fields along the direction of $C_{I=1,2}$ become massive, and only the gauge fields within $[\{C_{I=1,2}\}^\perp \subset W_{\rm frame}]$ remain massless. Since it is motivated from the perspective of physics to collect vacua with a given unbroken gauge group, it will be interesting to consider, for a given rank-16 $= rk_7$ lattice $W_{\rm unbroken}$, the vacuum ensemble associated with

$$\Big\{(W_{\rm frame}, \{C_{I=1,2}\}) \mid W_{\rm frame} \in \amalg_{X_{[a\ b\ c]} \in {\rm Isom}(\Lambda_{\rm K3})\backslash D_{\rho=20}} \mathcal{J}_2(X_{[a\ b\ c]}), \quad C_{I=1,2} \in W_{\rm frame},\ [\{C_{1,2}\}^\perp \subset W_{\rm frame}] = W_{\rm unbroken}\Big\}\,. \tag{5.12}$$

For this reason, it also makes sense to use the notation $W_{\rm noscan}$ instead of $W_{\rm unbroken}$. These two are used interchangeably in section 5.2, but they are distinguished in section 5.4.

If we are to take the rank-16 lattice to be e.g. $W_{\rm unbroken} = E_8 \oplus E_8$ or $D_{16}; \mathbb{Z}_2\,\langle \mathbf{sp}\rangle$, then for all the attractive K3 surfaces X, there is an embedding[61] of the transcendental lattice T_X, the hyperbolic plane lattice $U_* \cong {\rm Span}_{\mathbb{Z}}\{[F_X], \sigma\}$ associated with elliptic fibration, and $W_{\rm unbroken}$ (which is an even unimodular lattice of signature $(0, 16)$) into the cohomology lattice $\Lambda^{(X)}_{\rm K3}$:

$$U_* \oplus (T_X \oplus T_X[-1]) \oplus W_{\rm unbroken} \hookrightarrow U_* \oplus (U \oplus U) \oplus W_{\rm unbroken} \cong \Lambda^{(X)}_{\rm K3}\,. \tag{5.13}$$

The Neron-Severi lattice is $S_X \cong U_* \oplus T_X[-1] \oplus W_{\rm unbroken}$, and the frame lattice is $W_{\rm frame} \cong T_X[-1] \oplus W_{\rm unbroken}$. Hence we choose the generators of the rank-2 lattice $T_X[-1] = [W^\perp_{\rm unbroken} \subset W_{\rm frame}]$ as $\{C_{I=1,2}\}$ [16, 24].

As another example of $W_{\rm unbroken}$, one can also think of $(D_4 \oplus D_4 \oplus D_4 \oplus D_4); (\mathbb{Z}_2 \times \mathbb{Z}_2)$, in which case a type IIB orientifold interpretation is given. It is known that there is an embedding[62]

$$(U[2] \oplus U[2]) \oplus (U_* \oplus W_{\rm unbroken}) \hookrightarrow \Lambda^{(X)}_{\rm K3}\,. \tag{5.14}$$

Furthermore, it is known that for attractive K3 surfaces $X_{[a\ b\ c]}$ with a, b, c even, there is an embedding $T_X \oplus T_X[-1] \hookrightarrow U[2] \oplus U[2]$ ([18, 61–63]). Thus, $W_{\rm frame} \cong T_X[-1] \oplus W_{\rm unbroken}$, and the generators of the rank-2 lattice $T_X[-1] = [W^\perp_{\rm unbroken} \subset W_{\rm frame}]$ are chosen as $\{C_{I=1,2}\}$s. [16, 24] Hence all the attractive K3 surfaces with even a, b, c contribute to the ensemble of vacua characterized by $W_{\rm unbroken} \cong (D_4^{\oplus 4}); (\mathbb{Z}_2 \times \mathbb{Z}_2)$.

[61] For an embedding of T_X into $U \oplus U$, $[T_X^\perp \subset U \oplus U]$ is not necessarily the same as $T_X[-1]$. For two even rank-2 lattices T_1 (positive definite) and T_2 (negative definite) with an isometric discriminant group, $U \oplus U$ can be constructed as an overlattice of $T_1 \oplus T_2$ [92].

[62] For Kummer surfaces associated with product type Abelian surfaces ($\rho_X = 18$), $X = {\rm Km}(E_\rho \times E_{\rho'}) = (E_\rho \times E_{\rho'})/\mathbb{Z}_2$, the Neron-Severi lattice is $S_X^{\rho=18} \cong U_* \oplus (D_4^{\oplus 4}); (\mathbb{Z}_2 \times \mathbb{Z}_2)$ and the transcendental lattice is $T_X^{\rho=18} \cong U[2] \oplus U[2]$.

JHEP04(2014)050

Let T_S be the transcendental lattice of the attractive K3 surface S. Modulo $\mathrm{Isom}(\Lambda_{\mathrm{K3}}^{(S)})$, it is always possible to embed T_S into $\Lambda_{\mathrm{K3}}^{(S)}$ as

$$T_S \hookrightarrow (T_S \oplus T_S[-1]) \hookrightarrow (U \oplus U) \oplus U \oplus E_8 \oplus E_8 \cong \Lambda_{\mathrm{K3}}^{(S)} . \tag{5.15}$$

This is not only always possible, but also unique in that any embedding to $\Lambda_{\mathrm{K3}}^{(S)} \cong \mathrm{II}_{3,19}$ (not to $\mathrm{II}_{2,18}$) can be brought in the form above modulo $\mathrm{Isom}(\Lambda_{\mathrm{K3}}^{(S)})$ [78]. Thus, $S_S \cong T_S[-1] \oplus U \oplus E_8 \oplus E_8$. Therefore, the flux $G_{\mathrm{tot}} = G_1 + G_0$ is introduced to the space[63]

$$[(T_X \otimes T_S)^* \oplus (T_X[-1] \otimes (T_S[-1] \oplus U \oplus E_8 \oplus E_8))^*] \cap H^2(X;\mathbb{Z}) \otimes H^2(S;\mathbb{Z}) . \tag{5.16}$$

Now, let us take the case $W_{\mathrm{unbroken}} = E_8 \oplus E_8$ as an example, and work out the details. In order to avoid inessential complexity, we restrict our attention to $Y = X \times S$ of the form $X_{[a\ b\ c]} \times X_{[a'\ b'\ c']}$ with $b = b' = 0$. Embeddings of (5.13), (5.15) are given by[64]

$$(p_1, P_1, q_1, Q_1) = (v_1, V_1, v_1', V_1') \begin{pmatrix} 1 & -1 & & \\ a & a & & \\ & & 1 & -1 \\ & & c & c \end{pmatrix} , \tag{5.17}$$

$$(p_2, P_2, q_2, Q_2) = (v_2, V_2, v_2', V_2') \begin{pmatrix} 1 & -1 & & \\ a' & a' & & \\ & & 1 & -1 \\ & & c' & c' \end{pmatrix} , \tag{5.18}$$

where $\{p_1, q_1\}$ (resp. $\{p_2, q_2\}$) are generators of T_X (resp. T_S), and $\{P_1, Q_1\}$ (resp. $\{P_2, Q_2\}$) are generators of $T_X[-1]$ (resp. $T_S[-1]$). The $(U \oplus U)$ sublattice of $\Lambda_{\mathrm{K3}}^{(X)}$ is generated by $\{v_1, V_1\}$ and $\{v_1', V_1'\}$, and that of $\Lambda_{\mathrm{K3}}^{(S)}$ by $\{v_2, V_2\}$ and $\{v_2', V_2'\}$. The intersection forms on the Us are given by $(v, v) = (V, V) = 0$ and $(v, V) = (V, v) = 1$.

It is now straightforward to enumerate the flux $G_{\mathrm{tot}} = G_1 + G_0$ in (5.16), using the basis give above:

$$\begin{aligned} G_1 = {} & \frac{n_{11}\mathrm{GCD}(a,a') + m_{11}}{2\mathrm{GCD}(a,a')}(p_1 \otimes p_2) + \frac{n_{22}\mathrm{GCD}(c,c') + m_{22}}{2\mathrm{GCD}(c,c')}(q_1 \otimes q_2) \\ & + \frac{n_{12}\mathrm{GCD}(a,c') + m_{12}}{2\mathrm{GCD}(a,c')}(p_1 \otimes q_2) + \frac{n_{21}\mathrm{GCD}(c,a') + m_{21}}{2\mathrm{GCD}(c,a')}(q_1 \otimes p_2), \end{aligned} \tag{5.19}$$

$$\begin{aligned} G_0 = {} & \frac{n_{11}\mathrm{GCD}(a,a') - m_{11}}{2\mathrm{GCD}(a,a')}(P_1 \otimes P_2) + \frac{n_{22}\mathrm{GCD}(c,c') - m_{22}}{2\mathrm{GCD}(c,c')}(Q_1 \otimes Q_2) \\ & + (P_1 \otimes F_P) + (Q_1 \otimes F_Q) \\ & + \frac{n_{12}\mathrm{GCD}(a,c') - m_{12}}{2\mathrm{GCD}(a,c')}(P_1 \otimes Q_2) + \frac{n_{21}\mathrm{GCD}(c,a') - m_{21}}{2\mathrm{GCD}(c,a')}(Q_1 \otimes P_2), \end{aligned} \tag{5.20}$$

[63] The $T_X[-1]$ part is meant to be $[W_{\mathrm{unbroken}}^{\perp} \subset W_{\mathrm{frame}}]$, which is the same as $T_X[-1]$ for all the three choices of W_{unbroken} mentioned in the text.

[64] This embedding can be used also for the case $W_{\mathrm{unbroken}} \cong D_{16}; \mathbb{Z}_2$, another even unimodular lattice of signature $(0, 16)$. For the case $W_{\mathrm{unbroken}} \cong (D_4^{\oplus 4}); (\mathbb{Z}_2 \times \mathbb{Z}_2)$, the embedding of $T_X = \mathrm{diag}[4A, 4C]$ and $T_X[-1]$ to $U[2] \oplus U[2]$ is given by the same expression, except that a and c are replaced by A and C.

JHEP04(2014)050

$$G_{\rm tot} = n_{11}(v_1\otimes v_2 + aa' V_1\otimes V_2) + m_{11}\frac{a' v_1\otimes V_2 + a V_1\otimes v_2}{\mathrm{GCD}(a,a')} + \cdots$$
$$+(P_1\otimes F_P) + (Q_1\otimes F_Q)\,. \tag{5.21}$$

Here, $n_{11}, m_{11}, \cdots, n_{22}, m_{22}$ are integers and $F_P, F_Q \in U\oplus E_8\oplus E_8 \subset \Lambda^{(S)}_{\rm K3}$. The denominators $\mathrm{GCD}(2a, 2a')$, $\mathrm{GCD}(2c, 2c')$ etc. in (5.19), (5.20) correspond to our earlier discussion around (5.9). G_1 and G_0 are not necessarily integral separately, but $G_{\rm tot}$ is. At this moment, it is not guaranteed that the $(4,0)+(0,4)$ Hodge components vanish. After imposing the $\langle W\rangle = 0$ condition, one is left with the following cases

i) $\mathcal{D} := \dim_{\mathbb{Q}} \mathbb{Q}[\tau_1, \tau_2] = 2$, i.e., the condition (2.23) is satisfied when $G_1 \neq 0$ and there are $(8-\mathcal{D}) = 6$ independent integers out of $\{n_{11}, \cdots, m_{22}\}$, in addition to F_P, F_Q. In this case there are $\mathcal{D} = 2$ less scanning integers just like in sections 2.1), (2.2 and [18].

ii) $\mathcal{D} = 4$, when $G_1 = 0$, and there are $(8-\mathcal{D}) = 4$ independent integers as well as F_P, F_Q (the "second branch" in section 5 of [22]).

The latter ii) cases leave 16 moduli of X and 18 of S unstabilized, and we restrict our attention only to the cases i) ,as [18] did, in the following.

Note, however, that the Kähler form and the primitivity condition on the flux has been ignored completely in the argument above. The Kähler form J_S on S needs to be introduced in the positive definite part of $[T_S^{\perp} \subset \Lambda_{\rm K3}]\otimes\mathbb{R}$, and the flux G_0 component has to be orthogonal to this J_S. We provide the following presentation for a fixed choice of J_S (rather than scanning over all possible J_S), and in particular, we choose

$$J_S = t_S(v_2'' + V_2'')\,, \tag{5.22}$$

where v_2'' and V_2'' are the generators of the third copy of the hyperbolic plane lattice U in $\Lambda^{(S)}_{\rm K3}$ in (5.15), so that the computation becomes as easy as possible. This means that the primitivity condition does not impose a constraint on the integers $\{n_{11}, \cdots, m_{22}\}$, and F_P, F_Q are chosen from the negative definite lattice $(-2)\oplus E_8\oplus E_8$. Here, (-2) is the lattice generated by $(v_2'' - V_2'')$, where $(v_2'' - V_2'')^2 = -2$.

Assuming that $W_{\rm unbroken} = E_8\oplus E_8$ (or $D_{16}; \mathbb{Z}_2\,\langle \mathbf{sp}\rangle$), we scan all possible pairs of attractive K3 surfaces of the form $X_{[a\ 0\ c]}\times X_{[a'\ 0\ c']}$ and list up all the possible fluxes (5.19), (5.20) satisfying (i) the condition that $\langle W\rangle = 0$, (ii) the primitivity condition with respect to the Kähler form (5.22) and (iii) the D3-tadpole condition

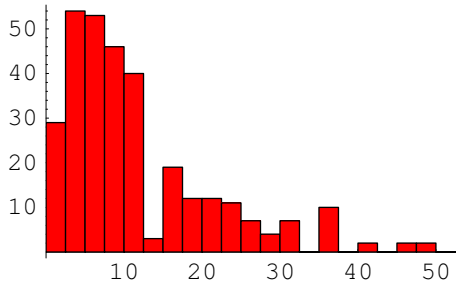
$$\frac{1}{2}G_{\rm tot}\cdot G_{\rm tot} \leq \frac{\chi(X\times S)}{24} = 24\,; \tag{5.23}$$

the remaining D3-brane charge is supplied by placing an appropriate number of D3-branes.

Scanning within the range of $0 < c \leq a \leq 50$ and $0 < c' \leq a' \leq 50$ for $Y = X\times S = X_{[a\ 0\ c]}\times X_{[a'\ 0\ c']}$, we found that there are 313 different choices of $X\times S$ admitting the flux satisfying all the three conditions above. The distribution of the value of a in these 313 choices are shown in figure 3. If both G_1 and G_0 were required to be integral, there would only be 28 different choices,[65] and the largest possible value of a would be 6.

[65] There are 8 pairs of $[a\ 0\ c]$ and $[d\ 0\ f]$ where $a = d$ and $c = f$ in table 2, and there are 10 pairs where either $a \neq d$ or $c \neq f$. Thus, there are $28 = 8 + 2\times 10$ different choices of $([a\ 0\ c], [a'\ 0\ c'])$.

JHEP04(2014)050



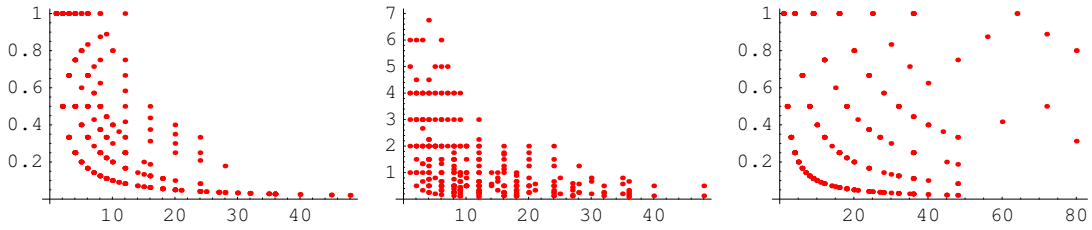


Figure 3. Variety in the choice of pairs of attractive K3 surfaces, $X \times S = X_{[a\ 0\ c]} \times X_{[a'\ 0\ c']}$ is shown in the form of histograms of $a \leq 50$. This distribution is not weighted by the number of flux choices available.

(i) a vs c/a (ii) a vs a'/a (iii) ac vs c/a

Figure 4. Scatter plots showing correlation between various modulus parameters X (horizontal axis) vs Y (vertical axis) for the 313 pairs of attractive K3 surfaces $X \times S = X_{[a\ 0\ c]} \times X_{[a'\ 0\ c']}$. No weight proportional to the number of flux choices is included. (the blank region in the lower right corner of (iii) is an artefact of cutting the scan at $a, a' \leq 50$).

Figure 4 shows the correlation among moduli parameters for the 313 pairs of attractive K3 surfaces admitting a flux satisfying all the three conditions above. For the first two scatter plots (i) and (ii) of figure 4, we can see clear correlations. When a is very large, there is presumably not much freedom to choose a' other than setting it to be comparable to a itself (see (ii)), so that GCD(a, a') is large, and the D3-tadpole contribution remains below the bound. On the other hand, there is no clear correlation to be read out from the plot (iii), we will have a comment on this in section 5.4.

There is a tremendous amount of combined choices of $X \times S = X_{[a\ 0\ c]} \times X_{[a'\ 0\ c']}$ and the fluxes on it. We found about 795×10^{15} choices satisfying all the three conditions on the flux by naively scanning $\{n_{ij}, m_{ij}, F_P, F_Q\}$ (apart from identification $\{n_{ij}, m_{ij}, F_P, F_Q\} \longleftrightarrow (-1) \times \{n_{ij}, m_{ij}, F_P, F_Q\}$). This large ensemble is dominated by the flux choices on a very small group of possibilities of $X_{[a\ 0\ c]} \times X_{[a'\ 0\ c']}$. There are about 777×10^{15} choices of flux for $X_{[1\ 0\ 1]} \times X_{[1\ 0\ 1]}$, 98% of the ensemble. Almost 99.6% of the ensemble is accounted for when we combine all the flux choices on $X_{[1\ 0\ 1]} \times X_{[1\ 0\ 1]}$, $X_{[2\ 0\ 1]} \times X_{[2\ 0\ 1]}$, $X_{[2\ 0\ 2]} \times X_{[1\ 0\ 1]}$, $X_{[1\ 0\ 1]} \times X_{[2\ 0\ 2]}$ and $X_{[2\ 0\ 2]} \times X_{[2\ 0\ 2]}$.

It is a fluke, though, that the statistics is dominated by a small number of pairs of attractive K3 surfaces. The large number of flux choices for $X_{[a\ 0\ c]} \times X_{[a'\ 0\ c']}$ with small

JHEP04(2014)050

values of a, c, a', c' is primarily due to[66] F_P, F_Q in $(-2) \oplus E_8 \oplus E_8 \subset \Lambda^{(S)}_{\rm K3}$. It is possible for such pairs of K3 surfaces to find a flux $(G_1 + G_0)$ on $(T_X \oplus T_X[-1]) \otimes (T_S \oplus T_S[-1])$ so that the contribution to the D3-tadpole is much smaller than 24. There is a lot of room left in the tadpole condition for an extra G_0-type flux in $T_X[-1] \otimes ((-2) \oplus E_8 \oplus E_8)$. It should be remembered that we should take a quotient of flux configurations on $X \times S = X_{[a\ 0\ c]} \times X_{[a'\ 0\ c']}$ (and elliptic fibration morphisms) by the subgroup of Γ that fixes the embeddings of $U_* \oplus T_X$ and T_S in (5.13), (5.15) and J_S in (5.22). Included in this stabilizer subgroup is $W_{E_8} \times W_{E_8}$, the Weyl group of $E_8 \oplus E_8 \subset \Lambda^{(S)}_{\rm K3}$.

The Weyl group W_{E_8} acts on the 240 roots transitively. We have also confirmed that the norm (-4), (-6), (-10) and (-12) points form single orbits of W_{E_8} on their own. There are at most two W_{E_8} orbits in the norm (-8) points, norm (-14) points and also in the norm (-16) points.[67] Thus, it is not a particularly bad estimate (for the counting of inequivalent flux vacuum) to assume that all the norm $(-2m)$ points in the E_8 root lattice form a single orbit of W_{E_8} for relatively small m such as $m \leq 12$, which is the range that matters under the tadpole condition (5.23). With this crude approximation of the modular group Γ action on fluxes, the total number of "inequivalent" choices of $X \times S = X_{[a\ 0\ c]} \times X_{[a'\ 0\ c']}$ and fluxes $G_{\rm tot}$ combined is reduced to about 7×10^6. About 80% of this ensemble of "inequivalent" vacua still come from fluxes on $X \times S = X_{[1\ 0\ 1]} \times X_{[1\ 0\ 1]}$, and the totality of the flux choices on the five $X \times S$ mentioned above (those with small a, c, a', c') account for 92%. Although the precise percentage values should not be taken too seriously because of the crude estimate of the modular group action (and artificial choice of J_S), it is trustable at the qualitative level that the vacuum statistics of K3 × K3 compactifications of F-theory with a $rk_7 = 16$ 7-brane gauge group $W_{\rm unbroken}$ is dominated by a small number of $X \times S = X_{[a\ b\ c]} \times X_{[a'\ b'\ c']}$ which have small values of a, c, a', c' so that the minimum possible value of $G^2_{\rm tot}/2$ is small. Consequently, the distribution of any observables/moduli parameters (such as $\mathrm{Im}(\rho_H) = \sqrt{ac}$) is determined simply by that of $X \times S = X_{[1\ 0\ 1]} \times X_{[1\ 0\ 1]}$ and a few others.

Before closing this section, it is worthwhile to mention that non-zero flux $G_{\rm tot} = G_1 + G_0$ does not imply that all the $18 + 20$ complex structure moduli in $\mathcal{M}^{(X)}_{{\rm K3};F} \times \mathcal{M}^{(S)}_{\rm K3}$ are stabilized. The mass matrix (quadratic part of the superpotential) can be written in the form of

$$\propto \frac{1}{2} \left(\delta\Pi^{(1)}, \delta\Pi^{(2)}\right) \begin{pmatrix} -\mathrm{Im}(\tau_2)\sqrt{Q_2}\gamma & C_I) \otimes (F_I \\ F_I) \otimes (C_I & -\mathrm{Im}(\tau_1)\sqrt{Q_1}\overline{\gamma} \end{pmatrix} \begin{pmatrix} \delta\Pi^{(1)} \\ \delta\Pi^{(2)} \end{pmatrix}, \tag{5.24}$$

where $\delta\Pi^{(X)}$ has 18 components on $W_{\rm frame}$ and $\delta\Pi^{(S)}$ 20 components on S_S. Mass terms in the diagonal block are from (4.33), while the off-diagonal block is due to the G_0 type flux. All the moduli would have non-zero masses if $G_1 \neq 0$ and G_0 were absent (and similarly, full rank G_0 type flux with $rk_7 = 0$ and vanishing G_1 would stabilize all but two complex structure moduli). When both are present, however, the diagonal masses from G_1 and

[66] The 240 roots of E_8 are the norm (-2) points on the E_8 root lattice; there are 2160 points of norm (-4) in the E_8 lattice, and the number of norm $(-2m)$ points scale as m^3 There are 490560 points of norm (-24) in the E_8 lattice [93]. These numbers were used in obtaining the flux choices of order 795×10^{15}.

[67] This is done by computing the $\mathrm{diag}(H_4, H_4)$ action on W_{D_8} orbits, see [93] for more information.

JHEP04(2014)050

off-diagonal masses from G_0 interfere and there may be a zero mass-eigenvalue (and an unstabilized direction of the moduli space) in principle.

One example is to choose $n_{ij} = 0$, $m_{11} = m_{12} = m_{22} = -m_{21} = 1$ and $F_P = F_Q = 0$ in (5.19), (5.20) for a series of infinite pairs of attractive K3 surfaces $X \times S = X_{[k\ 0\ k]} \times X_{[k\ 0\ k]}$ (where $k = 1, 2 \cdots, \infty$). Under this choice of the flux, a one parameter (k) deformation of the complex structure $\Omega_X \wedge \Omega_S = [(v_1 + kV_1) + i(v_1' + kV_1')] \otimes [(v_2 + kV_2) + i(v_2' + kV_2')]$ remains a flat direction, and all the $\rho_X = \rho_S = 20$ points $X_{[k\ 0\ k]} \times X_{[k\ 0\ k]}$ just sit in this flat direction.

Such flux vacua with an unstabilized direction have been removed from the vacuum ensemble studied in this section. To be more precise, our numerical code examined the 4×4 mass matrix on $P_1 \delta\Pi^{(1)}_{P_1} + Q_1 \delta\Pi^{(1)}_{Q_1}$ and $P_2 \delta\Pi^{(2)}_{P_2} + Q_2 \delta\Pi^{(2)}_{Q_2}$, and threw away all the flux configurations for which there is a zero eigenvalue in this mass matrix. Certainly, one should examine the eigenvalues of a $(18 + 20) \times (18 + 20)$ mass matrix for each flux configuration,[68] but we believe that our short-cut approach does not qualitatively distort the distribution of observables in the landscape.

5.3 U(1) flux, heterotic-F-theory duality, and GUT 7-brane flux

The unbroken symmetry W_{unbroken} of interest for a sub-ensemble of vacua can be chosen at one's will. We can choose it to be rank-18 as in sections 2.1, 2.2 and 4.3, or to be rank-16 as in section 5.2, but other choices such as $W_{\text{unbroken}} \cong A_4$, a $\text{SU}(5)_{\text{GUT}}$ landscape, are just as appropriate.

Studies such as the one in section 5.2 are dedicated to a landscape of vacua of individual choices of W_{unbroken}, which we call the W_{unbroken} landscape. Beyond such an analysis, however, it is natural to ask such questions as how properties of the algebraic information W_{unbroken} generally characterize distributions within the W_{unbroken}-landscape, or how the number of vacua in the W_{unbroken}-landscape depends on W_{unbroken}. As a preparation for such a discussion in section 5.4, we make a few remarks in this section.

When we write down the G_0 type flux in the form (5.1), we can take the generators $\{C_I\}_{I=1,\cdots,18}$ of $W_{\text{frame}*}$ to be such that some are from $W_{\text{U}(1)}$, and others from W_{root}. We call the G_0 flux with C_I from $W_{\text{U}(1)}$ a U(1) flux or Mordell-Weil flux, and that with C_I from W_{root} a GUT-brane flux or singular fibre flux. The GUT 7-brane flux corresponds to the line bundles introduced on GUT 7-branes in F-theory (such as those in [94]), or line bundles on a stack of multiple D7-branes in type IIB Calabi-Yau orientifolds. The U(1) flux requires [20] a special choice of complex structure so that there is a non-vertical *algebraic* cycle, meaning that the Mordell-Weil group is non-trivial; the unavoidable tuning of complex structure is an expression equivalent to moduli stabilization.

5.3.1 U(1) flux/Mordell-Weil flux

Let us first ask what the U(1) flux looks like in the light of the duality between F-theory and heterotic string theory. As discussed in the literature (such as [32–34]), there must be

[68] In the case of $rk_7 = 16$, this problem is reduced to that of a $(2 + 20) \times (2 + 20)$ matrix, since the mass matrix of the moduli $\delta\Pi^{(1)}$ in W_{unbroken} does not interfere with the rest.

JHEP04(2014)050

a component of four-form U(1) flux in F-theory whose origin in heterotic string is a flux on the spectral surface. Suppose that $\pi_Z : Z = T^2 \times S \longrightarrow S$ is the elliptically fibred Calabi-Yau threefold for the dual heterotic string compactification, and $(C, \mathcal{N})$ the spectral data describing the vector bundle on Z. The spectral surface C is a subspace of $Z = \mathrm{Jac}(T^2) \times S$ characterized by the zero points of the elliptic functions

$$a_0^{\mathrm{v}} + a_2^{\mathrm{v}} x + a_3^{\mathrm{v}} y + \cdots = 0, \qquad a_0^{\mathrm{h}} + a_2^{\mathrm{h}} x + \cdots = 0 \tag{5.25}$$

on T^2, and $\mathcal{N} = \mathcal{O}_C(\gamma)$ is a line bundle on C specified by a divisor γ on C. *For any complex structure* of Z, S and C [30], one can always find a divisor

$$\gamma_{\mathrm{FMW}} \propto (n\sigma - \pi_C^*(nK_S + \eta)) \,, \tag{5.26}$$

where $\pi_C = \pi_Z|_C$, η is a divisor on S, K_S the canonical divisor of S, and we assume $\mathrm{SU}(n) \subset E_8^{\mathrm{vis}}$ is the structure group of the vector bundle. None of the U(1) fluxes we talk about here, however, should correspond to this Friedman-Morgan-Witten flux in the heterotic "dual". If this flux were to be dual to the U(1) flux in F-theory, we would run into a contradiction immediately: an arbitrary complex structure is allowed on the heterotic side, while it has to be tuned in F-theory. In fact, the generic Friedman-Morgan-Witten flux (5.26) always vanishes, $\gamma = 0$, when the dual F-theory is a K3 $\times$ K3 compactification.

For finely tuned complex structure of the heterotic string compactification data, (Z, S, C), however, there is more variety in the choice of γ on the spectral surface [30]. Suppose that the base K3 surface S is not the general complex analytic one, but has Picard number $\rho_S \geq 2$. This means that we might be able to find a set of $\{F_A\} \subset [J_S^{\perp} \subset S_S]$ generating a rank-k sublattice of S_S. We only consider vector bundles with the structure group contained in $G_{\mathrm{str}}^{\mathrm{v}} \times G_{\mathrm{str}}^{\mathrm{h}} = \mathrm{SU}(N_v) \times \mathrm{SU}(N_h)$. It then appears that we can think of a vector bundle for compactification,

$$V = \oplus_{i=1}^{N_v+N_h} \mathcal{O}_S(D_i) \otimes \mathcal{O}_{T^2}(p_i - e), \qquad D_i = \sum_A n_{(i)}^A F_A \,, \tag{5.27}$$

where the $\{p_i\}$ and e are the zeros and the pole, respectively, of the elliptic functions (5.25). The spectral surface is of the form $C = \cup_i C_{p_i}$ with $C_{p_i} \simeq S$'s corresponding to $p_i \in \mathrm{Jac}(T^2)$, and $\gamma|_{C_{p_i}} = D_i$. This vector bundle is poly-stable with respect to the Kähler form $J_Z = J_{T^2} + J_S$. The unbroken symmetry should be $E_{9-N_v}^{\mathrm{v}} \times E_{9-N_h}^{\mathrm{h}}$ within $E_8 \times E_8$. Moduli parameters include ρ_H and τ_H of T^2, and $(N_v - 1) + (N_h - 1)$ parameters of the flat bundles in (5.25), and hence,in addition to those from the base S, there are $N_v + N_h$ of them.

Dual to this heterotic string compactification should be F-theory on $Y = X \times S$ where the elliptically fibred K3 surface X has the following Neron-Severi and transcendental lattices:[69]

$$\Lambda_{\mathrm{K3}}^{(X)} \supset S_X \oplus T_X = [U_* \oplus E_{9-N_v} \oplus E_{9-N_h}] \oplus [U \oplus U \oplus A_{N_v-1} \oplus A_{N_h-1}] \,. \tag{5.28}$$

K3 surfaces X of this form have Picard number $\rho_X = (20 - N_v - N_h)$, so that the moduli space has dimension $(N_v + N_h)$, which agrees with the counting above. If we are to find

[69] A detailed description of the transcendental lattice is found in [85] for the case of $N_v = 3$.

JHEP04(2014)050

a four-form flux in F-theory dual to γ, that dual flux must be associated with non-U_* cycles that are orthogonal to the unbroken symmetry part $E_{9-N_v} \oplus E_{9-N_h}$. This means that the flux is not in an algebraic cycle, and such a configuration is not stable. The complex structure moduli dynamically tune themselves (due to the GVW potential) so that the associated cycle becomes algebraic. In order to introduce k independent U(1) fluxes in (5.1), the number of unstabilized directions in the moduli space should be reduced by k, and the moduli space becomes $(N_v + N_h - k)$-dimensional [20].[70]

This reduction of the moduli space should also be understandable in the heterotic string description. Certainly V in (5.27) is a holomorphic vector bundle and satisfies the condition $\int J \wedge J \wedge F = 0$ as well as the Bianchi identity of the B-field,

$$0 = \operatorname*{tr}_{\mathfrak{so}(6)} \left[\left(\frac{R}{2\pi} \right)^2 \right] - T_R^{-1} \operatorname{tr}_R \left[\left(\frac{F}{2\pi} \right)^2 \right] + 4\delta^{(4)}_{M5} = 4 \left(-c_2(TZ) - \mathrm{ch}_2(V) + \delta^{(4)}_{M5} \right) , \quad (5.29)$$

where $\delta^{(4)}_{M5}$ is the delta-function valued four-form associated with individual M5-branes wrapped on holomorphic curves in $Z = T^2 \times S$, and $\mathrm{ch}_2(V)$ is the second Chern character of the rank $(N_v + N_h)$ vector bundle V (with the structure group $\mathrm{SU}(N_v) \times \mathrm{SU}(N_h)$). There is a condition that is stronger than (5.29), however:

$$0 = H := dB + \frac{\alpha'}{4} \left(\mathrm{tr} \left[\omega d\omega + \frac{2}{3} \omega\omega\omega \right] - T_R^{-1} \mathrm{tr}_R \left[AdA - i\frac{2}{3} AAA \right] \right) + (\mathrm{source})_{M5} , \quad (5.30)$$

if we are to stick to the framework of heterotic string compactification on a Kähler manifold and constant dilation configuration (Chap.16, [95]). This constraint may also be understood as a combination of the F-term condition of

$$W_{\mathrm{Het}} \propto \int_Z \Omega_Z \wedge H + (2\pi)^2 \alpha' \int_{\Gamma(M5)} \Omega_Z \quad (5.31)$$

with respect to the complex structure moduli of Z and $\langle W_{\mathrm{Het}} \rangle = 0$ for vanishing cosmological constant.[71] $\Gamma(M5)$ is a real 3-chain in $Z = T^2 \times \mathrm{K3}$ whose boundary contains the curves on which M5-branes are wrapped [96]. The exterior derivative of this condition (5.30) reproduces (5.29).

The B-field Bianchi identity, (5.29), can be satisfied by wrapping an appropriate number (N_{M5}) of heterotic NS5-branes (M5-branes in heterotic M-theory) on the fibre T^2. As is well-known in the literature,

$$c_2(TZ) = (24\ \mathrm{pt}_{K3}) \otimes 1_{T^2}, \qquad \mathrm{ch}_2(V) = \frac{1}{2} \sum_{i=1}^{N_v+N_h} (D_i)^2 , \quad (5.32)$$

and the only non-trivial part, which is a four-form on S and scalar on T^2, of the condition (5.29) gives rise to

$$\frac{1}{2}(G_H^{(4)})^2 + N_{M5} = 24 . \quad (5.33)$$

[70] On top of this, G_1 type flux is introduced to fix the remaining moduli. But in the context of heterotic-F-theory duality, we take the G_1 component out of the picture (or assume that it is absent).

[71] Flux of Friedman-Morgan-Witten type γ (5.26) does not vanish in the case of a general Calabi-Yau threefold Z with elliptic fibration (although it vanishes in the present case). This type of flux, however, does not restrict complex structure moduli because it induces a vanishing Chern-Simons term.

JHEP04(2014)050

Here, $G_H^{(4)}$ takes values in the lattice[72] $(A_{N_v-1} \oplus A_{N_h-1}) \otimes [J_S^\perp \subset S_S]$, and is given by

$$G_H^{(4)} = \sum_{I=1}^{N_v-1} C_I \otimes D_I + \sum_{I=1}^{N_h-1} C_I \otimes D_I, \qquad D_I = -(D_{i=1} + \cdots + D_{i=I})\,. \tag{5.34}$$

The condition (5.30) in the two-form component on S and one-form on T^2, however, contains information that is not captured by the Bianchi identity (5.29). In the presence of U(1) flux $\mathcal{O}_S(D_i)$ on S and a flat bundle $\mathcal{O}_{T^2}(p_i - e)$ (i.e., Wilson line) on T^2, there is no contribution to the Chern character, but the Chern-Simons form can be non-zero. Keeping in mind that M5-branes wrapped on T^2 as well as gravitational Chern-Simons form only contribute to (5.30) in the component purely three-form on S, we see that

$$\left(dB - \frac{\alpha'}{4} T_R^{-1}\, \mathrm{tr}_R\,[AdA]\right)\Big|_{\text{2-form on } S,\ \text{1-form on } T^2} = 0\,, \tag{5.35}$$

where the A^3 term in the Chern-Simons form has also been dropped for the Cartan flux configuration. Since the Polyakov action remains invariant by changing the B-field background by $(2\pi)^2\alpha'$ times an integral two-form on the target space, it is possible that the B-field background configuration expanded by using the same set of F_A as in (5.27)

$$B = \sum_A b_A F_A (2\pi)^2 \alpha' \tag{5.36}$$

may have scalars b_A varying topologically on T^2, so that $db_A = \check{\alpha} n_A^8 + \check{\beta} n_A^9$ for some integers n_A^8 and n_A^9 and a basis $\{\check{\alpha}, \check{\beta}\}$ of $H^1(T^2;\mathbb{Z})$. When k independent F_A's in $[J_S^\perp \subset S_S]$ are involved, we find the k independent conditions on the Wilson lines $A = A_I C_I$, $A_I = (2\pi)(\check{\alpha} a_I^8 + \check{\beta} a_I^9)$:

$$\left[db_A + \frac{A_I}{2\pi}\,(C_I, C_J)\, n_A^{(J)}\right] \otimes F_A = 0, \qquad 2n_A^8 - a_I^8 q_A^I = 0, \quad 2n_A^9 - a_I^9 q_A^I = 0, \tag{5.37}$$

where $n_A^{(J)} := -(n^A_{(i=1)} + \cdots + n^A_{(i=J)})$ and $q_A^I := -(C_{IJ}) n_A^{(J)}$. Hence k combinations of the Wilson lines A_I are required to be torsion points of $\mathrm{Jac}(T^2)$ (equivalent to the origin of $\mathrm{Jac}(T^2)$ when multiplied by some non-zero integer).[73] This is equivalent to k conditions imposed on the spectral surface data ($a^{\mathrm{v}}_{0,2,3,\ldots}$ and $a^{\mathrm{h}}_{0,2,\ldots}$) and f_0 and g_0 (equivalently τ_H).

Let us now translate this interplay among the Cartan flux, B-field topological configuration and the reduction (stabilization) of the moduli space in the language of Narain moduli. The Narain moduli covers not just the region with parametrically large $[\mathrm{vol}(T^2)/\ell_s^2]$ (where supergravity approximation is good), but also the stringy region. When there is a Cartan flux and corresponding topological dB configuration, our observation above —

[72] Note that we define the A–D–E lattice to have negative definite symmetric pairing in this article, and that D_i's are also negative definite, because of the signature $(1, \rho_S - 1)$ of S_S.

[73] It is no longer surprising that $a_3^{\mathrm{v}} y = 0$ and $a_3^{\mathrm{h}} y = 0$ are the spectral surface equation read out from (4.48). These equations mean that the $N_v = 3$-fold spectral cover (also $N_h = 3$) consists of three irreducible pieces sitting at the three 2-torsion points of $\mathrm{Jac}(T^2)$.

JHEP04(2014)050

some combinations of A_I's are forced to be torsions of $\mathrm{Jac}(T^2)$ — is translated into the existence of k vectors[74][75]

$$n_A := (2n_A^8, 0, 2n_A^9, 0, q_A^I)^T \in \mathrm{II}_{2,18}\,, \tag{5.38}$$

satisfying[76]

$$\langle \mathcal{Z}^R, n_A\rangle = 0, \qquad \mathcal{Z}^R \propto \left(-\tau_H,\ -\tilde{\rho}_H,\ 1,\ -\tau_H\tilde{\rho}_H - (a)^2/2,\ a_I\right); \tag{5.39}$$

see appendix A for background material on Narain moduli in heterotic string theory. This mechanism is precisely the same, mathematically, as how algebraic cycles emerge for special choice of complex structure on the other side of the duality.

It must be be obvious that one should define a lattice element

$$\widetilde{G}_H^{(4)} := \sum_A n_A \otimes F_A \in [U \oplus U \oplus A_{N_v-1} \oplus A_{N_h-1}] \otimes [J_S^{\perp} \subset S_S] \tag{5.40}$$

in heterotic string language in order to formulate the Cartan flux and topological dB configuration combined. Within the framework that we have assumed in this section so far,[77] where $Z = T^2 \times S$ is Kähler, $\langle\phi\rangle_{\mathrm{Het}} = \mathrm{const}$ and $\langle H\rangle = 0$ on the heterotic side, the duality map of the flux is given by

$$\widetilde{G}_H^{(4)} = G_0 = G_{\mathrm{tot}}\,. \tag{5.41}$$

Within this class of Cartan flux, the norm of $\widetilde{G}_H^{(4)}$ remains the same as that of $G_H^{(4)}$, because with $w^8 = w^9 = 0$, only n_8^A and n_9^A are allowed to be non-zero. Therefore, the Bianchi identity (5.33) becomes dual to the D3-tadpole condition (5.23).

The duality dictionary above is a generalization and refinement of the preceding discussion in [30, 32–34, 97, 98], in that we can deal with a more general class of fluxes on the heterotic spectral surface (by allowing non-trivial $\langle dB\rangle$), keep track also of flux quanta in the $U \oplus U$ components in the form of $\widetilde{G}_H^{(4)} = G_{\mathrm{tot}}$ or n_A, maintain a clear distinction between algebraic and transcendental cycles on the F-theory side and are able to understand how the dimension of moduli space is reduced.

The conventional dictionary using the stable degeneration limit of K3 surfaces is understood in the following way from the present perspective. Within the framework we have

[74] It is worth drawing attention to the fact that such vectors cannot always be brought into the $[A_{N_v-1} \oplus A_{N_h-1}]$ part of $[U \oplus U \oplus A_{N_v-1} \oplus A_{N_h-1}]$. The flux vectors that can be brought purely into $E_8 \oplus E_8$ may be associated with the flux on a trivial spectral surface in heterotic language, and are dual to the singular fibre flux (GUT brane flux) in F-theory.

[75] We wonder if we have made an error causing the factor of 2?

[76] This condition in heterotic string theory means that there is a class of states (vertex operators) with $(k^R, k^L) \in \mathbb{R}^{2,18}$ satisfying $(\alpha'/4)(k^R)^2 = 0$ and $(\alpha'/4)(k^L)^2 = -(n_A)^2/2 = -(q_A)^2/2$. As we are considering U(1)/Mordell-Weil fluxes here, rather than a GUT 7-brane/singular fibre flux, n_A should belong to $W_{\mathrm{frame}} \backslash W_{\mathrm{root}}$, meaning that $-(n_A)^2 \geq 4$. Thus, none of vertex operators for physical states with this (k^R, k^L) appear in the massless spectrum.

[77] Obviously this is not the most general form of G_{tot}, in particular when $G_1 = 0$. For a fully general choice of G_{tot} on the F-theory side, it is considered that we have to turn on $\langle H\rangle \neq 0$, a non-constant dilaton configuration and non-Kähler metric on the Heterotic string side [23].

JHEP04(2014)050

considered so far, the moduli space of $\mathcal{Z}^R$ ($\propto \Omega_X$) still maintains a free choice of at least τ_H and $\tilde{\rho}_H$, even after maximally possible Cartan fluxes (rank $= N_v + N_h - 2$) are introduced in the $\mathrm{SU}(N_v) \times \mathrm{SU}(N_h)$ structure group (no G_1 component yet, in particular). Thus, from this moduli space we can extract a family of K3 surfaces parametrized by $\tilde{\rho}_H$. This family $\pi : \mathcal{X} \longrightarrow D$ is defined on a disc $D \subset \mathbb{C}$ with $t = 1/\tilde{\rho}_H$ as the coordinate, just like the discussion in footnote 46 for the family defined by (4.35). Mathematically, this family may be augmented by providing the degeneration limit corresponding to $t = 1/\tilde{\rho}_H = 0 \in D$, which is called the central fibre. Each fibre (K3 surface) $\pi^{-1}(\tilde{\rho}_H)$ for some $1/\tilde{\rho}_H \in D$ contains an algebraic cycle (curve) corresponding to n_A in (5.38), (5.39), and those algebraic cycles (curves) for various $\tilde{\rho}_H$ are collectively regarded as an algebraic family of curves, or equivalently as a divisor in $\mathcal{X}$. The intersection of this divisor with the central fibre, $\pi^{-1}(0) = dP_9 \cup dP_9$, determines an algebraic cycle in $dP_9 \cup dP_9$. In this way, the stable degeneration limit of n_A is obtained.

Appendix B describes the behaviour of a semistable degeneration of a K3 surface and its algebraic cycles using a concrete example given by (4.48). We will see there how the semistable degeneration limit of an algebraic cycle can have an image in only one of the two dP_9's (only in visible/hidden sector dP_9).

Just like in the heterotic string picture of F-terms (5.31) leading to the stabilization of Wilson line moduli $\langle A \rangle_I$, we can also understand[78] the stabilization of the D7-brane positions in the dual type IIB theory on the orientifold $K3 \times T^2/\mathbb{Z}_2$. The type IIB version of the superpotential (5.31) is

$$W_{\mathrm{IIB}} \propto \int_M \Omega_M \wedge G^{(3)} + \int_S i_{X*}\Omega_M \wedge F = \int_M \Omega_M \wedge G^{(3)} + \int_S \Omega_{M;ijk}\, \mathrm{tr}\left[X^i F_{lm}\right] , \quad (5.42)$$

where X^i is the fluctuation of D7-brane in the transverse direction. Let us assume that we give a vev D_i to the gauge field strength for the i-th D7-brane. Its contribution can also be described by rewriting the last term above as $W = \int_{\Gamma(D7)} \Omega_M$. Here, $\Gamma(D7)$ is a 3-chain whose boundary consists of a two-cycle Poincaré dual (in S) to D_i and a reference two-cycle D_0. We can expand $D_i = n_i^A F_A$. Furthermore, we can introduce a three-form flux $G^{(3)} = F^{(3)} - \phi H^{(3)}$. Here ϕ is the type IIB axiodilaton and $F^{(3)}$ and $H^{(3)}$ are the type IIB R-R and NS-NS fluxes, respectively. We also expand $G^{(3)} = F^{(3)} - \phi H^{(3)} = (m_F^A - \tau m_H^A) F_A$ for a basis of two-cycles F_A of the $K3$ surface S and some $m_F^A, m_H^A \in H^1(T^2; \mathbb{Z})$. Using that $\Omega_M = \Omega_S \wedge dz$, we can evaluate the superpotential to be

$$W_{\mathrm{IIB}} \propto \sum_A \int_S \Omega_S \wedge F_A \sum_i \left(m_F^A - \phi m_H^A + \int_0^{X_i} n_A^i \, dz \right) . \quad (5.43)$$

The orientifold involution demands that we supply an image D7-brane at $\hat{X}_i = -X^i$ for any D7-brane at X^i. The U(1) gauge field surviving the orientifold involution is $\hat{A}^i - A^i$, so that the image brane also carries a flux $\hat{D}^i = -D^i$ and the two signs cancel in (5.43). The orientifold involution also sends $G^{(3)} \mapsto -G^{(3)}$, so that the only modes that survive are

[78] A closely related discussion is found in section7.3 of [22], see also [21, 23]. The presentation here, however, is for $\langle H \rangle = 0$ and Kähler metric in the heterotic description.

JHEP04(2014)050

those expanded into odd three-forms. All three-forms used for the expansion of $G^{(3)}$ are odd, so that this is already taken care of. We can hence capture the effect of orientifolding by only considering 16 branes at X^i with fluxes D_i on their worldvolume and putting a factor of two in front of the last term in (5.43). The conditions for supersymmetry coming from the superpotential are then written as

$$\sum_i \left(m_F^A - \phi m_H^A + 2 \int_0^{X_i} n_A^i \, dz \right) = 0 \,. \tag{5.44}$$

Just as for the Wilson lines, the positions of the branes should add up to a torsion point of T^2, so that the above can be cancelled by an appropriate choice of F_3. Note that $\phi \to i\infty$ in the weak coupling limit, so that (assuming n_A^i is finite) we cannot use H_3 for the same purpose. This is as expected, as the three-form dB, which took part in the same mechanism on the heterotic side, is turned into $F_3 = dC_2$ under the duality map.

The need to put (some of) the D7-branes at special loci on $T^2/\mathbb{Z}_2$ in order to have supersymmetric world-volume flux and the connection to the existence of algebraic cycles in the F-theory K3 has also been discussed in [20].

A lesson to be learnt from this is that instead of considering G_3 alone, the combination of $G^{(3)}$ and the contribution from D7-branes we see above should be of type $(2,1)$ [24]. This is just like the corresponding condition in heterotic string theory, where the vanishing of H including both dB and the Chern-Simons terms is required. Even for three-form fluxes $H^{(3)}$ and $F^{(3)}$ that cannot be made purely type $(2,1)$ and primitive for any choice of $\langle\phi\rangle$ and complex structure of M, there may be supersymmetric configurations for an appropriate choice of D7/O7-brane configuration. Turning this argument around, one can also see that once a $G^{(3)}$ configuration is found so that the supersymmetric conditions are satisfied for a D7/O7-brane configuration, then all the supersymmetric configurations consist of a sum of this special combination of flux plus any primitive pure $(2,1)$ form.

5.3.2 GUT 7-brane flux/singular fibre flux

Let us also make a brief remark on the GUT 7-brane flux (singular fibre flux), before moving on to the next section. Suppose that a flux (5.1) is introduced for C_I (i.e., the corresponding F_I does not vanish) in an irreducible component R of $W_{\rm root}$. Although there is a gauge theory on 7-brane ($\simeq S \times \mathbb{R}^{3,1}$) with the gauge group R, the flux turns on a non-trivial line bundle on the 7-brane and the symmetry of R is broken down to $[C_I^\perp \subset R]$ in the effective theory below the Kaluza-Klein scale.

The field contents in the effective theory can be described in terms of irreducible representations of the unbroken symmetry group $[C_I^\perp \subset R]$. Let α be a root of R that does not belong to $[C_I^\perp \subset R]$, and $D_\alpha = \sum_I (\alpha, C_I) F_I$ a divisor on S. Since we have assumed from the outset that $F_I \in [J_S^\perp \subset S_S]$, we have that $H^0(S; \mathcal{O}_S(D_{\pm\alpha})) = 0$, as long as the Kähler form J_S is in Amp_S (defined as an open set). If $H^0(S; \mathcal{O}_S(D_\alpha))$ or $H^0(S; \mathcal{O}_S(D_{-\alpha}))$ were non-trivial, then either D_α or $D_{-\alpha}$ is a divisor class represented by an effective curve, which should have a positive intersection number with any other divisor (including J_S) in the ample cone Amp_S. If, however, we allow some (-2)-curves to have zero volume under J_S (i.e., $J_S \in \overline{\mathrm{Amp}_S} \backslash \mathrm{Amp}_S$), some effective divisors may have zero volume and

JHEP04(2014)050

$H^0(S;\mathcal{O}_S(D_{\pm\alpha})) \neq \phi$ is not ruled out mathematically. This is also true when we cannot rely entirely on the local field theory approximation. Just like in toroidal orbifold examples where symmetry may sometimes be restored even in the presence of symmetry-breaking orbifold twists, stringy effects at zero-volume cycles may bring about consequences beyond the local field theory/supergravity approximation. Keeping in mind that

$$\begin{aligned} h^0(S;\mathcal{O}_S(D_\alpha)) + h^0(S;\mathcal{O}_S(D_{-\alpha})) &= h^0(S;\mathcal{O}_S(D_\alpha)) + h^2(S;\mathcal{O}_S(D_\alpha)), \\ &\geq \chi(S;\mathcal{O}_S(D_\alpha)) = 2 + \frac{(D_\alpha)^2}{2} \end{aligned} \tag{5.45}$$

on a K3 surface S, there is always such a zero-volume (-2) curve for a flux such that $(D_\alpha)^2 = -2$. For fluxes where $(D_\alpha)^2 \leq -4$, however, there is no such immediate consequence.

As long as we stay within the field theory approximation (which means that $J_S \in \mathrm{Amp}_S$, or at least $h^0(S;\mathcal{O}_S(D_\alpha)) = 0$), the number of chiral multiplets in the irreducible component containing the root $\pm\alpha$ is given by

$$h^1(S;\mathcal{O}_S(D_{\pm\alpha})) = -\chi(S;\mathcal{O}_S(D_{\pm\alpha})) = -\frac{(D_\alpha)^2}{2} - 2. \tag{5.46}$$

Note that there is no net chirality because of $(D_\alpha, K_S) = 0$.

5.4 Vacuum distribution based on continuous approximation

There have been attempts, most notably in [2, 17, 28, 29], of going beyond a case-by-case analysis of flux configuration counting. We initiate an effort of generalizing their approach by implementing various concepts that we have already developed in this section, so that we can ask statistical questions that are of interest in the context of particle physics, not just in cosmology. To do so, we use what we call the *restricted complex structure moduli space*, which is the space of complex structure deformations leaving a chosen set of divisors algebraic. For a K3 surface (or K3 × K3), we denote this by $\mathcal{M}_*(J_S, W_{\mathrm{noscan}})$. It is the moduli space of complex structures for which the (fixed) Kähler form J_S stays purely of type $(1,1)$ and the divisors spanning W_{noscan} remain algebraic. This means that we only consider complex structures such that $\Omega \cdot W_{\mathrm{noscan}} = 0$.[79] For more general fourfolds (where $H^{2,0} = 0$) the first condition, J_Y being of type $(1,1)$, is automatically satisfied, so that we simply use the notation $\mathcal{M}_*(W_{\mathrm{noscan}})$ here.

I. An approach of [28, 29] is to replace the sum over all the flux configurations taking their value in a lattice by continuous integration. In a theory where there are flux quanta N specified by K integers, the vacuum index density $d\mu_I$ is defined on $\mathcal{M}_*(J_S, W_{\mathrm{noscan}})$ (of complex dimension m) by

$$d\mu_I = d^{2m}z \sum_N \Theta(L_* - L)\delta^{2m}(D_a W, \overline{D_b W}) \det \begin{pmatrix} D_c D_d W & \partial_c \overline{D_d W} \\ \bar\partial_{\bar c} D_d W & \overline{D_c D_d W} \end{pmatrix}_{2m\times 2m} \tag{5.47}$$

$$\approx d^{2m}z \int_N d^K N\, \Theta(L_* - L)\delta^{2m}(D_a W, \overline{D_b W}) \det \begin{pmatrix} D_c D_d W & \partial_c \overline{D_d W} \\ \bar\partial_{\bar c} D_d W & \overline{D_c D_d W} \end{pmatrix}_{2m\times 2m} \tag{5.48}$$

[79] K3 surfaces with this kind of constraint are called *lattice polarized* in the mathematics literature.

JHEP04(2014)050

Here, the z^a are complex local coordinates on $\mathcal{M}_*$. The definition of this index density $d\mu_I$ is independent of the choice of local coordinates on $\mathcal{M}_*$ and becomes an (m,m)-form on $\mathcal{M}_*/\Gamma_*$, where Γ_* is the modular group. The vacuum index density can be used to set a lower bound in the number of vacua (without the condition $\langle W_{\rm GVW}\rangle = 0$).

In type IIB compactification on a Calabi-Yau threefold M_3 with an orientifold projection yielding n irreducible O7-planes, for example, $\mathcal{M}_*(D_4^{\oplus n})$ is the same as the moduli space of complex structures of M_3 together with the axi-dilaton. We only consider configuration of 7-branes such that they appear in the combination of SO(8) 7-brane gauge groups, i.e. we out four D7-branes on each O7-plane. Then the restricted moduli space $\mathcal{M}_*$ has complex dimension $m = (h^{2,1}_{-,\rm prim.}(M_3)+1)$ and there are $K = 4(h^{2,1}_{-,\rm prim.}(M_3)+1)$ integers for type IIB three-form quanta satisfying the primitiveness condition $G^{(3)}\wedge J_M = 0$. The delta functions (F-term conditions) reduce the flux space to be integrated from real K dimensions to $K-2m$ dimensions. The remaining integral in the flux space (at each point in the moduli space $\mathcal{M}_*/\Gamma_*$) is over primitive and (2,1) or (0,3)-type (i.e., imaginary self-dual) three-form fluxes $G^{(3)}$ in type IIB Calabi-Yau orientifold. It is bounded in region, because the contribution of such flux to the D3-tadpole

$$\frac{1}{2}G^{(4)}_{\rm tot}\cdot G^{(4)}_{\rm tot} \longrightarrow \frac{i}{2}\frac{G^{(3)}\wedge\overline{G^{(3)}}}{{\rm Im}(\phi)} = H^{(3)}\wedge F^{(3)} \tag{5.49}$$

is positive definite and is bounded from above by L_*, the total O3 plane charge in M_3. The vacuum index density thus becomes a finite-valued distribution (m,m)-form on the moduli space $\mathcal{M}_*/\Gamma_*$.

By following the argument of [28, 29], it is not hard to realize that the integral over the finite $(K-2m)$-dimensional region within the flux space d^KN yield a factor $L_*^{(K-2m)/2}$ for $z\in\mathcal{M}_*$. The Jacobian between the moduli space coordinates z_a and the remaining real $2m$ coordinates of the continuous flux space d^KN gives rise to another factor $(L_*)^{2m/2}$. Hence the vacuum index density of the landscape is given by

$$d\mu_I = \frac{1}{(K/2)!}(2\pi L_*)^{K/2}\times\rho_{\rm ind.}, \tag{5.50}$$

where $\rho_{\rm ind.}$ is an (m,m)-form on $\mathcal{M}_*/\Gamma_*$. Note that K and m are distinguished intentionally; although the relation $K=4m$ holds in type IIB Calabi-Yau orientifolds, it does not necessarily hold when one pays attention to a restricted subset of the full complex structure moduli space of M_3 (e.g., $K=3$ and $m=1/2$ model for $M_3=T^6$ in [17]), or in applications to F-theory. The (m,m)-form $\rho_{\rm ind.}$ in (5.50) does not depend on L_* primarily.[80] For this reason, the factor $(L_*)^{K/2}/(K/2)!$ roughly determines the overall number of flux vacua in the landscape on $\mathcal{M}_*/\Gamma_*$ and the distribution within the moduli space $\mathcal{M}_*/\Gamma_*$ is controlled by $\rho_{\rm ind.}$.

[80] It frequently happens, though, that the integral of $\rho_{\rm ind.}$ over $\mathcal{M}_*/\Gamma_*$ is not finite, and/or the continuous approximation of the flux quanta (from (5.47) to (5.48)) in some regions of $\mathcal{M}_*/\Gamma_*$ becomes bad, and/or some regions of $\mathcal{M}_*/\Gamma_*$ correspond to decompactification "limits" in dual theories. Because the cut-off for the region in $\mathcal{M}_*/\Gamma_*$ for the continuous approximation depends on the value of L_*, the integral of $\rho_{\rm ind.}$ with cut-off may depend on L_*. See [17] for such an example.

JHEP04(2014)050

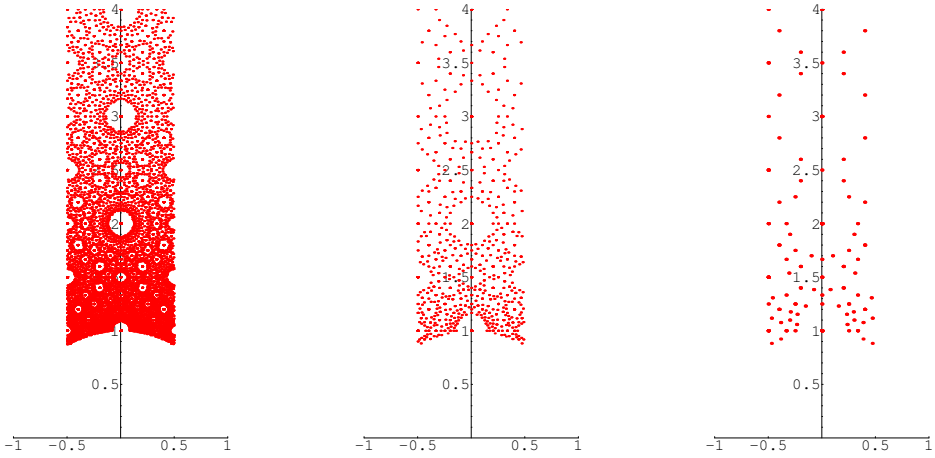

Figure 5. Vacuum distribution in the rigid Calabi-Yau model of [17, 28, 29] shown in the fundamental domain of the axi-dilaton moduli space. Depending on the value of L_*, D3-tadpole, the distribution of vacua in the moduli space can be either almost continuous or genuinely discrete.

Whether the continuous approximation is good or bad crucially depends on the value of L_*. To take an example, let us consider the rigid Calabi-Yau threefold model studied in [17, 28, 29], where $h^{2,1}(M_3) = 0$ and the moduli space $\mathcal{M}$ is that of the axi-dilaton of type IIB string theory. The distribution of flux vacua is presented in figure 5 without making the continuous approximation for three different values of L_*. For the one with $L_* = 150$, which is also found in [29], the continuous approximation looks reasonably good. For cases with small value of L_*, however, the continuous approximation is not very good, as in figure 5 with $L_* = 20$.

When the continuous approximation is not good, it is more appropriate to i) specify the set of points in $\mathcal{M}_*/\Gamma_*$ that admit integral fluxes, and ii) describe how many choices of such integral flux configurations are available at such points [17]. Suppose the dilaton vev $\langle\phi\rangle$ takes its value in an algebraic extension field $\mathcal{F}$ over $\mathbb{Q}$ with $\mathcal{D} := \dim_{\mathbb{Q}}\mathcal{F} = 2$, and the complex structure moduli of M_3 are such that $[\Omega_{M_3}] \in \mathcal{F}\mathbb{P}[H^3(M_3)]$ and $[D_i\Omega_{M_3}] \in \mathcal{F}\mathbb{P}[H^3(M_3)]$ for $i = 1, \cdots, h^{2,1}(M_3)$. Then the number of flux quanta at our disposal (while preserving the F-term conditions) is

$$\kappa = 4(h^{2,1}(M)_{-,\text{prim.}} + 1) - (\mathcal{D} = 2) \times (h^{2,1}(M)_{-,\text{prim.}} + 1), \tag{5.51}$$

which is reduced to

$$\kappa' = 4(h^{2,1}(M)_{-,\text{prim.}} + 1) - (\mathcal{D} = 2) \times (h^{2,1}(M)_{-,\text{prim.}} + 1) - (\mathcal{D} = 2) \tag{5.52}$$

when $\langle W_{\text{GVW}}\rangle = 0$ is required. Consequently, the number of flux configuration scales for a given complex structure $(\langle\phi\rangle, \langle z^a\rangle)$ as $(L_*)^{\kappa/2}$ or $(L_*)^{\kappa'/2}$, respectively [17]. The overall number of flux vacua, estimated to be $(L_*)^{2(h^{2,1}(M)_{-,\text{prim.}}+1)}$, should be reproduced partially from $(L_*)^{\kappa/2}$ times the number of such $\mathcal{D} = 2$ vacua in the fundamental domain

JHEP04(2014)050

of the moduli space, and the rest must come from similar contributions from vacua with different value of the extension degree $\mathcal{D}$.

The $rk_7 = 16$ landscapes of F-theory on K3 × K3 in section 5.2 fits very well with this discrete picture in two different ways. First, L_* in the type IIB language comes from $\chi(Y_4)/24$ in F-theory, which remains small for $Y_4 = \text{K3} \times \text{K3}$. This is visible most clearly in figure 1, or in the relatively short list of vacuum points (there are 66) in the moduli space in table 2 or merely 170 pairs found in the analysis of section 5.2. These results definitely look closer to the $L_* = 20$ picture in figure 5 than the one with $L_* = 150$.

The second reason is that the number of scanning flux quanta κ available at each isolated point in $\mathcal{M}_*(J_S, W_{\text{noscan}})$ remains the same for all the W_{noscan}-landscapes for F-theory on K3 × K3 with $rk_7 = \text{rank}(W_{\text{noscan}}) = 16$. This is obvious in the case of the $W_{\text{noscan}} = (D_4^{\oplus 4}); (\mathbb{Z}_2 \times \mathbb{Z}_2)$-landscape, because this is the type IIB orientifold compactification on $M_3 = T^2 \times K3$ with all the O7-planes accompanied by four D7-branes on top of them. But, even for other choices with $\text{rank}(W_{\text{noscan}}) = 16$, the number of scanning flux quanta κ, and hence the estimate of the number of $\mathcal{D} = 2$ vacua should remain much the same, even if W_{noscan} contains $E_{6,7,8}$ type gauge group. The number of flux quanta freely scanned over for a given Kähler form (5.3) and a rank-16 W_{noscan} was

$$\kappa = 8 + 2 \times 17, \qquad \kappa' = 6 + 2 \times 17 \tag{5.53}$$

in the study in section 5.2, which agrees with the type IIB orientifold value (5.51), (5.52) for $h^{2,1}(T^2 \times \text{K3})_{-,\text{prim.}} = 1 + 19$.

The action of the modular group Γ_* is implemented in the continuous approximation of [28, 29] by simply restricting the complex m-dimensional restricted moduli space $\mathcal{M}_*$ to its fundamental region. If L_* is small and one is in a situation of maintaining the discrete approach, one can still restrict the space $\mathcal{M}_*$ to its fundamental region under the action of the modular group Γ_*. Furthermore, one has to take a quotient of integral flux configurations admitted for a given point $[z] \in \mathcal{M}_*/\Gamma_*$ by the residual modular group $\Gamma_*(z)$, the stabilizer subgroup of a representative point $z \in \mathcal{M}_*$ [17]. In the example of type IIB on a rigid Calabi-Yau threefold [17, 28, 29], the first few axi-dilaton vevs for small flux contribution to the D3-tadpole sit at a special point in the axi-dilaton moduli space, $\langle\phi\rangle = i$, where the stabilizer subgroup of the moduli space $\Gamma_* = \text{SL}(2;\mathbb{Z})$ is non-trivial. Flux configurations for $\langle\phi\rangle = i$ have to be modded out by the non-trivial residual modular group.

Exactly the same phenomenon takes place in the case of compactification of F-theory on K3 × K3. For any point (ω_X, ω_S) in the moduli space $D^{(X)} \times D^{(S)}$, the stabilizer subgroup of Γ in (4.26) contains

$$\left(\left[W^{(2)}(S_X) \rtimes \text{Aut}(X)\right] \times \left[W^{(2)}(S_S) \rtimes \text{Aut}(S)\right]\right) . \tag{5.54}$$

$\mathcal{M}_*(J_S, W_{\text{noscan}})$, however, further specifies an embedding of $[J_S] \in S_S \otimes \mathbb{R}/\mathbb{R}_{\geq 0}$ and $(U_* \oplus W_{\text{noscan}}) \subset S_X$. Thus, only the subgroup of (5.54) preserving this embedding remains as the residual modular group Γ_* acting on the flux configuration. None of the reflection subgroup $W^{(2)}(S_S)$ will be left in the residual modular group as long as J_S is in the interior of the cone $\overline{\text{Amp}}_S$. In our numerical study in section 5.2 J_S is sitting on a boundary of

JHEP04(2014)050

$\overline{\text{Amp}}_S$, so that the $W_{E_8} \times W_{E_8}$ Weyl group in $W^{(2)}(S_S)$ is in the residual modular group Γ_*. Similarly, most of $W^{(2)}(S_X)$ is also gone from the residual modular group because of the embedding of $U_* \oplus W_{\text{noscan}}$. At a point $\omega_X \in D^{(X)}$ where an extra non-Abelian factor of W_{root} emerges outside of W_{noscan}, however, its Weyl group is still a part of Γ_*. The automorphisms in $\text{Aut}(X) \cap \Gamma_*$ at least preserve the elliptic fibration morphism and the zero-section, so this is a small subgroup of $\text{Aut}(X)$. We should also remark that our vacuum counting in section 4.2 exploited all possible $\text{Aut}(S)$ to take a quotient of the set of G_1-type fluxes. Since the argument there does not refer to the choice of J_S, one either has to count varieties in J_S or use only the subgroup of $\text{Aut}(S)$ preserving $J_S \in \overline{\text{Amp}}_S$ when taking a quotient of the flux configurations.

In landscapes where L_* is small, there is a pronounced void structure in the vacuum distribution on $\mathcal{M}_*/\Gamma_*$, and a significant fraction of vacua are accumulated at the special points at the centre of the voids [17, 29]. Sample statistics in section 4.3 and, in particular, section 5.2 must have been strongly influenced by this effect. Especially when it comes to the fraction of symmetric vacua in the statistics (such as the fraction of CP preserving vacua in section 4.3), the small value of L_* from $\chi(Y_4)/24 = 24$ must have a strong impact. Keeping this in mind, one should not view the high fraction of CP symmetric vacua as a generic prediction of F-theory.

II. From the perspective of F-theory, there is no reason to focus our attention only to W_{noscan}-landscapes with $rk_7 = \text{rank}(W_{\text{noscan}}) = 16$. It is thus natural to discuss flux vacuum distribution on the restricted moduli space $\mathcal{M}_*(J_S, W_{\text{noscan}})$. In the rest of this section, we treat $\chi(Y_4)/24$ (or L_*) as if it were a free parameter. By doing so, we can get a feeling for how the vacuum distribution depends on such parameters as rk_7 — the rank of fixed 7-brane gauge groups — in F-theory compactification on general elliptic Calabi-Yau fourfolds (not necessarily K3 × K3). With this in mind, we use the continuous approximation to the space of flux quanta [17, 28, 29].

For K3 × K3, the restricted moduli space $\mathcal{M}_*(J_S, W_{\text{noscan}})$ is of complex dimension $m = (18 - rk_7) + 19$. The vacuum index density (5.48) of [28, 29] in this set-up becomes an (m, m)-form on $\mathcal{M}_*$. Summation over the flux configuration is replaced by an integral, $d^K N$, and the delta functions (F-term condition) remove the integral over the $(3,1)+(1,3)$ Hodge components of the flux. Since we restrict the flux to be orthogonal to W_{noscan}, there are only complex $m = (20-2-rk_7)+(20-1)$ dimensions of such $(3,1)$ components to begin with, and hence all the integrals of the $(3,1)+(1,3)$ components are removed from $\int d^K N$ in (5.48). There are still remaining integrals over real $K - 2m = 2 \times 2 + (18 - rk_7) \times 19$ dimensions of the space of flux configuration; contribution to the D3-brane tadpole is positive definite in this space. This argument will lead to the vacuum index distribution that is an (m, m)-form $\rho_{\text{ind.}}$ on $\mathcal{M}_*(J_S, W_{\text{noscan}})/\Gamma_*$ multiplied by a factor $(L_*)^{K/2}$ with $K = [(20 - rk_7) \times 21]$. By requiring that $\langle W_{\text{GVW}} \rangle = 0$, K is replaced by $K' = K - 2$. Therefore, the number of vacua in the ensemble of a given W_{noscan} and J_S roughly scales as $(L_*)^{-(21/2)\times rk_7}$ as a function of rk_7.

In order to study the ratio of the number of SO(10) vacua to SU(5) vacua in F-theory on K3 × K3 flux vacua, one should also address Kähler moduli stabilization, and

JHEP04(2014)050

the vacuum counting on the choice of J_S need to be used as the weight multiplied on top of the distribution on $\mathcal{M}_*(J_S, W_{\rm noscan})/\Gamma_*$. It will be arguable whether the K3 × K3 compactification of F-theory is phenomenologically interesting enough to motivate such a laborious study. Unless the weight factor from Kähler moduli stabilization contains very strong rk_7-dependence, it seems very difficult to overturn the statistical ratio of $(L_*)^{-10.5}$ of SO(10) vacua to SU(5) vacua simply coming from the flux statistics for fixed J_S.

In such cases as $W_{\rm noscan} = A_4$ or D_5 in $Y = X \times S =$ K3 × K3 compactification of F-theory, there exists a primitive embedding $\phi : U \oplus W_{\rm noscan} \hookrightarrow \Lambda_{\rm K3}^{(X)} \cong H_2(X;\mathbb{Z})$. Furthermore, such an embedding is unique modulo $\mathrm{Isom}^+(\Lambda_{\rm K3}^{(X)})$ due to Theorem 1.14.4 of [99] and Theorem 2.8 of [78] (which is also quoted as Thm. ϵ in [26]). Thus, the restricted moduli space $\mathcal{M}_*$ can be constructed out of a single piece[81] of the restricted period domain

$$\mathbb{P}\left[\left\{\Omega_X \in (\Lambda_{\rm K3}^{(X)})^* \otimes \mathbb{C} \;\middle|\; \Omega_X \wedge \Omega_X = 0,\ \langle \Omega_X, \phi(U \oplus W_{\rm noscan})\rangle = 0,\ \Omega_X \wedge \overline{\Omega}_X > 0\right\}\right]. \tag{5.55}$$

If an attractive K3 surface $X = X_{[a\ b\ c]}$ admits an elliptic fibration whose $W_{\rm frame}$ contains a $W_{\rm noscan}$ as above, its Ω_X (equivalently a primitive embedding of its T_X into $[\phi(U \oplus W_{\rm noscan})^\perp \subset \Lambda_{\rm K3}^{(X)}]$) should be found in this single piece of restricted period domain. Such an embedding of T_X, however, is no longer unique under the subgroup of $\mathrm{Isom}^+(\Lambda_{\rm K3})$ preserving the embedding $\phi : (U \oplus W_{\rm noscan}) \hookrightarrow \Lambda_{\rm K3}^{(X)}$. In sections 4.1 and 4.2.3, we discussed multiplicities of elliptic fibration on a given attractive K3 surface X and a given isometry class of frame lattice. This multiplicity appears as a part of the non-uniqueness of the embedding of T_X into $[\phi(U \oplus W_{\rm noscan})^\perp \subset \Lambda_{\rm K3}^{(X)}]$ modulo the remaining subgroup of $\mathrm{Isom}^+(\Lambda_{\rm K3})$.

III. Having seen how the vacuum statistics depend on the rank of gauge groups, the next question of interest will be how it depends on the number of generations of matter fields. Since it is impossible to generate a non-zero net chirality on non-Abelian 7-branes in the K3 × K3 set-up, we content ourselves with studying the dependence on the number of vector-like pairs on a non-Abelian 7-brane. As we have seen in section 5.3, the singular fibre fluxes generate some vector-like pairs of matter fields, while reducing the symmetry group on the non-Abelian 7-brane associated with the singular fibre. Thus, we set the problem as follows. For some choice of J_S and $W_{\rm noscan} \subset W_{\rm frame}$ as before, let us specify

$$G_{\rm fix} = \sum_A (C_A \otimes F_A), \qquad C_A \in W_{\rm noscan} \cap W_{\rm root}, \qquad F_A \in [J_S^\perp \subset S_S]. \tag{5.56}$$

An ensemble of flux vacua is generated, by allowing the four-form flux $G^{(4)}$ to be $G_{\rm scan} + G_{\rm fix}$ for any $G_{\rm scan}$ orthogonal to J_S and $W_{\rm noscan}$. The vacuum index density distribution of such a landscape is obtained as an (m,m) form over the restricted moduli space $\mathcal{M}_*(J_S, W_{\rm noscan})/\Gamma_*$. Landscapes with different $G_{\rm fix}$ share the same restricted moduli space as long as $W_{\rm noscan}$ and J_S remain the same. When we take $W_{\rm noscan}$ to be E_7, E_6 or D_5, for

[81] In principle, it is possible that primitive embeddings of $(U \oplus W_{\rm noscan})$ into $\Lambda_{\rm K3}^{(X)}$ are not unique modulo $\mathrm{Isom}^+(\Lambda_{\rm K3}^{(X)})$, depending on what $W_{\rm noscan}$ is. In such cases, the restricted moduli space $\mathcal{M}_*/\Gamma_*$ consists of multiple connected components.

JHEP04(2014)050

example, and $G_{\rm fix} = (C_A \otimes F_A)$ so that the unbroken symmetry becomes E_6, D_5 or A_4, the singular fibre flux $G_{\rm fix}$ determines the number of vector-like pairs in the $\mathbf{27}+\overline{\mathbf{27}}$, $\mathbf{16}+\overline{\mathbf{16}}$ and $\mathbf{10}+\overline{\mathbf{10}}$ representations, respectively, through (5.46). By comparing the numbers of vacua of the ensembles of $(J_S, W_{\rm noscan}; G_{\rm fix})$ with the common $(J_S, W_{\rm noscan})$ and different $G_{\rm fix}$, we can determine the statistical cost of leaving vector-like pairs of matter fields in certain classes of representations in the effective theory.[82]

The result is simple. Our estimate of the number of vacua in such an ensemble is given by

$$(L_{*,\rm eff.})^{K'/2}; \qquad L_{*,\rm eff.} = \frac{\chi(X\times S)}{24} - \frac{1}{2}(G_{\rm fix})^2, \tag{5.57}$$

replacing $L_* = \chi(Y)/24$ by the remaining D3-tadpole $L_{*,\rm eff.}$ to be cancelled by the flux other than $G_{\rm fix}$. The more the number of vector-like pairs, the less the effective value $L_{*,\rm eff.}$. If $L_* = \chi(Y)/24$ were fairly large (and $K'/2$ is not particularly large), then requiring one or two vector-like pairs of the matter field does not reduce the number of vacua too much, relatively. If L_* is not particularly large, then the number of vacua with a few more vector-like pairs of matter fields becomes much smaller. Clearly, this effect is further enhanced when $K'/2$ is large.

IV. Finally, let us study the (m,m)-form distribution $\rho_{\rm ind.}$ over $\mathcal{M}_*/\Gamma_*$ in the context of F-theory compactification, not just the overall number of flux vacua. We begin with a review of what is known about $\rho_{\rm ind}$ in [2, 28, 29].

The most robust result on $\rho_{\rm ind}$ states that, for F-theory compactification without much restriction on the space of scanning four-form fluxes $G^{(4)}_{\rm scan}$, $\rho_{\rm ind}$ is written in the form of the Euler class $e(\nabla)$ on $\mathcal{M}_*$ (which means that it is a differential $2m$-form) associated with a connection ∇ on a real vector bundle with rank $2m$ [2]. The formula [28, 29]

$$\rho_{\rm ind} = \det\left(-\frac{R}{2\pi i} + \frac{\omega}{2\pi}\mathbf{1}\right)_{m\times m} = e(T\mathcal{M}_*\otimes\mathcal{L}^{-1}) = c_n(T\mathcal{M}_*\otimes\mathcal{L}^{-1}), \tag{5.58}$$

is a special case of the more robust result $\rho_{\rm ind} = e(\nabla)$ [2]. Here, ω is the Kähler form and R the curvature $(1,1)$ form of the holomorphic vector bundle $T\mathcal{M}_*$, $\mathcal{L}$ is the line bundle whose first Chern class is $-\omega/(2\pi)$ and $c = \det(-kR/(2\pi i) + \mathbf{1}) = \sum_k c_k t^k$ defines the Chern classes. It takes an extra effort to find for which real vector bundle $\rho_{\rm ind} = e(\nabla)$ for general cases.

It is known that the formula (5.58) can be used at least for two categories of landscapes.

A : type IIB on a Calabi-Yau orientifold M_3 with full scanning of three-form fluxes $G^{(3)}_{\rm scan}$ and with all the D7-branes appearing as an SO(8) configuration [29], i.e. four D7-branes on each O7-plane.

B : F-theory compactification on a Calabi-Yau fourfold Y_4 with the four-form flux scanning in a sufficiently large space.

[82] The net chirality would be proportional to the first power of the four-form flux, while the number of vector-like pairs scales as a square of the flux. This difference should be kept in mind. Note also that the number of vector-like pairs of matter fields may also depend on the representation, even for a given non-Abelian gauge group. Thus, it is dangerous to extract too many lessons out of this result.

JHEP04(2014)050

An example of category B is given by [2]:

$$G^{(4)}_{\rm scan} \in \left[H^{4,0}(Y;\mathbb{C}) + \text{h.c.}\right] \oplus \left[H^{3,1}(Y;\mathbb{C})_{\rm prim.} + \text{h.c.}\right] \oplus \left[\left(H^{2,2}(Y;\mathbb{R})_V\right)^{\perp} \subset H^{2,2}(Y;\mathbb{R})\right]. \tag{5.59}$$

Here, $H^{(2,2)}(Y;\mathbb{R})_V$ is the subspace of $H^{2,2}(Y;\mathbb{R})$ spanned by the intersection of any pair of divisors of Y (this naive definition is made more precise shortly).

Let us explain what we mean by a "sufficiently large space" when we introduced category B. Let $V \subset H^4(Y;\mathbb{R})$ be the subspace in which the four-form is scanned to generate a landscape, and let $\{\psi_{I=1,2,\cdots}\}$ be a basis of V. The assumption made (implicitly) in [2] is that the vector space V is large enough that one can make a replacement

$$\left(\int_Y \psi_I \wedge \varphi\right)(A^{-1})^{IJ}\left(\int_Y \psi_J \wedge \chi\right) \Longrightarrow \int_Y \varphi \wedge \chi, \qquad A_{IJ} := \int_Y \psi_I \wedge \psi_J \tag{5.60}$$

for arbitrary differential forms ψ and χ that belong to the vector space[83]

$$G^{(4)}_{\rm scan} \in \left[H^{4,0}(Y_z;\mathbb{C}) + H^{0,4}(Y_z;\mathbb{C})\right] \oplus \left[H^{3,1}(Y_z;\mathbb{C})_* + H^{1,3}(Y_z;\mathbb{C})_*\right] \oplus H^{2,2}(Y_z;\mathbb{R})_{H*}. \tag{5.61}$$

The quantities $[H^{3,1}(Y_z;\mathbb{C})_*$ and $H^{2,2}(Y_z;\mathbb{R})_{H*}$ are defined in the next paragraph and (5.63).

It is a natural generalization of the category B landscapes above to require extra divisors corresponding to extra 7-brane gauge groups, i.e. introduce a $W_{\rm noscan}$ as done earlier in this section. The moduli space $\mathcal{M}_*(J_Y, W_{\rm noscan})$ is then reduced in dimensions from the full space of complex structure moduli of Y compatible with a Kähler form J_Y. The $H^{3,1} + H^{1,3}$ components of the flux is then not only required to be primitive, $G^{(4)}_{\rm scan} \wedge J_Y = 0$, but the same condition is required with regard to the divisors in $W_{\rm noscan}$. Let $[H^{3,1}(Y_z;\mathbb{C})_* + H^{1,3}(Y_z;\mathbb{C})_*]$ denote the resulting smaller subspace. The $(H^{2,2}_V)^{\perp}$ component of the flux space is also reduced, because $H^{2,2}(Y_z;\mathbb{R})_V$ is larger in dimensions. This new $H^{2,2}(Y_z;\mathbb{R})_V$ is denoted by $H^{2,2}(Y_z;\mathbb{R})_{V*}$. We then have an ensemble of vacua with the four-form flux scanning over the vector space

$$G^{(4)}_{\rm scan} \in \left[H^{4,0}(Y;\mathbb{C}) + \text{h.c.}\right] \oplus \left[H^{3,1}(Y;\mathbb{C})_* + \text{h.c.}\right] \oplus \left[\left(H^{2,2}(Y;\mathbb{R})_{V*}\right)^{\perp} \subset H^{2,2}(Y;\mathbb{R})\right]; \tag{5.62}$$

Let us refer to these landscapes as category B'.

In order to state the relation between the category A landscapes and category B' landscapes, we need to prepare the following language. Consider a family of Calabi-Yau fourfolds $\pi : \mathcal{Y} \longrightarrow \mathcal{M}_*$, where $Y_z := \pi^{-1}(z)$ is the Calabi-Yau fourfold corresponding to $z \in \mathcal{M}_*$. We have in mind a restricted moduli space $\mathcal{M}_*$ for a specific choice of Kähler form J_Y and some set of divisors $W_{\rm noscan}$ corresponding to the 7-brane gauge groups. The $H^{2,2}(Y_z;\mathbb{R})$ vector space over $\mathbb{R}$ for each $z \in \mathcal{M}_*$ is decomposed as follows. First, $H^{2,2}(Y_z;\mathbb{R})_{V*}$ is defined[84] as the subspace spanned by intersection of Y_z with any pair of

[83] See equations (6.16) and (6.17) and compare with (6.33) and (6.34) in [2].

[84] This (more precise) definition of $H^{2,2}(Y_z;\mathbb{R})_V$ is not the same as the naive "definition" right after (5.59), when $z \in \mathcal{M}_*$ is in a special locus of $\mathcal{M}_*$ so that there are more divisors in Y_z than in generic points of $\mathcal{M}_*$. Contributions from such extra divisors are not included in $H^{2,2}(Y_z;\mathbb{R})_V$ in the precise definition.

JHEP04(2014)050

divisors of $\mathcal{Y}$. Secondly, another subspace $H^{2,2}(Y_z;\mathbb{R})_{H*} \subset H^{2,2}(Y_z;\mathbb{R})$ is defined as

$$\mathrm{Span}_{\mathbb{C}}\left\{(D_aD_b\Omega_Y), \overline{(D_cD_d\Omega_Y)}\right\}|_{a,b,c,d\in 1,\cdots,m} \cap H^{2,2}(Y_z;\mathbb{R})\,, \qquad m = \dim \mathcal{M}_*\,. \tag{5.63}$$

It is known that [2]

i) the vector space of (2,2) Hodge components is divided into $H^{2,2}_{\ell=0} \oplus H^{2,2}_{\ell=1} \oplus H^{2,2}_{\ell=2}$

ii) the intersection form is positive definite on $H^{2,2}_{\ell=0} \oplus H^{2,2}_{\ell=2}$ and negative definite on $H^{2,2}_{\ell=1}$

iii) $H^{2,2}_{\ell=1} \oplus H^{2,2}_{\ell=2}$ is contained in $H^{2,2}(Y_z;\mathbb{R})_{V*}$

The differential forms in the first component, $H^{2,2}_{\ell=0}$ are the primitive $(2,2)$ forms. Thus, the intersection form is positive definite on the orthogonal complement $[(H^{2,2}(Y_z;\mathbb{R})_{V*})^{\perp} \subset H^{2,2}(Y_z;\mathbb{R})]$, and there is a well-defined orthogonal decomposition of the $H^{2,2}(Y_z;\mathbb{R})$ vector space:

$$H^{2,2}(Y_z;\mathbb{R}) = H^{2,2}(Y_z;\mathbb{R})_{H*} \oplus H^{2,2}(Y_z;\mathbb{R})_{RM} \oplus H^{2,2}(Y_z;\mathbb{R})_{V*}. \tag{5.64}$$

Note that the remnant subspace $H^{2,2}(Y_z;\mathbb{R})_{RM}$ is not empty in general [100]. In particular, as explained in detail in appendix C, this happens already in the case of $Y = \mathrm{K3}\times\mathrm{K3}$. As discussed in appendix C, the landscape of category A (roughly speaking, type IIB orientifolds with three-form scanning (C.11)) corresponds to scanning the four-form in the $H^{2,2}(Y;\mathbb{R})_{H*}$ subspace in addition to the first two components of (5.59), i.e., the space (C.5). This is a smaller subspace than (5.62), in principle, in the sense that $H^{2,2}(Y;\mathbb{R})_{RM}$ can be non-empty. This indicates that the scanning space of the flux can be sufficiently large, for the condition (5.60) to hold (and the formula (5.58) also holds consequently), even when the scanning space is smaller than (5.62).

As discussed in appendix C, the four-form scanning we have introduced in this section also corresponds to the vector space (C.5). It is thus reasonable to think of one more category of landscapes in F-theory which contains both the category A landscapes and the ones on $Y = \mathrm{K3}\times\mathrm{K3}$ with arbitrary rk_7 we have considered. Let us call category A' any landscapes generated by scanning four-form flux in the vector space (C.5) for an elliptic fibred Calabi-Yau fourfold[85] $\pi_Y : Y \to B_3$. This is to be contrasted with those in category B' where the four-form flux is scanned in (5.62).

It must now be obvious that the formula (5.58) holds, not just for the landscapes in category B', but also for the landscapes in category A'. Since the condition (5.60) requires that $\psi_I(A^{-1})^{IJ}\psi_J$ be an insertion of a complete system only for φ, χ in (C.5), it is equivalent to say that the entire vector space (C.5) is contained in the space of four-form scanning (or not). Appendix C also provides an alternative (more down to earth) derivation of the formula (5.58) following the line of argument in one of the original articles [29]), rather than the refined version of [2], with an assumption (C.15) and a little more concrete consequence (C.29). We understand that the argument here is enough to justify the formula (5.58) for landscapes in category A'.

[85] A more appropriate way to phrase this is a family of elliptically fibred Calabi-Yau fourfolds $\pi : \mathcal{Y} \longrightarrow \mathcal{M}_*$ for which a generic fibre is not necessarily in the form of K3 × K3 or a K3-fibration.

JHEP04(2014)050

There is an immediate consequence of this observation. Any landscape (an ensemble of vacua) in category B' is decomposed into multiple landscapes (ensembles of vacua) in category A' labelled by $G_{\rm fix}^{(4)}$ in $H^{2,2}(Y;\mathbb{R})_{\rm RM}$. Since all of these landscapes in category A' share the same restricted moduli space $\mathcal{M}_*$, and since the formula (5.58) determines $\rho_{\rm ind}$ only in terms of geometry of $\mathcal{M}_*$, the vacuum index distribution $d\mu_I$ for these landscapes in category A' are the same apart form the $G_{\rm fix}^{(4)}$-dependent overall normalization (5.57).

Let us use (5.58) to derive an explicit result on the distribution of moduli parameters. Consider a landscape of F-theory compactification on $Y = X\times S = {\rm K3}\times{\rm K3}$ with some rank-16 $W_{\rm noscan}$ and $G_{\rm fix}^{(4)}$. Then the restricted moduli space is of the form $\mathcal{M}_* = \mathcal{M}_{\rho_1}\times\mathcal{M}_{\rho_2}\times\mathcal{M}_{\rm K3}(S;J_S)$. This is because the lattice $[(U_*\oplus W_{\rm noscan})^\perp\subset H^2(X;\mathbb{Z})]$ is always signature $(2,2)$, and the intersection form can be made $U\oplus U$ for some $\mathbb{R}$-coefficient basis of the vector space obtained by tensoring $\mathbb{R}$ with the signature $(2,2)$ lattice above. The Kähler forms of the moduli spaces $\mathcal{M}_{\rho_1}$ and $\mathcal{M}_{\rho_2}$ are $K^{(\rho_1)} = -\ln[(\rho_1-\bar\rho_1)/i]$ and $K^{(\rho_2)} = -\ln[(\rho_2-\bar\rho_2)/i]$, respectively. The modulus ρ_1 is interpreted as the axi-dilaton of type IIB orientifold in the case of $W_{\rm noscan} = D_4^{\oplus 4};(\mathbb{Z}_2\times\mathbb{Z}_2)$. By closely following the computation of section 3.1.2 in [29], we obtain

$$\rho_{\rm ind} = \left(-\frac{R^{(\rho_1)}}{2\pi i}+\frac{\omega^{(S)}}{2\pi}+\frac{\omega^{(\rho_1)}}{2\pi}+\frac{\omega^{(\rho_2)}}{2\pi}\right)\wedge\left(-\frac{R^{(\rho_2)}}{2\pi i}+\frac{\omega^{(S)}}{2\pi}+\frac{\omega^{(\rho_1)}}{2\pi}+\frac{\omega^{(\rho_2)}}{2\pi}\right)\wedge \det\left(-\frac{R^{(S)}}{2\pi i}+\left(\frac{\omega^{(S)}}{2\pi}+\frac{\omega^{(\rho_1)}}{2\pi}+\frac{\omega^{(\rho_2)}}{2\pi}\right)\mathbf{1}\right), \tag{5.65}$$

$$= 2\frac{\omega^{(\rho_1)}}{2\pi}\wedge\frac{\omega^{(\rho_2)}}{2\pi}\wedge\left\{c_{m-2}^{(S)}+\left(\frac{\omega^{(S)}}{2\pi}\right)^2\wedge c_{m-4}^{(S)}\right\}, \tag{5.66}$$

where $\omega^{(\rho_1)}$, $\omega^{(\rho_2)}$ and $\omega^{(S)}$ are the Kähler forms on the moduli spaces $\mathcal{M}_{\rho_1}$, $\mathcal{M}_{\rho_2}$ and $\mathcal{M}_{\rm K3}(S;J_S)$, respectively, and $R^{(S)}$, $R^{(\rho_2)}$ and $R^{(\rho_1)}$ the curvature $(1,1)$-forms of the tangent bundles of those moduli spaces.[86] $c_r^{(S)}$'s are the r-th Chern class of the holomorphic rank-$(m-2)$ vector bundle $T\mathcal{M}_{\rm K3}(S;J_S)\otimes(\mathcal{L}^{(S)})^{-1}$, where $\mathcal{L}^{(S)}$ is the line bundle whose first Chern class is $-\omega^{(S)}/2\pi$. Thus, in these set-ups the vacuum index density distribution $\rho_{\rm ind.}$ is factorized for the three pieces of the moduli space. If one is interested only in the distribution of any one among ρ_1, ρ_2 and moduli of the K3 surface S, but not altogether, then the distribution $\rho_{\rm ind}$ can be integrated over the irrelevant coordinates first. For the moduli ρ_1 and ρ_2, in particular,

$$\rho_{\rm ind.}(\rho_1)\propto d[{\rm Re}\rho_1]d[{\rm Im}\rho_1]\frac{1}{({\rm Im}(\rho_1))^2},\qquad \rho_{\rm ind.}(\rho_2)\propto d[{\rm Re}\rho_2]d[{\rm Im}\rho_2]\frac{1}{({\rm Im}(\rho_2))^2}. \tag{5.67}$$

Applying this result to the $W_{\rm noscan} = E_8\oplus E_8$-landscape, in particular, the prediction in the continuous approximation (5.67) for ρ_2 can also be read as that of $[{\rm vol}(T^2)/\ell_s^2]_{\rm Het}$. Our numerical results (not relying on continuous approximation) in section 5.2 agree with this prediction based on the continuous approximation qualitatively in that large ${\rm Im}(\tilde\rho_H) =$

[86] They satisfy $R^{(\rho_i)} = 2i\omega^{(\rho_i)}$.

JHEP04(2014)050

$[\mathrm{vol}(T^2)/\ell_s^2]_{\mathrm{Het}}$ is statistically disfavoured. Note that this happens although we should not expect the continuous approximation to be very good because $\chi(Y)/24 = 24$ is not particularly large.

The result (5.67) also indicates that there is no correlation between the distribution of ρ_1, ρ_2 and the moduli of K3 surface S, if we ignore the difference between the vacuum distribution and the vacuum index distribution. Figure 4 (iii) in section 5.2 may be regarded as a manifestation of the absence of any correlation between ρ_1 and ρ_2.

It is an interesting question how ρ_{ind} depends on $\mathrm{Im}(\tilde{\rho}_H)$ for different values of rk_7. ρ_{ind} is not expected to have a factorized form as (5.67), but it will be in the form of

$$\rho_{\mathrm{ind}} = c^{(X)}_{18-rk_7} c^{(S)}_{19} + \omega^{(X)}\omega^{(S)} c^{(X)}_{17-rk_7} c^{(S)}_{18} + (\omega^{(X)}\omega^{(S)})^2 c^{(X)}_{16-rk_7} c^{(S)}_{17} + \cdots , \tag{5.68}$$

where $c^{(X)}_r$'s are the r-th Chern class of the rank-$(18 - rk_7)$ holomorphic vector bundle $T\mathcal{M}_{\mathrm{K3}}(X; U_* \oplus W_{\mathrm{noscan}}) \otimes \mathcal{L}^{-1}_{(X)}$. It must still be possible to extract the leading power-law behaviour in $\mathrm{Im}(\tilde{\rho}_H)$ in the large $\mathrm{Im}(\tilde{\rho}_H)$ region of the moduli space, using the parametrization (A.6). We leave this as an open problem in this article.

Acknowledgments

We thank Kazuo Hosomichi for useful comments, and Tetsuji Shioda for giving a lecture on Mordell-Weil lattice on K3 surface, in January 2010 at IPMU, Tokyo. A. P. B. likes to thank the IPMU Tokyo for kind hospitality during his visit in summer of 2012, which initiated this collaboration. The work of A. P. B. was supported by a JSPS postdoctoral fellowship under grant PE 12530, and by the STFC under grant ST/J002798/1 and that of T. W. by WPI Initiative, MEXT, Japan and a Grant-in-Aid for Scientific Research on Innovative Areas 2303.

A A note on heterotic string Narain moduli

Although Narain compactificaiton of heterotic string theory is a well-known subject, we leave a brief note here for summary of conventions used in the main text of this article.

A compactification of heterotic string theory on T^2 is specified by embedding an even self-dual lattice $\mathrm{II}_{2,18}$ in a space

$$\mathbb{R}^{2,18} = \left\{ \sqrt{\frac{\alpha'}{2}} (k^R_8, k^R_9, k^L_8, k^L_9, k_{i=11,\cdots,26})^T \right\} \tag{A.1}$$

where the metric on $\mathbb{R}^{2,18}$ is $\mathrm{diag}(\mathbf{1}_{2\times 2}, \mathbf{1}_{18\times 18})$. Let $\{e_{K8}, e_{\bar{w}8}, e_{K9}, e_{\bar{w}9}, e_{I=11,\cdots,26}\}$ be a set of generators of $\mathrm{II}_{2,18}$ (as well as its image in $\mathbb{R}^{2,18}$) where $U = \mathrm{Span}_Z\{e_{K8}, e_{\bar{w}8}\}$, $U = \mathrm{Span}_{\mathbb{Z}}\{e_{K9}, e_{\bar{w}9}\}$, and $E_8 \oplus E_8$ is generated by the rest, $\{e_{I=11,\cdots,26}\}$. Thus, the data

JHEP04(2014)050

of this compactification is written in the form of a $(2+18)\times(2+2+16)$ matrix,

$$\mathcal{Z}=[e_{K8},e_{\bar{w}8},e_{K9},e_{\bar{w}9},e_{I=11},\cdots,e_{I=26}]\,,\quad \mathcal{Z}^T\cdot\begin{pmatrix}\mathbf{1}_{2\times2} & \\ & -\mathbf{1}_{18\times18}\end{pmatrix}\cdot\mathcal{Z}=\begin{pmatrix}U & & & \\ & U & & \\ & & C_{E_8} & \\ & & & C_{E_8}\end{pmatrix}, \tag{A.2}$$

where the U in (A.2) denotes the matrix $\begin{bmatrix}&1\\1&\end{bmatrix}$ and C_{E_8} the negative of the Cartan matrix of E_8, which is also the (negative definite) intersection form of the E_8 root lattice. General elements of $\mathrm{II}_{2,18}$ are written in the form of $n_8e_{K8}+(-w^8)e_{\bar{w}8}+n_9e_{K9}+(-w^9)e_{\bar{w}9}+\sum_I q^Ie_I$, which is also denoted by $(n_8,-w^8,n_9,(-w^9),q^I)^T$ in the component description. The generators $e_{K8,K9}$ correspond to states with elementary Kaluza-Klein excitation in T^2, and $e_{\bar{w}8,\bar{w}9}$ to states winding T^2 once.

The first two rows of the matrix $\mathcal{Z}$ are denoted by $\mathcal{Z}^R_m$ with $m=8,9$. Introducing $\mathcal{Z}^R:=\mathcal{Z}^R_8+i\mathcal{Z}^R_9$, it follows from relation (A.2) that

$$\mathcal{Z}^R\,.\begin{pmatrix}U^{-1} & & & \\ & U^{-1} & & \\ & & (C_{E_8})^{-1} & \\ & & & (C_{E_8})^{-1}\end{pmatrix}\cdot\left(\mathcal{Z}^R\right)^T=0\,. \tag{A.3}$$

Because $\mathcal{Z}^R$ can be regarded as an element of $\mathrm{Hom}(\mathrm{II}_{2,18},\mathbb{C})$,

$$\begin{aligned}&\mathcal{Z}^R:(n_8,-w^8,n_9,-w^9,q^I)^T\\ &\quad\longmapsto\sqrt{\frac{\alpha'}{2}}(k^R_8+ik^R_9)\text{ component of }\left(e_{K8}n^8+e_{\bar{w}8}(-w^8)+\cdots+\sum_I e_Iq^I\right),\end{aligned}$$

we see that the relation above can also be written as $(\mathcal{Z}^R,\mathcal{Z}^R)=0$ using the symmetric pairing of the dual lattice $\mathrm{II}^*_{2,18}$ naturally extended bilinearly to $\mathrm{II}^*_{2,18}\otimes\mathbb{C}$. With the same notation, it also follows that

$$\left(\mathcal{Z}^R,\overline{\mathcal{Z}^R}\right)=+2. \tag{A.4}$$

The moduli space of this Narain compactification is parametrized by 18 complex numbers. With a parametrization that is understood intuitively in the supergravity approximation of heterotic $E_8\times E_8$ string theory, $k^R_{m=8,9}$ in $\mathcal{Z}^R$ are written as follows [101]:

$$k^R_m=\frac{n_m}{R_m}-\frac{R_mw^m}{\alpha'}-\sum_I q^IA_{I,m}+\frac{1}{2}\sum_{I,J}A_{I,m}C^{IJ}\left(\sum_n w^nR_nA_{J,n}\right);\quad\text{(no summation in } m) \tag{A.5}$$

$A_{I,m}$'s ($m=8,9$ and $I=11,\cdots,26$) are the Wilson lines on T^2 for the simple roots of $E_8\times E_8$, and $R_{m=8,9}$ the radii of the two directions of T^2. Together with two more $\mathbb{R}$-valued parameters that we have omitted here ($\langle B\rangle=0$, and T^2 is rectangular, just for better readability), there are 2×18 parameters in total. C^{IJ} is the inverse of the

JHEP04(2014)050

matrix $C_{E_8\times E_8}$. Therefore, $\mathcal{Z}^R$ is parametrized by 18 complex numbers. In the component description of $[U\oplus U\oplus E_8\oplus E_8]^*\otimes\mathbb{C}$, it is given by

$$\mathcal{Z}^R=\frac{i}{\sqrt{2\mathrm{Im}(\tau_H)\mathrm{Im}(\tilde{\rho}_H)+\mathrm{Im}(a_P)C^{PQ}\mathrm{Im}(a_Q)}}(-\tau_H,\ -\tilde{\rho}_H,\ 1,\ -\tau_H\tilde{\rho}_H-a_KC^{KL}a_L/2,\ a_I), \tag{A.6}$$

where (under the condition that $\langle B\rangle=0$ and T^2 is rectangular)

$$\tau_H=i\frac{R_9}{R_8},\quad \rho_H=i\frac{R_8R_9}{\alpha'},\quad a_I=iR_9(A_{I,8}+iA_{I,9})=\sqrt{\alpha'\tau_H\rho_H}(A_{I,8}+iA_{I,9}), \tag{A.7}$$

and

$$\tilde{\rho}_H=\rho_H-\frac{a_IC^{IJ}(a-\bar{a})_J}{4i\,\mathrm{Im}(\tau_H)}. \tag{A.8}$$

B Heterotic Cartan flux and semistable degeneration

B.1 Set-up

In this appendix, the discussion on heterotic-F-theory duality of Cartan/Mordell-Weil flux of section 5.3 is made explicit by using the two-parameter family of K3 surfaces (4.48), (4.49) for F-theory (and its heterotic dual) as an example.

If we are to require a pair of IV* singular fibres, this specifies a family of $\rho_X=12+2=14$ K3 surfaces, whose moduli space has dimension 6. Let

$$T_X^{\rho=14}=U\oplus U\oplus A_2\oplus A_2,\qquad W_{\mathrm{frame}}^{\rho=14}=E_6\oplus E_6. \tag{B.1}$$

The two parameter family of K3 surfaces, $X=\mathrm{Km}(E_{\rho_1}\times E_{\rho_2})$, has four more independent algebraic cycles, $\rho_X=18$, and the transcendental lattice is only of rank 4, $T_X^{\rho=18}=U[2]\oplus U[2]$. Such a special family of K3 surfaces can be identified by an embedding $T_X^{\rho=18}\longrightarrow T_X^{\rho=14}$:

$$(\overline{C}_{32},\overline{C}_{14},\overline{C}_{12},\overline{C}_{43})\longmapsto(v,V,v',V',\alpha_1^{\mathrm{v}},\alpha_2^{\mathrm{v}},\alpha_1^{\mathrm{h}},\alpha_2^{\mathrm{h}})\left[\begin{array}{cc|cc}1&1&&\\&2&&\\\hline&&1&1\\&&&2\\\hline&1&&\\&&&1\\\hline&-1&&\\&&&1\end{array}\right], \tag{B.2}$$

where $\overline{C}_{32,14,12,43}$ are generators of $T_X^{\rho=18}=U[2]\oplus U[2]$, $\{v,V,v',V'\}$ those of $U\oplus U\subset T_X^{\rho=14}$, and $\{\alpha_{1,2}^{\mathrm{v}}\}$ and $\{\alpha_{1,2}^{\mathrm{h}}\}$ those of the structure group $A_2=\mathrm{SU}(3)$ in the visible and hidden sectors, respectively.

In this two parameter family of K3 surfaces (Kummer surfaces), the four extra independent algebraic cycles are the generators of the orthogonal complement of the image of

JHEP04(2014)050

$T_X^{\rho=18}$ within $T_X^{\rho=14}$. This lattice is also regarded as the orthogonal complement of the $E_6 \oplus E_6$ lattice within the frame lattice $W^{\rho=18}$ for $\rho = 18$. Hence this is also the essential lattice $L(X) = W_{\mathrm{U}(1)}$ of this elliptic fibration. $L(X) = W_{\mathrm{U}(1)}$ is generated by

$$(P, Q, P', Q') = (v, V, v', V', \alpha_1^{\mathrm{v}}, \alpha_2^{\mathrm{v}}, \alpha_1^{\mathrm{h}}, \alpha_2^{\mathrm{h}}) \left[\begin{array}{cc|cc} & 2 & & -1 \\ & & & \\ \hline -1 & & 2 & \\ & & & \\ \hline 1 & 1 & & \\ & & 1 & 1 \\ \hline 1 & -1 & & \\ & & 1 & -1 \end{array}\right]. \tag{B.3}$$

The period integral is therefore in the form of

$$\mathcal{Z}^R \propto \Omega_X = \left(-\tau_H, -\tilde{\rho}_H; 1, -\tau_H\tilde{\rho}_H + \frac{\tau_H^2+1}{2}; \tau_H + \frac{1}{2}, -\left(\frac{\tau_H}{2}+1\right), 0^6; -\left(\tau_H - \frac{1}{2}\right), \frac{\tau_H}{2} - 1, 0^6\right) \tag{B.4}$$

in the component description of $[U \oplus U \oplus E_8 \oplus E_8]^* \otimes \mathbb{C}$. In the component description using $(T_X^{\rho=18})^* \otimes \mathbb{C}$ (and irrelevant $(W_{\mathrm{U}(1)} \oplus E_6 \oplus E_6)^* \otimes \mathbb{C}$), this becomes

$$(-\tau_H, -(2\tilde{\rho}_H - \tau_H), 1, -\tau_H(2\tilde{\rho}_H - \tau_H)). \tag{B.5}$$

Thus, in the parametrization of Ω_X in terms of τ_H and $\tilde{\rho}_H$, the K3 surface $X = \mathrm{Km}(E_{\rho_1} \times E_{\rho_2})$ varies as

$$\rho_1 = \tau_H, \qquad \rho_2 = 2\tilde{\rho}_H - \tau_H. \tag{B.6}$$

Obviously the parametrization (B.4) follows the convention of Narain moduli for heterotic string compactification, and the correspondence (B.6) should be read as the duality map between the coordinates of the heterotic and F-theory moduli spaces.

In the heterotic string language, the component description of $\mathcal{Z}^R$ in (B.4) is a manifest consequence of the condition (5.39), with the flux data n_A's in (5.38) given by the $k = 4$ column vectors in (B.3). The Wilson lines are constrained to be torsion points in $\mathrm{Jac}(T^2)$ of the heterotic compactification:

$$\mathrm{diag}\left(\frac{\tau_H}{2}, -\frac{\tau_H+1}{2}, \frac{1}{2}\right) \subset \mathfrak{su}(3)^{\mathrm{vis.}}, \qquad \mathrm{diag}\left(-\frac{\tau_H}{2}, \frac{\tau_H-1}{2}, \frac{1}{2}\right) \subset \mathfrak{su}(3)^{\mathrm{hid.}}. \tag{B.7}$$

Wilson lines in the dimension-3 representations of the structure group $\mathrm{SU}(3)^{\mathrm{vis.}} \times \mathrm{SU}(3)^{\mathrm{hid.}}$ take values in 2-torsion points in this case, which is also the direct consequence of the spectral surface equations $a_3^{\mathrm{v}} y = 0$ for the visible sector and $a_3^{\mathrm{h}} y = 0$ for the hidden sector.

JHEP04(2014)050

B.2 Mordell-Weil group and narrow Mordell-Weil group

In the two parameter family of K3 surfaces $X = \mathrm{Km}(E_{\rho_1} \times E_{\rho_2})$ with an elliptic fibration of type $2\mathrm{IV}^* + 8I_1$, the essential lattice is

$$L(X) = W_{\mathrm{U}(1)} \cong A_2[2] \oplus A_2[2] \cong \mathrm{Span}_{\mathbb{Z}}\{P, P'\} \oplus \mathrm{Span}_{\mathbb{Z}}\{Q, Q'\}. \tag{B.8}$$

$E_6 \oplus E_6$ forms the root lattice W_{root} of the frame lattice W_{frame} for generic ρ_1 and ρ_2, and the frame lattice is obtained by adding, to $W_{\mathrm{root}} \oplus W_{\mathrm{U}(1)}$, such glue vectors as

$$\frac{2P + P'}{3} + \omega^{\mathrm{v}}_{\mathbf{27}} + \omega^{\mathrm{h}}_{\mathbf{27}}, \qquad \frac{P + 2P'}{3} + \omega^{\mathrm{v}}_{\mathbf{27}} + \omega^{\mathrm{h}}_{\mathbf{27}} \tag{B.9}$$

$$\frac{2Q + Q'}{3} + \omega^{\mathrm{v}}_{\mathbf{27}} + \omega^{\mathrm{h}}_{\overline{\mathbf{27}}}, \qquad \frac{Q + 2Q'}{3} + \omega^{\mathrm{v}}_{\overline{\mathbf{27}}} + \omega^{\mathrm{h}}_{\mathbf{27}}, \tag{B.10}$$

where $\omega^{\mathrm{v,h}}_{\mathbf{27}}$ [resp. $\omega^{\mathrm{v,h}}_{\overline{\mathbf{27}}}$] are the weights of the $\mathbf{27}$ [resp. $\overline{\mathbf{27}}$] representation of the visible/hidden sector E_6 symmetry. The quotient space $W_{\mathrm{frame}}/W_{\mathrm{root}} \cong MW(X) \cong \mathbb{Z}^{\oplus 4}$ is generated by those four elements and the height pairing of the Mordell-Weil lattice is $A_2^*[-2] \oplus A_2^*[-2]$ in this basis (as is well-known in the literature).

Reference [86] provides explicitly expressions of four generators of $MW(X) \cong \mathbb{Z}^{\oplus 4}$ for the $2\mathrm{IV}^* + 8I_1$-type elliptic fibration on $X = \mathrm{Km}(E_{\rho_1} \times E_{\rho_2})$. The Weierstrass model of X given by (4.48) has four independent non-zero sections, two of which — denoted by $\bar{P}_4$ and $\bar{P}_8$ — are given by

$$(X_4, Y_4) = (-4\lambda_1\lambda_2 z^2, -4z^2(\lambda_1(\lambda_1 - 1)z^2 + \lambda_2(\lambda_2 - 1))), \tag{B.11}$$

$$(X_8, Y_8) = (-4z^2, 4z^2(\lambda_1(\lambda_1 - 1)z^2 + \lambda_2(\lambda_2 - 1)))\,. \tag{B.12}$$

Readers interested in the expressions for the two other sections $\bar{P}_7$ or $\bar{P}_5$ are referred to [86]. We follow [65] and denote rational points of the elliptic curve, as well as the corresponding divisors and elements of the Neron-Severi lattice or the Mordell-Weil group, by P and the corresponding curves by $\bar{P}$.

Modulo $U_* = \mathrm{Span}_{\mathbb{Z}}\{[F], [\sigma + F]\}$ and W_{root}, these four sections generate the Mordell-Weil group $MW(X)$, P_4 and P_8 for one $A_2^*[-2]$, and P_7 and P_5 for the other $A_2^*[-2]$. All four of those sections, however, meet the E_6 singularities at $z = 0$, $(X, Y) = (0, 0)$ and at $z = \infty$, $(X/z^4, Y/z^6) = (0, 0)$. Hence they are not contained within the narrow Mordell-Weil group, $MW(X)^0$, which is consistent with the fact that the generators (B.10) contain weights of non-singlet representations of E_6^{vis} and $E_6^{\mathrm{hid.}}$.

Just like the generators of the essential lattice $L(X) \cong W_{\mathrm{U}(1)}$, $\{P, P', Q, Q'\}$, are obtained as $\mathbb{Z}$-linear combinations of the generators in (B.10), the corresponding sections for the generators of the narrow Mordell-Weil lattice $MW(X)^0$ should also be obtained through the group-law sum of the sections $\bar{P}_{4,8}$ and $\bar{P}_{7,5}$. Sections corresponding to $(2P_4 - P_8) \in MW(X)$ and $(2P_8 - P_4) \in MW(X)$ are given — by using the ordinary group law sum on

JHEP04(2014)050

elliptic curves — by

$$X_{2P_4-P_8} = \frac{4\{\lambda_2^2(\lambda_2-1)^2 + z^2(\lambda_2^2(\lambda_1^2-1)-\lambda_1^2) + z^4\lambda_1^2(\lambda_1-1)^2\}}{(\lambda_1+\lambda_2-\lambda_1\lambda_2)^2}, \tag{B.13}$$

$$Y_{2P_4-P_8} = \frac{4\left\{\begin{array}{c} 2\lambda_2^3(\lambda_2-1)^3 + z^2(\lambda_2^5(\lambda_1-1)^2(\lambda_1+1)+O(\lambda_2^4)) \\ +2z^6\lambda_1^3(\lambda_1-1)^3 + z^4(\lambda_2^3(\lambda_1-1)^3\lambda_1(\lambda_1+1)+O(\lambda_2^2)) \end{array}\right\}}{(\lambda_1+\lambda_2-\lambda_1\lambda_2)^3}, \tag{B.14}$$

$$X_{2P_8-P_4} = \frac{4\{\lambda_2^2(\lambda_2-1)^2 - z^2\lambda_1\lambda_2(\lambda_2^2+\lambda_1^2-1) + z^4\lambda_1^2(\lambda_1-1)^2\}}{(1-\lambda_1-\lambda_2)^2}, \tag{B.15}$$

$$Y_{2P_8-P_4} = \frac{4\left\{\begin{array}{c} 2\lambda_2^3(\lambda_2-1)^3 - z^2(\lambda_2^5(2\lambda_1-1)+O(\lambda_2^4)) \\ +2z^6\lambda_1^3(\lambda_1-1)^3 - z^4(\lambda_2^3\lambda_1(\lambda_1-1)(2\lambda_1-1)+O(\lambda_2^2)) \end{array}\right\}}{(1-\lambda_1-\lambda_2)^3}. \tag{B.16}$$

They belong to the narrow Mordell-Weil group $MW(X)^0$. Indeed,

$$(X_{2P_4-P_8}, Y_{2P_4-P_8})|_{z=0} = \left(\left(\frac{2\lambda_2(\lambda_2-1)}{\lambda_1+\lambda_2-\lambda_1\lambda_2}\right)^2, \left(\frac{2\lambda_2(\lambda_2-1)}{\lambda_1+\lambda_2-\lambda_1\lambda_2}\right)^3\right) \neq (0,0), \tag{B.17}$$

$$\left(\frac{X_{2P_4-P_8}}{z^4}, \frac{Y_{2P_4-P_8}}{z^6}\right)\Big|_{z=\infty} = \left(\left(\frac{2\lambda_1(\lambda_1-1)}{(\lambda_1+\lambda_2-\lambda_1\lambda_2)^2}\right)^2, \left(\frac{2\lambda_1(\lambda_1-1)}{(\lambda_1+\lambda_2-\lambda_1\lambda_2)^2}\right)^3\right) \neq (0,0), \tag{B.18}$$

and a similar calculation proves that the section $(2P_8 - P_4)$ also stays away from the two E_6 singularities at $z = 0$ and $z = \infty$. The height pairing is $A_2[-2]$ on the basis of $\{2P_4 - P_8, 2P_8 - P_4\}$, the opposite of $A_2[2] \subset L(X) = W_{\mathrm{U}(1)}$, as expected.

Similarly, we can construct section contained in the narrow Mordell-Weil group from the sections $\bar{P}_7$ and $\bar{P}_5$. We have computed the sections corresponding to $(2P_7 - P_5)$ and $-(P_7 + P_5)$ in $MW(X)$ and confirmed that they indeed belong in $MW(X)^0$. The height pairing on the basis $\{2P_7 - P_5, -(P_7 + P_5)\}$ is $A_2[-2]$. Since we use the explicit expressions of these sections later, we leave them here as a record:

$$X_{2P_7-P_5} = \frac{4\{\lambda_2^2(\lambda_2-1)^2 - z^2\lambda_1(\lambda_2^2(\lambda_1^2-1)+1) + z^4\lambda_1^2(\lambda_1-1)^2\}}{(\lambda_2-\lambda_1\lambda_2-1)^2}, \tag{B.19}$$

$$Y_{2P_7-P_5} = \frac{4\left\{\begin{array}{c} 2\lambda_2^3(\lambda_2-1)^3 - z^2(\lambda_2^5\lambda_1^2(\lambda_1-2)+O(\lambda_2^4)) \\ +2z^6\lambda_1^3(\lambda_1-1)^3 + z^4(\lambda_2^3\lambda_1^3(\lambda_1-1)(\lambda_1-2)+O(\lambda_2^2)) \end{array}\right\}}{(\lambda_2-\lambda_1\lambda_2-1)^3}, \tag{B.20}$$

$$X_{-(P_7+P_5)} = \frac{4\{\lambda_2^2(\lambda_2-1)^2 - z^2(\lambda_2^3\lambda_1+O(\lambda_2^2)) + z^4\lambda_1^2(\lambda_1-1)^2\}}{(\lambda_1-\lambda_2)^2}, \tag{B.21}$$

$$Y_{-(P_7+P_5)} = \frac{4\left\{\begin{array}{c} 2\lambda_2^3(\lambda_2-1)^3 + z^2(\lambda_2^5(2\lambda_1-1)+O(\lambda_2^4)) \\ -2z^6\lambda_1^3(\lambda_1-1)^3 - z^4(\lambda_2^3(2\lambda_1-1)\lambda_1(1-\lambda_1)+O(\lambda_2^2)) \end{array}\right\}}{(\lambda_1-\lambda_2)^3}. \tag{B.22}$$

None of the four sections corresponding to $(2P_4 - P_8)$, $(2P_8 - P_4)$, $(2P_7 - P_5)$ and $-(P_7 + P_5)$ in $MW(X)^0$ meet the zero section, σ, of the Weierstrass model given by (4.48).

JHEP04(2014)050

Therefore, $\overline{(2P_4 - P_8)} - \sigma$ and $\overline{(2P_8 - P_4)} - \sigma$ generate $A_2[2] \subset W_{\mathrm{U}(1)}$, and $\overline{(2P_7 - P_5)} - \sigma$ and $\overline{-(P_7 + P_5)} - \sigma$ generate the other $A_2[2] \subset W_{\mathrm{U}(1)}$. Dual to the rank-$k = 4$ Cartan flux in the heterotic string $\mathrm{SU}(N_v = 3) \times \mathrm{SU}(N_h = 3)$ bundle compactification should be four-form fluxes involving the Poincaré dual of these algebraic cycles in X.

B.3 Semistable degeneration

In the large $\mathrm{Im}(\tilde{\rho}_H)$ region of moduli space, where the supergravity description is a good approximation of heterotic string theory, it is more intuitive to choose $\{P + Q, P' + Q'\}$ and $\{P - Q, P' - Q'\}$ as the basis of the rank-$k = 4$ lattice of Cartan flux quanta. The first two generate the $A_2[4]$ sublattice for the visible sector $\mathrm{SU}(N_v = 3)$ structure group and the last two another $A_2[4]$ sublattice for the hidden sector $\mathrm{SU}(N_h = 3)$. In F-theory language, the Poincaré dual of the algebraic cycles $\{P + Q, P' + Q'\}$ and $\{P - Q, P' - Q'\}$ should thus be interpreted as those for the visible and hidden sectors, respectively.

Let us take one step further and identify the equivalent of the visible and hidden sector basis $\{P \pm Q, P' \pm Q'\}$ not just in terms of the heterotic string, or in algebraic (lattice) language for F-theory, but also in terms of the geometry of the K3 surface of F-theory. We have identified four independent algebraic cycles in $W_{\mathrm{U}(1)}$, which are also in one-to-one correspondence with elements in $MW(X)^0$. $\{(2P_4 - P_8), (2P_8 - P_4), (2P_7 - P_5), -(P_7 + P_5)\} \subset MW(X)^0$ are generators of $W_{\mathrm{U}(1)} \cong A_2[2] \oplus A_2[2]$ and are equivalent to $\{P, P', Q, Q'\}$. We claim that the visible and hidden sector basis is given by

$$\text{(visible sect.)} \qquad \overline{(2P_4 - P_8)} - \overline{-(2P_7 - P_5)}, \qquad \overline{(2P_8 - P_4)} - \overline{(P_7 + P_5)}, \tag{B.23}$$

$$\text{(hidden sect.)} \qquad \overline{(2P_4 - P_8)} - \overline{(2P_7 - P_5)}, \qquad \overline{(2P_8 - P_4)} - \overline{-(P_7 + P_5)}. \tag{B.24}$$

This idea comes from the following observations in geometry.

As we have already made clear, the coordinate rescaling in footnote 54 and the coordinate redefinition in footnote 46 allow us to see (4.49) as a family of elliptic K3 surface showing semistable degeneration. In one of the affine patches, the set of equations

$$\begin{cases} \tilde{\eta}^2 = \left(\xi + \frac{4}{\lambda_2}\right)\left(\xi + 4\left(1 + \frac{\lambda_1}{\lambda_2}\right)\right)(\xi + 4\lambda_1) + 2^3\left((1 - 1/\lambda_2)u + \lambda_1(\lambda_1 - 1)v\right)\,\tilde{\eta}, \\ uv = 1/\lambda_2 \end{cases} \tag{B.25}$$

defines a family of K3 surfaces elliptically fibred over a curve $\{uv = t | (u, v) \in \mathbb{C}^2\}$ parametrized by $t := 1/\lambda_2 \in D \subset \mathbb{C}$. In the large λ_2 limit, $t = 0$, the base curve splits into two irreducible pieces, and the K3 surface also splits into two rational elliptic surfaces (a.k.a dP_9) glued together at one common fibre elliptic curve.

$$\tilde{\eta}^2 = \xi\,(\xi + 4)\,(\xi + 4\lambda_1) + 2^3 u\,\tilde{\eta}\,, \qquad v = 0\,, \tag{B.26}$$

$$\tilde{\eta}^2 = \xi\,(\xi + 4)\,(\xi + 4\lambda_1) + 2^3\lambda_1(\lambda_1 - 1)v\,\tilde{\eta}\,, \qquad u = 0\,, \tag{B.27}$$

are the visible and hidden sector dP_9's, respectively. The E_6 singularities are at $u = \infty$ in the visible sector dP_9 and at $v = \infty$ in the hidden sector dP_9. The common fibre at $u = v = 0$ is given by

$$\tilde{\eta}^2 = \xi(\xi + 4)(\xi + 4\lambda_1)\,. \tag{B.28}$$

JHEP04(2014)050

The two dP_9's (rational elliptic surfaces) should be "type No.27" in the classification in [102].

The sections $\overline{(2P_4 - P_8)}$, $\overline{(2P_8 - P_4)}$, $\overline{(2P_7 - P_5)}$ and $\overline{-(P_7 + P_5)}$, as well as the sections corresponding to their inverse elements in $MW(X)^0$, such as $\overline{(P_7 + P_5)}$, define divisors in the threefold given by (B.25). Intersection of those divisors with the $t = 1/\lambda_2 = 0$ divisor — $dP_9 \cup dP_9$ — defines their semistable degeneration limits mathematically (whatever this means in physics). Working this out explicitly, we found that the limit of both sections $\overline{(2P_4 - P_8)}$ and $\overline{(2P_7 - P_5)}$ are precisely the same in the visible sector dP_9,

$$\xi = \left(\frac{2}{1-\lambda_1}\right)^2 u^2, \qquad \tilde{\eta} = \left(\frac{2}{1-\lambda_1}\right)^3 \left\{u^3 + \frac{1}{2}(\lambda_1 - 1)^2(\lambda_1 + 1)u\right\}. \tag{B.29}$$

This common limit in the visible sector passes through one of the 2-torsion point $(\xi, \tilde{\eta}) = (0, 0)$ in the common elliptic fibre. The semistable degeneration limit of the two sections, however, remain different in the hidden sector dP_9. In the fibre in $v = \infty$, for example,

$$\left(\frac{\xi}{v^2}, \frac{\tilde{\eta}}{v^3}\right) \to \left((-2\lambda_1)^2, (-2\lambda_1)^3\right) \qquad \text{v.s.} \qquad \to \left((2\lambda_1)^2, (2\lambda_1)^3\right) \tag{B.30}$$

for $\overline{(2P_4 - P_8)}$ and $\overline{(2P_7 - P_5)}$, respectively. They are inverse elements under the group law of the elliptic curve. This is why the algebraic cycle $\overline{(2P_4 - P_8)} - \overline{(2P_7 - P_5)}$ is considered to be purely in the hidden sector dP_9. It must also be easy to see that the algebraic cycle $\overline{(2P_4 - P_8)} - \overline{-(2P_7 - P_5)}$ is purely in the visible sector dP_9. A similar story holds also for the pair of sections $\overline{(2P_8 - P_4)}$ and $\overline{-(P_7 + P_5)}$. We do not present details here, except noting that those sections pass through another 2-torsion point in the common elliptic fibre: $(\xi, \tilde{\eta}) = (-4\lambda_1, 0)$.

Back in the regime of finite $|\lambda_2|$, the two sections $\overline{(2P_4 - P_8)}$ and $\overline{(2P_7 - P_5)}$ both cover the entire base $\mathbb{P}^1$, from the visible sector 7-brane at $z = 0$ to the hidden sector 7-brane at $z = \infty$. These two sections are distinct, but they remain very close in the small z region (near the visible sector), with the difference scaling as $1/\lambda_2 \sim e^{2\pi i \tilde{\rho}_H}$. It is thus reasonable to understand this as a stringy effect. When we ignore differences of order $\mathcal{O}(1/\lambda_2)$ to restore the supergravity approximation, the geometric picture described above (using $dP_9 \cup dP_9$) is a reasonably good approximation for large $|\lambda_2|$ and fits perfectly with our intuitive understanding of Cartan fluxes in the visible as well as hidden sector structure group. This is how we were led to the claim (B.23), (B.24), and it is this interesting behaviour of sections under the semistable degeneration of K3 surfaces that reconciles the notion of having Cartan flux purely in the visible/hidden sector with considering sections of the elliptic K3 surface.

Before closing this section, let us try to place the observations based on the example characterized by (B.1) and (B.2) (or equivalently by (B.1) and (B.3)). It is more natural from the perspective of heterotic string theory to take (B.3) as input data for compactification because they are flux data of the gauge fields and B-field. In F-theory language, the essential lattice $L(X) = W_{\mathrm{U}(1)}$ of an elliptic fibration is specified by (B.3), while the embedding (B.2) determines the transcendental lattice of a $\rho = 18$ (two parameter) family of K3 surfaces. When we replace (B.2), (B.3) by some other choice, this means we

JHEP04(2014)050

take different flux quanta for the rank-$k = 4$ Cartan flux in the SU(3) $\times$ SU(3) bundle compactification of heterotic string theory, or to use a $\rho = 18$ family of K3 surfaces different from $X = \mathrm{Km}(E_{\rho_1} \times E_{\rho_2})$. There is nothing wrong in doing so. For all different choices of (B.2), (B.3), one can construct a two parameter family of K3 surfaces with four independent sections in the narrow Mordell-Weil group.

Since we are not interested in literally taking $\mathrm{Im}(\rho_H) = [\mathrm{vol}(T^2)/\ell_s^2]_{\mathrm{Het}}$ to infinity for practical applications, we do not need to study the semistable degeneration limit of K3 surfaces, but rather want to consider $\mathrm{Im}(\rho_H)$ very large, but finite.

Given the fact that literature referring to the heterotic-F-theory duality dictionary on the flux has often relied on the stable degeneration limit, however, it is not uninteresting to ask whether the $dP_9 \cup dP_9$ picture loses some information. When compactification data is given in terms of a one parameter family of $dP_9 \cup dP_9$ both in the "type No.27" of [102], along with $G_H^{(4)}$ in (5.34), one has to make sure that the sections pass through some torsion points in the common elliptic fibre. Using these torsion points and the Cartan flux quanta $G_H^{(4)}$, the B-field flux quanta on T^2 must be reproduced at least to some extent. Thus, apart from how far one should go back from the semistable degeneration limit (e.g., the value of λ_2), a great deal of information may be recovered from the description using ($dP_9 \cup dP_9$, $G_H^{(4)}$) by paying attention to such subtleties. We remain inconclusive about this question, however.

C Ashok-Denef-Douglas formula for F-theory

In this section, we begin with a review of the derivation of the vacuum index density distribution (5.58) in [28, 29] for type IIB Calabi-Yau orientifolds, and then generalize its derivation for more general landscapes based on F-theory compactifications, where the four-form fluxes are scanned within the subspace $H^{2,2}(Y_z;\mathbb{R})_H$. We largely follow the presentation in [29], which maintains more intuitive control over what is being done than the sophisticated and polished-up style of [2]. Along the way, we will see that the three-form scanning in type IIB orientifolds and the four-form scanning considered in section 5.4 correspond to scanning only in $H^{2,2}(Y_z;\mathbb{R})_H$ rather than the entire orthogonal complement $[(H^{2,2}(Y_z;\mathbb{R})_V)^\perp \subset H^{2,2}(Y_z;\mathbb{R})] = H^{2,2}(Y_z)_H \oplus H^{2,2}(Y_z)_{RM}$.

The vacuum index density for F-theory flux vacua is defined by [28, 29][87]

$$d\mu_I = d^{2m}z \sum_N \Theta(L_* - L)\delta^{2m}(D_a W, \overline{D_a W}) \det \begin{pmatrix} D_a D_b W & \partial_a \overline{D_d W} \\ \bar\partial_{\bar c} D_b W & \overline{D_c D_d W} \end{pmatrix}_{2m\times 2m}, \quad \text{(C.1)}$$

where $a, b, c, d \in \{1, \cdots, m\}$ label m local complex coordinates of some restricted moduli space $\mathcal{M}_*$ (see section 5.4 for various $\mathcal{M}_*$ of interest). In dealing with such integrals, we

[87] It is worth noting that the diagonal blocks $D_a D_b W$ and $\overline{D_c D_d W}$ are the same as the fermion mass matrix of the low energy effective field theory below the Kaluza-Klein scale or below the moduli mass scale $M_{KK}^3/M_{\mathrm{Str}}^2$. Fluctuations in the directions tangential to $\mathcal{M}_*$ are just as heavy as those in the directions normal to the restricted moduli space generically. The determinant of the $2m$ x $2m$ matrix just makes sure that each topological flux N contributes to $\int d\mu_I$ by 1 (TW thanks T. Eguchi and Y. Tachikawa for discussion).

JHEP04(2014)050

have adopted the conventions of [101], where $\int d^2z\delta^2(z,\bar{z}) = 1$. The tadpole L and the superpotential are given by

$$W \propto \int_Y G^{(4)}_{\rm scan} \wedge \Omega_Y, \qquad L = \frac{1}{2}\int_Y G^{(4)}_{\rm scan} \wedge G^{(4)}_{\rm scan}\,. \tag{C.2}$$

This $d\mu_I$ is a distribution function over the space $\mathcal{M}_*$ and captures all the flux vacua for which the D3-tadpole from the flux configuration L is not more than L_*. The sum over flux quanta $\sum_N$ is replaced by its continuous approximation $\int d^K N$. This expression can be rewritten as [28]

$$d\mu_I = \frac{(\alpha_0 L_*)^{K/2}}{(K/2)!}\rho_{\rm ind}(\alpha_0), \tag{C.3}$$

$$\rho_{\rm ind}(\alpha_0) := d^{2m}z \int d^K N e^{-\alpha_0 L}\delta^{2m}(D_aW, \overline{D_aW}){\rm det}\begin{pmatrix} D_aD_bW & \partial_a\overline{D_dW} \\ \bar{\partial}_{\bar{c}}D_bW & \overline{D_cD_dW}\end{pmatrix}; \tag{C.4}$$

since $\rho_{\rm ind}(\alpha_0)$ scales as $(\alpha_0)^{-K/2}$, the vacuum index density $d\mu_I$ does not depend on the choice of α_0. By setting $\alpha_0 = L_*^{-1}$, one can see where (and how) the L_* dependence arises in the expression of $\rho_{\rm ind}(L_*^{-1})$. In contrast, by setting $\alpha_0 = 2\pi$, the L_*-dependence of the overall number of vacua in this landscape is seen clearly. We take $\alpha_0 = 2\pi$ throughout this article (as in [28, 29]), and $\rho_{\rm ind}(\alpha_0 = 2\pi)$ is simply denoted by $\rho_{\rm ind}$. The distribution $\rho_{\rm ind}$ can be rewritten in a more useful form in some cases, and that is the subject of the following.

The formulation in [29] accommodates scanning four-form fluxes in

$$G^{(4)}_{\rm scan} \in \left[H^{4,0}(Y_z;\mathbb{C}) + H^{0,4}(Y_z;\mathbb{C})\right] \oplus \left[H^{3,1}(Y_z;\mathbb{C})_* + H^{1,3}(Y_z;\mathbb{C})_*\right] \oplus H^{2,2}(Y_z;\mathbb{R})_{H*}, \tag{C.5}$$

where $H^{3,1}(Y_z;\mathbb{C})_*$ has been introduced in p. 65, and $H^{2,2}(Y_z;\mathbb{R})_{H*}$ was defined in (5.63). The first two components of $G^{(4)}_{\rm scan}$ is parametrized as follows, by $1+m$ complex numbers $\{N_X, N_Y^a\}|_{a=1,\cdots,m}$ ($m = \dim_{\mathbb{C}}\mathcal{M}_*$):

$$\Delta G^{(4)}_{\rm scan} = \left[N_X\Omega_Y + \bar{N}_X\overline{\Omega}_Y\right] + \left[N_Y^a(D_a\Omega_Y) + \bar{N}_Y^{\bar{b}}(\bar{D}_{\bar{b}}\overline{\Omega}_Y)\right], \tag{C.6}$$

using Ω_Y and $\{(D_a\Omega_Y)\}_{a=1,\cdots,m}$ as the basis of $H^{4,0}(Y_z;\mathbb{C})$ and $H^{3,1}(Y_z;\mathbb{C})_*$, respectively. Here,

$$D_a\Omega_Y = \partial_a\Omega_Y + K_a\Omega_Y, \qquad D_aD_b\Omega_Y = (\partial_a + K_a)D_b\Omega_Y - \Gamma^c_{ba}D_c\Omega_Y \tag{C.7}$$

$$K = -\ln\left[\int_Y \Omega_Y \wedge \overline{\Omega}_Y\right], \qquad K_a := \partial_a K. \tag{C.8}$$

The last component, $H^{2,2}(Y_z;\mathbb{R})_{H*}$, is parametrized by

$$\Delta G_{\rm scan} = \sum_{I=1}^{\widetilde{K}} \tilde{N}_I\Omega_I^{(2,2)}, \qquad A_{IJ} := \int_Y \Omega_I^{(2,2)} \wedge \Omega_J^{(2,2)}, \tag{C.9}$$

JHEP04(2014)050

by using a basis $\{\Omega_I^{(2,2)}\}|_{I=1,\cdots,\widetilde{K}}$ of the vector space $H^{2,2}(Y_z;\mathbb{R})_{H*}$ over $\mathbb{R}$; the generators $(D_aD_b\Omega_Y)$ and $\overline{(D_cD_d\Omega_Y)}$ of $H^{2,2}(Y_z;\mathbb{R})_{H*}$ are not necessarily linearly independent. Thus, the continuous approximation $\int d^KN$ of the flux configuration $\sum_N$ is given by

$$\int dN_X d\bar{N}_X e^{-K} \int \prod_{a=1}^{m} [dN_Y^a d\bar{N}_Y^{\bar{a}}] e^{-mK} \det(K_{c\bar{d}})_{m\times m} \int d^{\widetilde{K}}\tilde{N}\sqrt{A_{IJ}}. \tag{C.10}$$

We expect very little confusion to arise from the fact that we use A_{IJ} as the intersection form on the vector space $H^{2,2}(Y_z;\mathbb{R})_{H*}$ here, while it is the intersection form on $H^4(Y_z;\mathbb{R})$ in (5.60).

In the case of a landscape based on a type IIB orientifold using a Calabi-Yau threefold M_3 with 7-branes in the SO(8) configuration and scanning three-form fluxes $F^{(3)}_{\rm scan}$ and $H^{(3)}_{\rm scan}$, the four-form is given by

$$G^{(4)}_{\rm scan} = \frac{1}{\phi-\bar{\phi}}\left[\overline{G^{(3)}}_{\rm scan}\wedge\Omega_{T^2} - G^{(3)}_{\rm scan}\wedge\overline{\Omega}_{T^2}\right], \qquad G^{(3)}_{\rm scan} := F^{(3)}_{\rm scan} - \phi H^{(3)}_{\rm scan}, \tag{C.11}$$

we can take [29]

$$N_Z^{\phi i}(D_\phi D_i\Omega_Y) + \text{h.c.} \qquad \left(i = 1,\cdots,m-1 = h^{2,1}_{-,\text{prim.}}(M_3)\right) \tag{C.12}$$

with $N_Z^{\phi i} \in \mathbb{C}$ as a non-redundant parametrization of $H^{2,2}(Y_z;\mathbb{R})_{H*}$. This is due to a relation

$$(D_jD_k\Omega_M)\wedge\Omega_{T^2} = -\mathcal{F}_{ljk}\mathcal{F}_\phi K^{\bar{i}l}K^{\bar{\phi}\phi}e^K\overline{(D_iD_\phi(\Omega_M\wedge\Omega_{T^2}))} \tag{C.13}$$

that follows from[88]

$$D_\phi\Omega_{T^2} = i\mathcal{F}_\phi e^{K^{(T^2)}}\overline{\Omega}_{T^2}, \qquad D_aD_b\Omega_M = i\mathcal{F}_{dab}K^{\bar{c}d}e^{K^{(M)}}\overline{D_c\Omega_M}. \tag{C.14}$$

Let us now consider a more general cases of F-theory compactifications where the moduli space $\mathcal{M}_*$ is not necessarily in the form of $\mathcal{M}_{\rm cpx}(M_3)\times\mathcal{M}_\phi$, or 7-branes are not necessarily in an SO(8) configuration. We consider a class of landscapes where the restricted moduli space $\mathcal{M}_*$ of a Calabi-Yau fourfold Y is specified by divisors J_Y and $W_{\rm noscan}$ such that there is a relation [103][89] among differential forms[90]

$$(D_aD_b\Omega_Y) = \mathcal{F}_{abcd}\tilde{B}^{cd,\bar{e}\bar{f}}e^K\overline{(D_eD_f\Omega_Y)}, \qquad \overline{(D_aD_b\Omega_Y)} = \overline{\mathcal{F}}_{\bar{a}\bar{b}\bar{c}\bar{d}}\tilde{B}^{cd,\bar{c}\bar{d}}e^K(D_cD_d\Omega_Y) \tag{C.15}$$

for some $^\exists\tilde{B}^{cd,\bar{e}\bar{f}}$ over the moduli space $\mathcal{M}_*$ $(a,b,c,d,e,f\in\{1,\cdots,m\})$.

[88] For T^2, $\mathcal{F}_\phi := \int_{T^2}\Omega_{T^2}\wedge(D_\phi\Omega_{T^2})$. For a Calabi-Yau threefold M, $\mathcal{F}_{ijk} := \int_M\Omega_M\wedge(D_iD_jD_k\Omega_M)$. For T^2, there is the relation $K_{\phi\bar{\phi}} = |\mathcal{F}_\phi|^2e^{2K^{(T^2)}}$. When we choose the normalization $\Omega_{T^2} = dx+\phi dy$, we have that $\mathcal{F}=1$.

[89] $\bar{D}_{\bar{g}}(D_aD_b\Omega_Y)$ has only $(3,1)$ Hodge components [103], although $\overline{D_g(D_eD_f\Omega_Y)}$ may also have $(2,2)$ components in addition. In this sense, $\mathcal{F}_{abcd}\tilde{B}^{cd,\bar{e}\bar{f}}$ plays the role of $S^{(2)}$ in eq. (2.20) of [103]. $\tilde{B}^{cd,\bar{e}\bar{f}}e^K$ in this article corresponds to $B^{cd,\bar{e}\bar{f}}$ in [103].

[90] For a Calabi-Yau fourfold Y, $\mathcal{F}_{abcd} := \int_Y\Omega_Y\wedge(D_aD_bD_cD_d\Omega_Y)$. Similarly, for a K3 surface X, $\mathcal{F}_{\alpha\beta} := \int_X\Omega_X\wedge(D_\alpha D_\beta\Omega_X)$.

JHEP04(2014)050

Obviously this is a generalization of (C.13). It is not hard also to see that $Y = X \times S =$ K3 $\times$ K3 also has this property. Using the relation

$$D_\alpha \Omega_X = \mathcal{F}^{(X)}_{\alpha\beta} K^{\bar{\gamma}\beta} e^{K^{(X)}} \overline{D_\gamma \Omega_X} \tag{C.16}$$

for a K3 surface X and the fact that $\mathcal{F}_{\alpha\beta\kappa\lambda} = \mathcal{F}^{(X)}_{\alpha\beta} \mathcal{F}^{(S)}_{\kappa\lambda}$, one can see that $\tilde{B}^{\beta\lambda,\bar{\gamma}\bar{\mu}} = K^{\bar{\gamma}\beta}_{(X)} K^{\bar{\mu}\lambda}_{(S)}$ do the job. We will comment on $\tilde{B}^{\alpha\beta,\bar{\kappa}\bar{\lambda}}$ later.

Under the condition that $\tilde{B}^{cd,\bar{c}\bar{d}}$ exists, one can choose $(D_a D_b \Omega_Y)$'s or $\overline{(D_c D_d \Omega_Y)}$'s as a (still possibly redundant) set of $\mathbb{C}$-coefficient generators of $H^{2,2}(Y_z;\mathbb{R})_{H*}$. Thus, the $H^{2,2}(Y_z;\mathbb{R})$ component (C.9) may be written as

$$\Delta G^{(4)}_{\text{scan}} = N^{ab}_Z (D_a D_b \Omega_Y) = \bar{N}^{\bar{c}\bar{d}}_Z \overline{(D_c D_d \Omega_Y)} \tag{C.17}$$

for some complex valued N^{ab}_Z or their complex conjugates $\bar{N}^{\bar{a}\bar{b}}_Z$. The following reality condition must be satisfied by the (in-principle) complex valued N^{ab}_Z, so that the two expressions agree:

$$\bar{N}^{\bar{c}\bar{d}}_Z = N^{ab}_Z \mathcal{F}_{abcd} \tilde{B}^{cd,\bar{c}\bar{d}} e^K, \qquad N^{cd}_Z = \bar{N}^{\bar{a}\bar{b}}_Z \overline{\mathcal{F}}_{\bar{a}\bar{b}\bar{c}\bar{d}} \tilde{B}^{cd,\bar{c}\bar{d}} e^K. \tag{C.18}$$

In the following, we closely follow the presentation in [29], and see that the formula (5.58) holds also in this case. The integration measure (C.10) is used as it is. The D3-tadpole contribution from the flux is written as[91]

$$L = e^{-K} \left(|N_X|^2 - K_{a\bar{b}} N^a_Y \bar{N}^{\bar{b}}_Y + \frac{1}{2} e^{2K} \tilde{B}^{ef,\bar{e}\bar{f}} \mathcal{F}_{abef} \overline{\mathcal{F}}_{\bar{a}\bar{b}\bar{e}\bar{f}} N^{ab}_Z \bar{N}^{\bar{c}\bar{d}}_Z \right); \tag{C.20}$$

the last term is of type $(2,2)$ and hence is positive definite. The F-term conditions (delta-functions)

$$\delta^{2m}(D_a W, \overline{D_b W}) = \delta^{2m}(N_Y, \bar{N}_Y) \ \left(e^{-mK} \det(K_{a\bar{b}}) \right)^{-2} \tag{C.21}$$

eliminate the flux space integral over the $(3,1)+(1,3)$ components from the measure (C.10), and all the remaining directions in the flux space have positive definite contributions to the D3-tadpole [29].

The parametrization of the $(2,2)$ flux component in terms of the N^{ab}_Z satisfying (C.18) may be redundant in general ($Y =$ K3 $\times$ K3 is an example; see the discussion later). Thus, a set of independent flux space coordinates $\tilde{N}_I \in \mathbb{R}$ $(I = 1, \cdots, \widetilde{K})$ is introduced and we parametrize

$$N^{ab}_Z = \sum_I Z^{ab}_I \tilde{N}_I, \qquad \bar{N}^{\bar{a}\bar{b}}_Z = \sum_I \bar{Z}^{\bar{a}\bar{b}}_I \tilde{N}_I \tag{C.22}$$

without redundancy. The integration measure (C.10) is still used, but now there is an alternative expression for A_{IJ}:

$$\begin{aligned} A_{IJ} &= Z^{ab}_I \int_Y (D_a D_b \Omega_Y) \wedge \overline{(D_a D_b \Omega_Y)} \bar{Z}^{\bar{a}\bar{b}}_J = Z^{ab}_I e^K \tilde{B}^{cd,\bar{c}\bar{d}} \mathcal{F}_{abcd} \overline{\mathcal{F}}_{\bar{a}\bar{b}\bar{c}\bar{d}} \bar{Z}^{\bar{a}\bar{b}}_J, \\ &= \bar{Z}^{\bar{c}\bar{d}}_I \overline{\mathcal{F}}_{\bar{a}\bar{b}\bar{c}\bar{d}} \bar{Z}^{\bar{a}\bar{b}}_J = Z^{ab}_I \mathcal{F}_{abcd} Z^{cd}_J. \end{aligned} \tag{C.23}$$

The last term in the D3-tadpole contribution is also written as $\Delta L = \tilde{N}_I \tilde{N}_J A_{IJ}/2$.

[91] The following relation is used [103, 104]:

$$\int (D_a D_b \Omega_Y) \wedge \overline{(D_c D_d \Omega_Y)} = -e^{-K} \left[R_{a\bar{c}b\bar{d}} - K_{a\bar{c}} K_{b\bar{d}} - K_{a\bar{d}} K_{b\bar{c}} \right] = e^K \tilde{B}^{ef,\bar{e}\bar{f}} \mathcal{F}_{abef} \overline{\mathcal{F}}_{\bar{c}\bar{d}\bar{e}\bar{f}}. \tag{C.19}$$

JHEP04(2014)050

In this case, we case, we can write the determinant in (C.1) as follows:

$$(-1)^m \det \begin{pmatrix} D_a D_b W & \partial_a \overline{D_d W} \\ \bar{\partial}_{\bar{c}}(D_b W) & \overline{D_c D_d W} \end{pmatrix} = \int d^m\theta d^m\bar{\theta} d^m\psi d^m\bar{\psi} \qquad \text{(C.24)}$$
$$\exp\Big[\ \theta^a\psi^b \mathcal{F}_{abdf} Z_I^{ef} \tilde{N}_I + \bar{\theta}^{\bar{c}}\bar{\psi}^{\bar{d}} \overline{\mathcal{F}}_{\bar{c}\bar{d}\bar{a}\bar{b}} \bar{Z}_J^{\bar{a}\bar{b}} \tilde{N}_I$$
$$+\theta^a\bar{\psi}^{\bar{d}} N_X e^{-K} K_{a\bar{d}} + \bar{\theta}^{\bar{c}}\psi^b \bar{N}_X e^{-K} K_{b\bar{c}}\Big] .$$

Carrying out Gaussian integrals over the complex N_X and real $\tilde{N}_I$ coordinates, we obtain the following formula:

$$\rho_{\text{ind}} = (-1)^m \frac{d^{2m}z}{(2\pi)^m}\, e^{mK} [\det(K_{a\bar{b}})]^{-1} \int d^m\theta d^m\bar{\theta} d^m\psi d^m\bar{\psi} \qquad \text{(C.25)}$$
$$\exp\Big[\ e^{-K}(\theta^a\bar{\psi}^{\bar{d}} K_{a\bar{d}})(\bar{\theta}^{\bar{c}}\psi^b K_{b\bar{c}})$$
$$+\Big(\theta^a\psi^b \mathcal{F}_{abcd} Z_I^{cd} + \bar{Z}_I^{\bar{a}\bar{b}} \overline{\mathcal{F}}_{\bar{a}\bar{b}\bar{c}\bar{d}} \bar{\theta}^{\bar{c}}\bar{\psi}^{\bar{d}}\Big) \frac{(A^{-1})^{IJ}}{2} \Big(\theta^p\psi^q \mathcal{F}_{pqrs} Z_J^{rs} + \bar{Z}_J^{\bar{p}\bar{q}} \overline{\mathcal{F}}_{\bar{p}\bar{q}\bar{r}\bar{s}} \bar{\theta}^{\bar{r}}\bar{\psi}^{\bar{s}}\Big)\Big] .$$

In fact, his expression can be further simplified to (5.58). To see this, note that possibly redundant set of generators $\{(D_a D_b \Omega_Y)\}$ or $\{\overline{(D_c D_d \Omega_Y)}\}$ can be written as

$$(D_a D_b \Omega_Y) = e_{ab}^I \Omega_I^{(2,2)}, \qquad \overline{(D_c D_d \Omega_Y)} = \bar{e}_{\bar{c}\bar{d}}^{\ I} \Omega_I^{(2,2)}, \qquad \text{(C.26)}$$

using a basis $\{\Omega_I^{(2,2)}\}_{I=1,\cdots,\tilde{K}}$ of the vector space $H^{2,2}(Y_z;\mathbb{R})_{H*}$ over $\mathbb{R}$. The complex valued coefficients e_{ab}^I and $\bar{e}_{\bar{c}\bar{d}}^{\ I}$ should satisfy

$$Z_I^{\ ab} e_{ab}^J = \delta_I^{\ J}, \qquad \bar{Z}_I^{\bar{a}\bar{b}} \bar{e}_{\bar{a}\bar{b}}^{\ J} = \delta_I^{\ J}. \qquad \text{(C.27)}$$

From this, we obtain $\mathcal{F}_{abcd} = e_{ab}^I Z_I^{\ ef} \mathcal{F}_{efcd}$.

Using this relation, the $\theta^2\psi^2$ term in the exponent of (C.25) can be rewritten as

$$\frac{1}{2}(\theta^a\psi^b e_{ab}^I)(A_{IK})(A^{-1})^{KL}(A_{LJ})(\theta^p\psi^q e_{pq}^J) = \frac{1}{2}(\theta^a\psi^b e_{ab}^I)(A_{IJ})(\theta^p\psi^q e_{pq}^J) = \frac{1}{2}\theta^a\psi^b \mathcal{F}_{abpq}\theta^p\psi^q.$$

This vanishes because of the totally symmetric nature of $\mathcal{F}_{abpq}$ and Grassmann nature of the $\theta^a\theta^p$. The $\theta\bar{\theta}\psi\bar{\psi}$ terms in the exponent, on the other hand, become

$$(\theta^a\psi^b e_{ab}^I)(A_{IK})(A^{-1})^{KL}(A_{LJ})(\bar{\theta}^{\bar{p}}\bar{\psi}^{\bar{q}}\bar{e}_{\bar{p}\bar{q}}^{\ J}) = (\theta^a\psi^b e_{ab}^I) A_{IJ} (\bar{\theta}^{\bar{p}}\bar{\psi}^{\bar{q}}\bar{e}_{\bar{p}\bar{q}}^{\ J})$$
$$= \theta^a\psi^b \mathcal{F}_{abef} \tilde{B}^{ef,\bar{e}\bar{f}} e^K \overline{\mathcal{F}}_{\bar{c}\bar{d}\bar{e}\bar{f}} \bar{\theta}^{\bar{c}}\bar{\psi}^{\bar{d}}.$$

Using all these relations above, one arrives at the expression

$$\rho_{\text{ind.}}$$
$$= (-1)^{\frac{3m^2-m}{2}} [\det(K_{a\bar{b}})]^{-1} \int d^m\theta d^m\bar{\theta} \exp\left[\theta^a\bar{\theta}^{\bar{b}}\Big(K_{a\bar{d}}K_{c\bar{b}} - e^{2K}\mathcal{F}_{acef}\tilde{B}^{ef,\bar{e}\bar{f}}\overline{\mathcal{F}}_{\bar{b}\bar{d}\bar{e}\bar{f}}\Big)\frac{dz^c\wedge d\bar{z}^{\bar{d}}}{2\pi i}\right]$$
$$= \det\left(-\frac{R^b_{\ a}}{2\pi i} + \frac{\omega}{2\pi}\delta_a^b\right), \qquad \text{(C.28)}$$

JHEP04(2014)050

Here

$$-R_{\bar{b}ac\bar{d}} = R_{a\bar{b}c\bar{d}} = K_{a\bar{d}}K_{c\bar{d}} + K_{a\bar{b}}K_{c\bar{d}} - e^{2K}\mathcal{F}_{acef}\tilde{B}^{ef,\bar{e}\bar{f}}\overline{\mathcal{F}}_{\bar{b}d\bar{e}\bar{f}}\,, \tag{C.29}$$

$$R^{b}{}_{a} = R^{b}{}_{ac\bar{d}}\; dz^{c}\wedge dz^{\bar{d}}\,, \qquad R^{b}{}_{ac\bar{d}} = K^{\bar{b}b}R_{\bar{b}ac\bar{d}}\,. \tag{C.30}$$

$R^{b}{}_{a}$ is the curvature $(1,1)$ form of the holomorphic tangent bundle $T\mathcal{M}_*$ and $\omega = iK_{c\bar{d}}\; dz^{c}\wedge dz^{\bar{d}}$ the Kähler form on $\mathcal{M}_*$. The determinant in (C.28) is computed with respect to the a,b indices, so that the result is a $2m$-form on moduli space.

Finally, let us work out detailed descriptions of the vector space $H^{2,2}(Y;\mathbb{R})_{H*}$ as well as the decomposition (5.64) in the case of $Y = X\times S$. There are $K = (20-rk_7)\times 21$ scanning (real-valued) flux quanta of $G^{(4)}_{\rm scan}$ introduced in the discussion of 5.4. Among them, two correspond to the $(4,0)+(0,4)$ components $N_X(\Omega_X\otimes\Omega_S)+\text{h.c}$, and $2m$ to the $(3,1)+(1,3)$ component

$$N^{\alpha}_{Y}\,[(D_\alpha\Omega_X)\otimes\Omega_S] + N^{\kappa}_{Y}\,[\Omega_X\otimes(D_\kappa\Omega_S)] + \text{h.c.} \tag{C.31}$$

in (C.6), where $\alpha = 1,\cdots,(18-rk_7)$ and $\kappa = 1,\cdots,19$. The remaining $2+(18-rk_7)\times 19$ real-valued flux quanta correspond to the coefficients of these differential forms:

$$\Omega_X\otimes\overline{\Omega}_S, \qquad \overline{\Omega}_X\otimes\Omega_S, \qquad (D_\alpha\Omega_X)\otimes(D_\kappa\Omega_S). \tag{C.32}$$

Noting that there is a relation $(D_\alpha D_\beta\Omega_X) = \mathcal{F}_{\alpha\beta}e^{K^{(X)}}\overline{\Omega}_X$ for a K3 surface X, one finds that i) all of $(D_\alpha D_\beta\Omega_X)\otimes\Omega_S$ for $\alpha,\beta = 1,\cdots,(18-rk_7)$ are the same as differential forms on $Y = X\times S$ up to normalization, at each given point in the moduli space $\mathcal{M}_*$, ii) all of the $2\times(18-rk_7)\times 19$ differential forms above belong to $H^{2,2}(Y;\mathbb{R})_{H*}$, and are furthermore linearly independent; iii) this is even a basis of $H^{2,2}(Y;\mathbb{R})_{H*}$, because all the differential forms in the form of $D_aD_b(\Omega_X\otimes\Omega_S)$ have already been exploited, given the relation (C.16). All of these observations combined indicate that the vector space of scanning four-form flux considered in section 5.4 corresponds precisely to the space (C.5).

In the case of $Y = X\times S = \text{K3}\times\text{K3}$, another vector subspace $H^{2,2}(Y;\mathbb{R})_{V*}\subset H^{2,2}(Y;\mathbb{R})$ is generated, on the other hand, by

$$H^4(X;\mathbb{R})\otimes 1_S, \qquad 1_X\otimes H^4(S;\mathbb{R}), \qquad (U_*\oplus W_{\rm noscan})\otimes J_S\otimes\mathbb{R}. \tag{C.33}$$

Thus, the remaining component, consisting of cycles which are neither "horizontal" or "vertical", is given by

$$H^{2,2}(Y_z;\mathbb{R})_{RM} \cong (U_*\oplus W_{\rm noscan})\otimes\Big[J_S^{\perp}\subset H^{1,1}(S;\mathbb{R})\Big]\oplus\Big[(U_*\oplus W_{\rm noscan})^{\perp}\subset H^{1,1}(X;\mathbb{R})\Big]\otimes[J_S]. \tag{C.34}$$

This is not empty, and in fact, the first component is where the singular fibre flux (GUT 7-brane flux) $G^{(4)}_{\rm fix}$ in section 5.3-II and 5.4-III is introduced.

For $\text{K3}\times\text{K3} = X\times S$, the Riemann curvature tensor should become block-diagonal, which is verified as in

$$\begin{aligned} R_{\alpha\bar{\beta}\kappa\bar{\lambda}} &= K^{(X)}_{\alpha\bar{\beta}}K^{(S)}_{\kappa\bar{\lambda}} - \mathcal{F}^{(X)}_{\alpha\gamma}\mathcal{F}^{(S)}_{\kappa\mu}\; K^{\bar{\delta}\gamma}_{(X)}K^{\bar{\nu}\mu}_{(S)}\; e^{2(K^{(X)}+K^{(S)})}\;\overline{\mathcal{F}}^{(X)}_{\bar{\beta}\bar{\delta}}\overline{\mathcal{F}}^{(S)}_{\bar{\lambda}\bar{\nu}} \\ &= K^{(X)}_{\alpha\bar{\beta}}K^{(S)}_{\kappa\bar{\lambda}} - K^{(X)}_{\alpha\bar{\beta}}K^{(S)}_{\kappa\bar{\lambda}} = 0. \end{aligned} \tag{C.35}$$

JHEP04(2014)050

Diagonal blocks are given by

$$R_{\alpha\bar{\beta}\gamma\bar{\delta}} = K^{(X)}_{\alpha\bar{\beta}} K^{(X)}_{\gamma\bar{\delta}} + K^{(X)}_{\alpha\bar{\delta}} K^{(X)}_{\gamma\bar{\beta}} - e^{2K^{(X)}} \mathcal{F}^{(X)}_{\alpha\gamma} \overline{\mathcal{F}}^{(X)}_{\bar{\beta}\bar{\delta}}, \tag{C.36}$$

where we used

$$\tilde{B}^{\alpha\beta,\bar{\alpha}\bar{\beta}} = \frac{K^{\bar{\alpha}\alpha}_{(X)} K^{\bar{\beta}\beta}_{(X)}}{\dim_{\mathbb{C}} \mathcal{M}_{\rm cpx}(X; U_* \oplus W_{\rm noscan})}, \qquad \tilde{B}^{\alpha\beta,\bar{\kappa}\bar{\lambda}} = \tilde{B}^{\kappa\lambda,\bar{\alpha}\bar{\beta}} = 0. \tag{C.37}$$

PHYSICAL REVIEW D **90,** 121901(R) (2014)

Distribution of the number of generations in flux compactifications

Andreas P. Braun[1] and Taizan Watari[2]

(Received 24 September 2014; published 30 December 2014)

Flux compactification of string theory generates an ensemble with a large number of vacua, called the landscape. By using the statistics of various properties of low-energy effective theories in the string landscape, one can therefore hope to provide a scientific foundation to the notion of naturalness. This article discusses how to answer such questions of practical interest by using flux compactification of F-theory. It is found that the distribution is approximately in a factorized form given by distribution on the choice of 7-brane gauge group, that on the number of generations $N_{\rm gen}$ and that on effective coupling constants. The distribution on $N_{\rm gen}$ is approximately Gaussian for the range $|N_{\rm gen}| \lesssim 10$. The statistical cost of higher-rank gauge group is also discussed.

I. INTRODUCTION

String theory with compactified extra dimensions gives rise to a large number of vacua. The diversity of vacua originates from the choice of topology of compact internal space and flux configurations on it [1]. String theory as understood in this way today therefore does not predict a unique low-energy effective theory. Despite this lack of prediction, there are still many ways in which we can take advantage of such an ensemble of string vacua for a better understanding of particle physics in the real world. Such an ensemble containing a large number of vacua provided by a fundamental theory is referred to as a landscape of vacua, or landscape for short.

At least two ideas have been proposed so far in how to take advantage of such landscape of string theory. One is in the context of understanding the nonvanishing (yet extremely small) dark energy. It has been realized that the very small value was predicted to be "natural" under the combination of three ansatzes, (i) that the universe is occupied with many distinct areas facilitating effective theories with different values of the cosmological constant [2], (ii) that the statistical distribution of dark energy is taken as a principle of arguing naturalness, and (iii) that the observational factor (anthropics) is taken into account in the statistical distribution [3]. The string landscape indeed give rise to such an ensemble of low-energy effective theories with different values of the cosmological constant [4], and eternal inflation has this ensemble of string vacua realized in the universe [5]. Thus the string landscape provides a theoretical foundation for the attempt of understanding dark energy along the lines of (i), (ii), and (iii).

The string landscape can also provide a scientific foundation for a notion of naturalness for various kinds of parameters of the standard model, not just for the value of dark energy. Naturalness has been exploited for decades as a guiding principle in the quest of models beyond the standard model. Arguments relying on naturalness, however, tend to depend on the class of vacua (an ensemble) one has in mind. Since string theory is able to provide a well-motivated ensemble of vacua on which naturalness arguments can be built, this is hence another place where string theory can contribute to progress of theoretical particle physics.

This article aims at making progress in the second direction above. It is known that flux compactification of Type IIB string theory/F-theory stabilizes not only complex structure moduli but also the brane configuration. This means that both gauge groups and coupling constants of the effective theory are determined once a topological flux configuration is given. Exploiting all of the theoretically possible topological flux configurations, an ensemble of low-energy effective theories with various gauge groups and coupling constants is generated in this framework, in principle. To get this done in practice, however, a clever approach is necessary. Low-energy effective theories are usually classified in terms of their algebraic information (such as gauge groups, matter representations and presence/absence of certain types of interactions) first, and then in terms of topological information (such as the number of generations of matter fields in a given representation). Effective theories with the same algebraic and topological information are then specified by the values of coupling constants. The string landscape will be of some use only when the statistical distribution of low-energy observables are presented and studied in compatibility with such a hierarchical classification of effective theories.

This can be done along the line described in [6], which is built on top of pioneering works [7,8]. The study of [6], however, used $\mathrm{K3} \times \mathrm{K3}$ compactification of F-theory, where analysis is a little easier, but we cannot even hope to obtain a semirealistic model of low-energy physics. This article applies the method to more general Calabi–Yau fourfolds for F-theory compactification, derives answers to

 © 2014 American Physical Society

questions of practical interest, and exemplifies the potential power of the method.

Section II is devoted to a review of the method in [6–8] along with new observations in [9]. The method is then applied to a class of compactifications that lead to semi-realistic supersymmetric grand unification (GUT) models in Sec. III. We derive distribution of the number of generations in flux vacua of SU(5) GUT models, and also study how the number of flux vacua scales when we require SO(10), SU(5) or no unification group on 7-branes, respectively. We find that the distribution is in a factorized form to a good approximation, independently of topological choice of geometry. Details and explanations omitted in this article are found in [9].

II. THE METHOD

A family of geometries over a restricted moduli space, $\pi\colon \mathcal{Y} \to \mathcal{M}_*$, is a useful concept when one wants to focus on flux vacua with a given algebraic information. A restricted family and its moduli space, $\pi\colon \mathcal{Y} \to \mathcal{M}_*^{A4}$ (resp. $\mathcal{M}_*^{D5}$), is specified for a topological choice of $(B_3, [S])$, where $[S]$ is a divisor class in B_3. Each member of the family, $\pi^{-1}(p) = Y_p$ for $p \in \mathcal{M}_*^{A4}$ (resp. $\mathcal{M}_*^{D5}$), is a smooth elliptically fibred Calabi–Yau fourfold $\pi_{Y_p}\colon Y_p \to B_3$ with a section, and the discriminant locus of the fibration π_{Y_p} contains an irreducible component in $[S]$ and the generic fiber over it is I_5 (resp. I_1^*) in the Kodaira classification. Any one of such fourfolds in the family over $\mathcal{M}_*^{A4}$ (resp. $\mathcal{M}_*^{D5}$) can be used for F-theory compactification that results in a vacuum with an $R = \mathrm{SU}(5)$ [resp. $R = \mathrm{SO}(10)$] unification group on 7-branes. $\mathcal{M}_*^{A4}$ or $\mathcal{M}_*^{D5}$ parametrizes the complex structure of such geometries.[1] Higher rank 7-brane gauge group implies a larger number of independent divisors

$$[\hat{C}_i] \in [H^2(Y_p;\mathbb{Z}) \cap H^{1,1}(Y_p;\mathbb{R})], \quad i = 1, \ldots, \mathrm{rank}(R), \tag{1}$$

for a generic geometry $\pi^{-1}(p) = Y_p$ in $p \in \mathcal{M}_*$.

An ensemble of F-theory flux vacua with a given algebraic and topological information is specified by a pair $(H_{\mathrm{scan}}, G_{\mathrm{fix}}^{(4)})$, where

$$H_{\mathrm{scan}} \subset [H^4(Y;\mathbb{Z})]_{\mathrm{ker}}, \qquad G_{\mathrm{fix}}^{(4)} \in [H^4(Y;\text{`}\mathbb{Z}\text{'})]_{\mathrm{prim}}; \tag{2}$$

the subscript "prim" implies $J \wedge G = 0 \in H^6(Y;\mathbb{R})$ (the D-term condition), and "ker" both $J \wedge G = 0$ and $i_{\hat{C}_i}^*(G) = 0 \in H^4(\hat{C}_i;\mathbb{Q})$. The last condition is to make sure that fluxes in H_{scan} do not introduce gauge symmetry breaking (cf. [9]). An ensemble of 4-form flux

$$\{G_{\mathrm{tot}}^{(4)} = G_{\mathrm{scan}}^{(4)} + G_{\mathrm{fix}}^{(4)} | G_{\mathrm{scan}}^{(4)} \in H_{\mathrm{scan}}\} \tag{3}$$

determines an ensemble of vacua of complex structure through the superpotential $W \propto \int_{Y_p} \Omega_{Y_p} \wedge G_{\mathrm{tot}}^{(4)}$.

Statistics of such an ensemble of vacua can be presented as a distribution over the restricted moduli space $\mathcal{M}_*$. The distribution was worked out analytically in a very robust way [7] for the vacuum index density $d\mu_I$,

$$d^{2m}z \sum_{G_{\mathrm{scan}}^{(4)}} \delta^{2m}(DW, \overline{DW}) \det \begin{bmatrix} D^2W & \bar{D}DW \\ D\overline{DW} & \overline{D^2W} \end{bmatrix}, \tag{4}$$

to which each flux vacuum on $\mathcal{M}_*$ contributes by a delta function with coefficient ± 1. Here, $m := \dim_{\mathbb{C}} \mathcal{M}_* = h^{3,1}(Y)$, and the dz's are local holomorphic coordinates on $\mathcal{M}_*$. Derivatives in DW, $\overline{DW}$ etc. are with respect to the fields corresponding to the complex structure moduli tangent to $\mathcal{M}_*$.

Making a continuous approximation [7] of the sum over flux configurations $\sum_{G_{\mathrm{scan}}^{(4)}}$ in (4), the vacuum index density is cast into the following form

$$d\mu_I = \frac{(2\pi L_*)^{K/2}}{(K/2)!}\rho_I, \qquad K := \dim_{\mathbb{R}}(H_{\mathrm{scan}} \otimes \mathbb{R}). \tag{5}$$

Here, L_* is the maximal D3-brane charge available. Although ρ_I depends on the choice of H_{scan}, it is given by

$$c_m(T\mathcal{M}_* \otimes \mathcal{L}) = \det\left(-\frac{R}{2\pi i} + \frac{\omega}{2\pi}\mathbf{1}_{m\times m}\right) \tag{6}$$

for the Kähler form ω on $\mathcal{M}_*$ whenever $(H_{\mathrm{scan}} \otimes \mathbb{R})$ contains the real primary horizontal subspace $H_{H*}^4(Y;\mathbb{R}) \subset H^4(Y;\mathbb{R})$ [6–8]. $H_{H*}^4(Y;\mathbb{R})$ is the real part of the primary horizontal subspace in [10],

$$\mathrm{Span}_{\mathbb{C}}\{\Omega_{Y_p}, D\Omega_{Y_p}, D^2\Omega_{Y_p}, \ldots\} \subset H^4(Y;\mathbb{C}), \tag{7}$$

which does not depend on the choice of $p \in \mathcal{M}_*$.

In order to see how H_{scan} should be chosen to achieve the goal we have set in this article, note that the vector space $H^4(Y;\mathbb{R})$ is decomposed as follows:

$$H_{H*}^4(Y;\mathbb{R}) \oplus H_{RM*}^{2,2}(Y;\mathbb{R}) \oplus H_{V*}^{2,2}(Y;\mathbb{R}); \tag{8}$$

the vertical component $H_{V*}^{2,2}(Y;\mathbb{R})$ is the subspace generated by the wedge products of integral (1,1)-forms on Y_p, which defines a subspace of $H^4(Y;\mathbb{R})$ independent of $p \in \mathcal{M}_*$. The remaining component $H_{RM*}^{2,2}(Y;\mathbb{R})$, thus, should not depend on $p \in \mathcal{M}_*$.

[1] As in [6] and literatures therein, we only consider flux vacua for $(B_3, [S])$ of a given topology and for a given choice of Kähler form J on Y_p that is in $H^2(Y_p;\mathbb{Q}) \cap H^{1,1}(Y_p;\mathbb{R})$ modulo multiplication of $\mathbb{R}^\times$. The (restricted) moduli space $\mathcal{M}$ or $\mathcal{M}_*$ therefore refers only to that of complex structure. It is beyond the scope of this article or [9] to include the scanning over $(B_3, [S])$'s of different topology or their Kähler moduli spaces.

We choose $H_{\rm scan}\otimes\mathbb{R}$ to be $H^4_{H*}(Y;\mathbb{R})$ in this article. As discussed in more detail in [9], $H^4_{H*}(Y;\mathbb{R})$ is contained in $[H^4(Y;\mathbb{R})]_{\rm ker}$. Thus, for this choice of $H_{\rm scan}$, all the vacua share the same symmetry group from 7-branes in the effective theories below the Kaluza–Klein scale. This argument does not exclude the option to take $H_{\rm scan}\otimes\mathbb{R}$ larger that $H^4_{H*}(Y;\mathbb{R})$, but we should not take it to be as large as $[H^{2,2}_{V*}(Y;\mathbb{R})]^{\perp}$. It is not hard to find families $\pi\colon\ \mathcal{Y}\to\mathcal{M}_*$ with $h^{2,0}(Y_p)=0$ where there are algebraic four-forms in $H^{2,2}_{RM*}(Y;\mathbb{R})\cap H^4(Y;\mathbb{Z})$ that break the symmetry of the 7-brane gauge group [9]. A similar phenomenon has also been observed in [6], where $Y={\rm K3}\times{\rm K3}$, and the fourform in $H^{2,2}_{RM*}(Y;\mathbb{R})$ is not dual to an algebraic cycle.

III. THE RESULTS

Let us apply the method described in the previous section to derive statistical distributions of observables of practical interest. The study in [6] used a family of ${\rm K3}\times{\rm K3}$ for compactification of F-theory, where all the 7-branes are parallel, and there is no light matter fields except those in the adjoint representation of the 7-brane gauge groups. Ensembles of flux vacua in such a setup do not include low-energy effective theories that look close to the (supersymmetric extensions of the) Standard Model. In this article, we therefore use a few other families of elliptically fibred Calabi–Yau fourfolds, for which the low-energy effective theories are at least semirealistic. These effective theories have SU(5) [resp. SO(10)] unification, and $N_{\rm gen}$ generations of matter fields in the $\mathbf{10}+\bar{\mathbf{5}}$ (resp. 16) representations. The task is to determine the value of L_* and K for such families and to study how those values depend on the choice of the unification group or the number of generations $N_{\rm gen}$.

A. Number of generations

We focus on a few choices of $(B_3,[S])$ for which the restricted moduli spaces and families for SU(5) unification are constructed in the way stated at the beginning of the previous section as examples. We choose

$$B_3=\mathbb{P}[\mathcal{O}_{\mathbb{P}^2}\oplus\mathcal{O}_{\mathbb{P}^2}(n)],\qquad -3\le n\le 3,\qquad (9)$$

which is a $\mathbb{P}^1$-fibration over $\mathbb{P}^2$, and let $[S]$ be the "north-pole section" of the $\mathbb{P}^1$-fibration corresponding to the zero of a section of $\mathcal{O}_{\mathbb{P}^2}$. The range of n is set so that the 7-brane unification group at the S can be as small as SU(5), while the gauge group at the hidden sector [corresponding to the zero of a section of $\mathcal{O}_{\mathbb{P}^2}(n)$] can be completely Higgsed away.

We set $(H_{\rm scan}\otimes\mathbb{R})=H^4_{H*}(Y;\mathbb{R})$, and choose $G^{(4)}_{\rm fix}$ to be the F-theory dual of the chirality-generating bundle twist in [11], parametrized by $\lambda_{FMW}\in 1/2+\mathbb{Z}$. This flux gives rise to the net chirality of the matter fields in the 10 vs $\overline{\mathbf{10}}$ (also $\bar{\mathbf{5}}$ vs 5) representation of the SU(5) unification group; $N_{\rm gen}=-(18-n)(3-n)\lambda_{FMW}$ [12]. Since the vanishing cycles for the chiral matter belong to $H^{2,2}_{V*}(Y;\mathbb{Q})$, any flux vacua in the ensemble (3) have the same $N_{\rm gen}$ [9]. In this way, we obtain an ensemble of F-theory flux vacua that share the same algebraic and topological ($N_{\rm gen}$) information. The F-theory dual description of $G^{(4)}_{\rm fix}$ has been determined in [13].

$L_*=\chi(Y)/24-(G^{(4)}_{\rm fix})^2/2$ is the upper bound on the net D3-brane charges from $G^{(4)}_{\rm scan}$. It depends on $N_{\rm gen}$ through $G^{(4)}_{\rm fix}$ [6] and a straightforward computation reveals that [9,13]

$$L_*=\frac{2163}{4}+\frac{125}{8}n(n+7)-\frac{5N^2_{\rm gen}}{2(18-n)(3-n)}.\qquad (10)$$

The maximal values of $L_*^{\max}$ range within ~300 to 800 for the families with $-3\le n\le 3$ (Table I); details of the calculation are found in [9]. L_* is always an upper convex quadratic function of $N_{\rm gen}$ in F-theory, not just for the choice in (9).

The other number we need to use in (5) is $K=\dim_{\mathbb{R}}H^4_{H*}(Y;\mathbb{R})$. This task boils down to the determination of the dimension of the horizontal component $H^{2,2}_{H*}(Y_p;\mathbb{R})$, since $K=2+2m+\dim_{\mathbb{R}}[H^{2,2}_{H*}(Y_p;\mathbb{R})]$. A general recipe is to use mirror symmetry and determine the dimension of the vertical component of the mirror manifold of Y. The authors derived in [9] the formula for $h^{2,2}_V$, $h^{2,2}_H$ and $h^{2,2}_{RM}$ that is valid for any Calabi–Yau hypersurface of a toric 5-dimensional ambient space.

We carried out the computation of $h^{2,2}_{V*}(Y)$, $h^{2,2}_{H*}(Y)$ and K; for the families for SU(5) unification with B_3 in (9), it turns out that $h^{2,2}_{RM}=0$. Details of the computation are found in [9], and only the results are recorded in Table I. Certainly the results on $L_*^{\max}$ and K in this table are only for a limited number of choices of B_3 and do not tell us whether they are typical among the results for all other choices of B_3 from 3-dimensional Fano varieties, or how much the values of $L_*^{\max}$ and K can vary for different B_3. But the table at least provides the first example of such calculations.

With this preparation, we can derive the distribution of the number of generations $N_{\rm gen}$ almost immediately. We

TABLE I. Various topological data of the families $\mathcal{Y}\to\mathcal{M}^{A4}_*$ of Calabi–Yau fourfolds for SU(5) unification, with B_3 given in (9). For $n=3$, $L_*^{\max}=\chi(Y)/24$, as $G^{(4)}_{\rm fix}=N_{\rm gen}=0$.

n	−3	−2	−1	0	1	2	3
$h^{3,1}_*$	1249	1423	1723	2148	2698	3373	4173
$h^{2,2}_{H*}$	5057	5755	6955	8655	10855	13555	16756
$h^{2,2}_{V*}$	9	9	9	9	9	9	8
$L_*^{\max}$	237	297	387	507	657	837	[1047]
K	7557	8603	10403	12953	16253	20303	25104

have constructed ensembles of flux vacua that are labeled by $\lambda_{FMW} \in 1/2 + \mathbb{Z}$. Each one of those ensembles consists of vacua that lead to effective theories with common algebraic information [SU(5) GUT with chiral matter in the $\mathbf{10} + \bar{\mathbf{5}}$ representation], but their topological information $N_{\rm gen} \propto \lambda_{FMW}$ varies from one ensemble to another. To compare the number of vacua that the individual ensembles contain, one simply needs to integrate ρ_I over $\mathcal{M}_*$, which is to ignore the difference in the value of the effective coupling constants of the vacua in a given ensemble. Since the integral of ρ_I over $\mathcal{M}_*$ usually yields a number of order unity (some region of $\mathcal{M}_*$ may have to be excluded; cf the discussion of D-limits in [7]), we simply make an approximation $\int_{\mathcal{M}_*} \rho_I \approx 1$. Only the prefactor $(2\pi L_*)^{K/2}/[(K/2)!]$ in (5) is then used as an estimate of the number of vacua in a given ensemble. We can use the value of K in Table I, and the $N_{\rm gen}$-dependence of L_* has already been discussed in this article. The number of vacua depends on $N_{\rm gen}$ in a way the volume of a K-dimensional sphere changes as the radius-square L_* decreases quadratically in $N_{\rm gen}$. There is an absolute upper limit on $N_{\rm gen}$ for a given family $\pi\colon \mathcal{Y} \to \mathcal{M}_*^{A4}$ due to the D3-tadpole constraint $L_* \geq 0$.

In the examples of $(B_3, [S])$ we have chosen at the beginning of this section, however, we have $L_* \ll K$ (see Table I). The continuous approximation [7] is not particularly good for such families, and should be replaced by $e^{L_* \ln(\sqrt{2\pi}K/L_*)}$, see [9] for a more detailed discussion.

In fact, it is commonplace to find $L_* \ll K$, not just in the families considered in this section, but in a broader class of families $\pi\colon \mathcal{Y} \to \mathcal{M}_*^R$ of interest. For B_3 with $h^{1,1}(B_3) \approx \mathcal{O}(1)$, for example, $h^{1,1}(Y)$ still remains $\mathcal{O}(1)$, while $h^{3,1}$ is much larger, due to the degrees of freedom for the complex structure of fibration. It is then a quite natural consequence that $h_V^{2,2}$ and $h_{RM}^{2,2}$ are not as large as $h_H^{2,2}$. From this, we find that $K \approx \chi(Y) \approx 24 L_*^{\max} \approx 8\pi L_*^{\max} \gg L_*$. The number of flux vacua for a family $\mathcal{Y} \to \mathcal{M}_*^R$ is then estimated by

$$e^{L_* \ln(\sqrt{2\pi}K/L_*)} \approx e^{K/6} e^{-5cN_{\rm gen}^2}, \tag{11}$$

where c is the coefficient of $N_{\rm gen}^2$ in (10), which remains of order unity. The expansion in $N_{\rm gen}^2$ in the exponent is valid for $N_{\rm gen} \lesssim 10$, since $\chi(Y)/24$ is often around 100–1000. The first factor of (11) depends on the choice of the 7-brane symmetry R [and on $(B_3, [S])$], while the second factor is a Gaussian distribution on $N_{\rm gen}$ for robust choice of $(B_3, [S])$. Algebraic and topological data of effective theories have a factorized distribution. One may further bring the distribution ρ_I on the effective coupling constants back to (11), without integrating it over $\mathcal{M}_*^R$.

TABLE II. Data for families over $\mathcal{M}$, $\mathcal{M}_*^{A4}$ and $\mathcal{M}_*^{D5}$.

	$h^{1,1}$	$h^{3,1}$	$h_{V*}^{2,2}$	$h_{H*}^{2,2}$	$\chi(Y)$	K
no gauge group	3	3277	4	13160	19728	19716
SU(5) model	7	2148	9	8655	12978	12953
SO(10) model	8	2138	10	8618	12924	12896

B. Cost of higher-rank gauge groups

The distribution (5), (6), (11) can be used to derive the statistical cost of requiring a higher rank gauge group on 7-branes. This idea was pursued already in [6], using $Y = \mathrm{K3} \times \mathrm{K3}$ for F-theory compactification; more examples are obtained in this article to estimate the systematics. The choices of $(B_3, [S])$ here are also more realistic than that of $\mathrm{K3} \times \mathrm{K3}$.

The SO(10) version of the family, $\pi\colon \mathcal{Y} \to \mathcal{M}_*^{D5}$, can also be constructed for the choice of $(B_3, [S])$ in (9) using toric geometry. Various topological data for the families over $\mathcal{M}_*^{D5}$, $\mathcal{M}_*^{A4}$ and $\mathcal{M}$ (where no 7-brane gauge symmetry is required) can be computed and the results are recorded in Table II for the $n = 0$ case. For more details of computations, see [9].

One can see from (11) that the difference in the value of K for different choices of 7-brane symmetry R determines the relative number of the corresponding flux quanta (vacua). Ensembles with higher rank 7-brane gauge group have smaller dimension K (Table II), confirming the same observation in [6] based on the family $Y = \mathrm{K3} \times \mathrm{K3}$. This leads to the observation that the rank-4 gauge group on 7-branes is *not* as statistically "natural" as vacua without a gauge group on 7-branes. In the choice of $(B_3, [S])$ in (9) with $n = 0$, for example, vacua with the rank-4 SU(5) unification constitutes only the fraction $e^{-\Delta K/6} \approx e^{-3000}$ of the entire flux vacua (smaller than the fraction 10^{-120} for the cosmological constant). The authors do not provide their interpretations for this inconvenient prediction; a popular attitude will be to hint at poor understanding of string theory, to count on cosmological factors that we did not study here, and/or to resort to anthropics.

IV. OUTLOOK

This article only deals with the easiest applications of the method explained in Sec. II. Various ideas of using (11) and ρ_I to address questions of practical interest are described in detail in [9].

Abstract: The four-form field strength in F-theory compactifications on Calabi-Yau fourfolds takes its value in the middle cohomology group H^4. The middle cohomology is decomposed into a vertical, a horizontal and a remaining component, all three of which are present in general. We argue that a flux along the remaining or vertical component may break some symmetry, while a purely horizontal flux does not influence the unbroken part of the gauge group or the net chirality of charged matter fields. This makes the decomposition crucial to the counting of flux vacua in the context of F-theory GUTs. We use mirror symmetry to derive a combinatorial formula for the dimensions of these components applicable to any toric Calabi-Yau hypersurface, and also make a partial attempt at providing a geometric characterization of the four-cycles Poincaré dual to the remaining component of H^4. It is also found in general elliptic Calabi-Yau fourfolds supporting SU(5) gauge symmetry that a remaining component can be present, for example, in a form crucial to the symmetry breaking $\mathrm{SU}(5) \longrightarrow \mathrm{SU}(3)_C \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$. The dimension of the horizontal component is used to derive an estimate of the statistical distribution of the number of generations and the rank of 7-brane gauge groups in the landscape of F-theory flux vacua.

1 Introduction

Work in string theory has traditionally focussed on the study of Calabi-Yau threefolds, as they are relevant to compactification of strings theories to four dimensions. From a mathematical point of view, it is very natural to ask about the properties of Calabi-Yau manifolds in (complex) dimensions other than three. Besides the omnipresent torus, two- and four-dimensional Calabi-Yau manifolds have subsequently acquired a central position within string theory.[1]

Two-dimensional Calabi-Yau manifolds, more commonly called K3 surfaces, form a single connected family and have a long history in mathematics (see e.g. the classic [2]). As the simplest non-trivial Calabi-Yau manifolds, they also have long been used to compactify string and supergravity theories. Their full relevance to string theory has only been appreciated with the advent of string dualities [3]. Besides appearing in relation to mirror symmetry [4], it was also in the context of string dualities, and in particular compactifications of F- and M-theory, that Calabi-Yau fourfolds became an intense object of interest. Refs. [5–12] form a partial list of early papers on the subject.

What is common to all Calabi-Yau n-folds is that their Kähler and complex structures are measured by integrating two special harmonic differential forms, the Kähler form $J \in H^{1,1}$ and the holomorphic top-form $\Omega \in H^{n,0}$, over appropriate cycles. However, we may already point out a crucial difference between Calabi-Yau threefolds on one side and K3 surfaces and Calabi-Yau fourfolds on the other side: whereas (powers of) J and $\Omega^{3,0}$ live in different cohomology groups in the case of Calabi-Yau manifolds of odd complex dimensions, $\Omega^{n,0}$ and $J^{n/2}$ share the middle cohomology for Calabi-Yau manifolds of even complex dimensions. For K3 surfaces this observation is tightly connected with the concept of polarization, where both J and $\Omega^{2,0}$ are confined to lie in mutually orthogonal subspaces of H^2. The Torelli theorem for lattice-polarized K3 surfaces states that the complex structure of a K3 surface with a lattice $W \subset H^2$ generated by algebraic cycles is parametrized by the period domain $\mathcal{M}_* = \mathbb{P}\left[\{\Omega \in [W^\perp \subset H^2 \otimes \mathbb{C}] \mid \Omega \wedge \Omega = 0, \Omega \wedge \overline{\Omega} > 0\}\right]$.

[1] See [1] for a discussion of M-theory compactifications on Calabi-Yau fivefolds.

JHEP01(2015)047

For Calabi-Yau fourfolds, however, there is no such convenient Torelli theorem. Consider a family of Calabi-Yau fourfolds $\pi : \mathcal{Z} \longrightarrow \mathcal{M}_*$ (i.e., $\hat{Z}_p := \pi^{-1}(p)$ for $p \in \mathcal{M}_*$ is a Calabi-Yau fourfold); $\mathrm{Pic}(\hat{Z}_p)$ for a generic choice of $p \in \mathcal{M}_*$ plays a role similar to the lattice polarization in the case of K3 surfaces. For any two classes in $\mathrm{Pic}(\hat{Z}_p)$ with representatives η_1 and η_2, we may form a *vertical cycle* $\eta_1 \wedge \eta_2$, which defines a class in $H^{2,2}(\hat{Z}_p;\mathbb{R}) \cap H^4(\hat{Z};\mathbb{Z})$. The subspace generated by such cycles (for p not in any one of the Noether-Lefschetz loci within $\mathcal{M}_*$) is called the *primary vertical component* of $H^{2,2}$, and is denoted by $H^{2,2}_V(\hat{Z}_p)$. It is identified within $H^4(\hat{Z};\mathbb{Z})$ defined in *topology*, independently of the choice of the "generic" $p \in \mathcal{M}_*$. The period integral $\int \Omega_{\hat{Z}_p}$ takes its value in $H^4(\hat{Z};\mathbb{C})$ and satisfies the obvious constraints $\Omega \wedge \Omega = 0$ and $\Omega \wedge \overline{\Omega} > 0$–(*), but the image of the period map does NOT occupy all of the complement of the primary vertical component. That is, the period domain satisfying (*) may be contained in a space much smaller than

$$\left[(H^{2,2}_V \otimes \mathbb{C})^{\perp} \subset H^4(\hat{Z};\mathbb{C})\right]. \tag{1.1}$$

References [4, 13] introduced another subspace $H^4_H(\hat{Z};\mathbb{C}) \subset H^4(\hat{Z};\mathbb{C})$ called the *primary horizontal* component (see section 2 for a brief review). The period map is locally injective for Calabi-Yau fourfolds and maps $\mathcal{M}_*$ into an $m := h^{3,1}(\hat{Z}_p) = \dim_{\mathbb{C}}\mathcal{M}_*$-dimensional subvariety of $\mathbb{P}[H^4(\hat{Z};\mathbb{C})]$; as we will elaborate on in the next section, $\mathcal{M}_*$ is in fact mapped into the projectivization of the horizontal component, $\mathbb{P}\left[H^4_H(\hat{Z};\mathbb{C})\right]$. The middle cohomology $H^4(\hat{Z};\mathbb{C})$ of a Calabi-Yau fourfold is then decomposed into

$$H^4(\hat{Z};\mathbb{C}) = H^4_H(\hat{Z};\mathbb{C}) \oplus H^{2,2}_{RM}(\hat{Z};\mathbb{C}) \oplus H^{2,2}_V(\hat{Z};\mathbb{C}), \tag{1.2}$$

where the decomposition is orthogonal under the intersection pairing. Unless the $H^4_{RM}(\hat{Z};\mathbb{C})$ component vanishes, the primary horizontal subspace $H^4_H(\hat{Z};\mathbb{C})$ is smaller in dimension than the non-vertical subspace (1.1).

There is another context — flux compactification of F-theory — where one is interested in the decomposition (1.2) of the middle cohomology above. An ensemble of flux vacua is specified by specifying a subspace of

$$\left[H^4(\hat{Z};\mathbb{Z})\right]_{\text{shift}} := H^4(\hat{Z};\mathbb{Z}) + \frac{c_2(T\hat{Z})}{2}; \tag{1.3}$$

when this subspace is affine, the vacuum index distribution over the moduli space $\mathcal{M}_*$ is given by a concise analytic formula [14, 15]. As discussed already in [16], and refined further in section 2 in this article, we can see that any pair of topological four-form fluxes whose difference belongs to the real part of the primary horizontal subspace $H^4_H(\hat{Z};\mathbb{R})$ shares the same symmetry group from 7-branes in their effective theories below the Kaluza-Klein scale. This motivates us to choose the affine subspace as some form of shift of $H^4_H(\hat{Z};\mathbb{R})$. Because the analytic formula of vacuum index density involves the dimension of the affine subspace, it is of interest in physics application of F-theory to know the dimension of $H^4_H(\hat{Z};\mathbb{R})$. Another question of interest is concerns how the space $H^{2,2}_{RM}(\hat{Z};\mathbb{R})$ arises geometrically, and which role it plays in phenomenology applications.

JHEP01(2015)047

Mirror symmetry indicates that [4, 13]

$$\left[H^4_H(\hat{Z};\mathbb{C}) \cap H^{2,2}(\hat{Z}_p;\mathbb{C})\right] =: H^{2,2}_H(\hat{Z}_p;\mathbb{C}) \quad \text{and} \quad H^{2,2}_V(\hat{Z}_{\mathrm{m}};\mathbb{C}) \tag{1.4}$$

have the same dimensions for a mirror pair $(\hat{Z}, \hat{Z}_m)$. This article shares the idea of using the dimension $h^{2,2}_V$ of the mirror $\hat{Z}_m$ to find the dimension $h^{2,2}_H$ of the original geometry $\hat{Z}$ with [17, 18]. References [17, 18] used the intersection ring of the vertical subspace of the mirror $\hat{Z}_m$ not just to determine the dimension $h^{2,2}_H(\hat{Z}) = h^{2,2}_V(\hat{Z}_m)$, but also to compute period integrals of $\hat{Z}$.

We combine this intersection ring in the mirror $\hat{Z}_m$ with a stratification of $\hat{Z}_m$ and a long exact sequence of morphisms of mixed Hodge structure, a combination of techniques that ref. [19] used in order to derive the formula for $h^{1,1}$ and $h^{k-1,1}$ of a toric-hypersurface Calabi-Yau k-fold. With this approach, we are not only able to determine the dimensions $h^{2,2}_V(\hat{Z}_m) = h^{2,2}_H(\hat{Z})$, $h^{2,2}_V(\hat{Z}) = h^{2,2}_H(\hat{Z}_m)$ and $h^{2,2}_{RM}(\hat{Z}) = h^{2,2}_{RM}(\hat{Z}_m)$, but also to construct the cycles representing the remaining component, study their geometry, and discuss their different roles in physics applications.

We start with an introductory discussion in section 2, which motivates the study of the space of non-vertical four-cycles (primary horizontal cycles in particular) in the context of the landscape of flux vacua in F-theory compactifications. Using mirror symmetry, we derive a combinatorial formula for $h^{2,2}_V$, $h^{2,2}_H$, and $h^{2,2}_{RM}$, the dimensions of the space of vertical, horizontal and remaining (i.e. non-vertical and non-horizontal) cycles for Calabi-Yau fourfolds obtained as hypersurfaces of toric varieties in section 3. Already in this simple class of Calabi-Yau fourfolds, the remaining component is found to be non-zero in general. We provide several examples in section 4.

A non-zero $H^{2,2}_{RM}(\hat{Z};\mathbb{C})$ already occurs for the family of Calabi-Yau fourfolds $\hat{Z} = \mathrm{K3} \times \mathrm{K3} = S_1 \times S_2$ with a lattice polarization $W_1 \subset H^2(S_1;\mathbb{Z})$ and $W_2 \subset H^2(S_2;\mathbb{Z})$. Here,

$$h^{2,2}_V = \rho_1\rho_2 + 2, \quad h^{2,2}_{RM} = \rho_1(22-\rho_2) + (22-\rho_1)\rho_2, \quad 2 + 2h^{3,1} + h^{2,2}_H = (22-\rho_1)(22-\rho_2), \tag{1.5}$$

where $\rho_i = \mathrm{rank}(W_i)$ [16]. In this example, the Poincaré duals of $H^{2,2}_{RM}(\hat{Z})$ are not represented by algebraic four-cycles.

Section 5 shows another example of a family $\pi : \mathcal{Z} \longrightarrow \mathcal{M}_*$ where $h^{2,2}_{RM} \neq 0$ and provides some more intuition for the geometry relevant to cycles in $h^{2,2}_{RM}$. This family is a simple example within the class of Calabi-Yau fourfolds motivated by [20, 21] for F-theory compactification where SU(5) unification symmetry is broken down to that of the Standard Model $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ without the hypercharge $\mathrm{U}(1)_Y$ vector field becoming massive. The remaining component $H^{2,2}_{RM}(\hat{Z})$ in this family contains forms that are Poincaré dual to four-cycles which are non-vertical, but still algebraic over generic points in moduli space. This observation plays an important role in the discussion of section 2, which discusses the relevance of the real primary horizontal subspace $H^4_R(\hat{Z};\mathbb{R}) \subset H^4(\hat{Z};\mathbb{R})$ in the context of the landscape of flux vacua in F-theory compactification.

In section 6, we discuss how the abundance of flux vacua depends on the unification group, and the number of generations. Under rather general assumptions, the dependence on the number of generations is found to factor from the distribution and to be given by a

JHEP01(2015)047

Gaussian quite generically for any choice of base manifold. We also develop an estimate for the dependence of the number of flux vacua on the gauge (unification) group, generalizing earlier attempts in [16]. We estimate that the abundance of flux vacua with e.g. gauge group SU(5) is suppressed by a factor of roughly $e^{\mathcal{O}(1000)}$ when compared to models with no non-abelian gauge group. One can think of this surpression as a fine-tuning wildly surpassing the fine-tuning of 10^{-120} needed to explain the smallness of the cosmological constant. Appendix B contains a further elaboration of how such estimates may be obtained. Finally, we discuss several open problems reserved for future investigation in section 7.

The appendices A and C mostly contain supplementary material and applications. Appendix A reviews details of the geometry of F-theory GUTs with gauge group SU(5) relevant for section 5. Appendix A.3 explains how to compute the Hodge diamond of exceptional divisors in such a geometry by using stratification. Appendix C reviews the construction of chirality-inducing four-form flux, and computation of the D3-tadpole from the geometry and this flux. The numerical results in the appendices B and C are used as input for the discussion in section 6.

A letter [22] by the same authors is focused on a subset of the subjects discussed in this article, and is addressed to a broader spectrum of readers. It covers the subjects of sections 2 and 6 and uses the results of section 4.4.1 and the appendices B and C, while omitting the (mostly technical) material of sections 3 and 5.

2 Ensembles of F-theory flux vacua and the primary horizontal subspace

Supersymmetric compactification of F-theory to 3+1-dimensions is specified by a set of data $(X, B_3, J, G^{(4)})$, where $\pi_X : X \longrightarrow B_3$ is an elliptic fibration with a section, $J \in H^{1,1}(B_3; \mathbb{R})$ a Kähler form on B_3 and a G_4 a four-form flux in $[H^4(X; \mathbb{Z})]_{\text{shift}}$. Once $G^{(4)}$ is given topologically, the superpotential $W \propto \int_X \Omega_X \wedge G^{(4)}$ determines the vacuum expectation value of the complex structure of X, B_3, π_X etc. For an ensemble of fluxes in $[H^4(X; \mathbb{Z})]_{\text{shift}}$, therefore, we obtain an ensemble of low-energy effective theories in 3+1-dimensions, called a landscape.

Flux compactification not only determines the values of low-energy coupling constants, but also the gauge group. Once the complex structure of the elliptic fibration $\pi_X : X \longrightarrow B_3$ is determined by the mechanism above, we know the configuration of 7-branes (i.e. the discriminant locus of π_X). Now, remember that we usually classify low-energy effective theories in their algebraic information such as gauge group, matter representations and unbroken symmetry first, in their topological information such as the number of generations next, and then finally in their values of the coupling constants. It is thus desirable to be able to classify flux vacua in a landscape also in the same way, sorting out first in the algebraic information, secondly in the topological data and finally in the moduli data [16]. This requires to work out what kind of topological flux $G^{(4)}$ results in an effective theory with a given algebraic and topological information.

In order to address this problem, it is useful to consider a family of elliptically fibred Calabi-Yau fourfolds characterized as follows [16]. First, let us choose $(B_3, [S])$ and an algebra R. We specify only the topology of an algebraic three-fold B_3, and let $[S]$ be a

JHEP01(2015)047

divisor class in $\mathrm{Pic}(B_3)$. R is an algebra in the A-D-E series, to be used for a unification group of one's interest. The family $\pi : \mathcal{X} \longrightarrow \mathcal{M}_*^R$ is that of *smooth* Calabi-Yau fourfolds X with an elliptic fibration $\pi_X : X \longrightarrow B_3$ with a section, so that there is a locus of singular fibres of type[2] R along a divisor S of B_3 that belongs to the class $[S]$. The restricted moduli space $\mathcal{M}_*^R$ parametrizes the complex structure of such fourfolds X. For a generic point $p \in \mathcal{M}_*^R$, the corresponding fourfold $X_p := \pi^{-1}(p)$ has the property that $\left[H^{1,1}(X_p;\mathbb{Q}) \cap H^2(X;\mathbb{Q})\right]$ is generated by divisors in the base, the zero-section σ, and $\{\hat{\mathcal{C}}_i\}_{i=1,\cdots,\mathrm{rank}(R)}$ called Cartan divisors. Such a family over the restricted moduli space $\mathcal{M}_*^R$ is a useful notion to express the flux vacua distribution, as we see in eqs. (2.8), (2.9).

There are a couple of physical conditions to be imposed on the fluxes. First of all, the flux preserves the SO(3, 1) symmetry in the effective theory on 3+1-dimensions if and only if the flux $G^{(4)}$ does not have a component that has either "two legs in the T^2 fibre" or "no legs in the T^2 fibre" [23]. This condition is best paraphrased as

$$\sigma \wedge \eta \wedge G^{(4)} = 0, \qquad \eta_1 \wedge \eta_2 \wedge G^{(4)} = 0, \tag{2.1}$$

where σ is (the differential form Poincaré dual to) the zero section, and η, $\eta_{1,2}$ are divisors on B_3, see [24–28]. The D-term condition (equivalently $\mathcal{N} = 1$ supersymmetry condition, primitiveness condition) is that

$$J \wedge G^{(4)} = 0 \in H^6(X;\mathbb{R}). \tag{2.2}$$

The subspace of $[H^4(X;\mathbb{Z})]_{\mathrm{shift}}$ satisfying the two conditions above, (2.1), (2.2), is denoted by $[H^4(X;\mathbb{Z})]_{\mathrm{shift}}^{\mathrm{Lor.prim.}}$. The subspace of $H^4(X;\mathbb{Z})$ without the shift by $c_2(TX)/2$ satisfying the condition (2.1), (2.2) is denoted by $[H^4(X;\mathbb{Z})]^{\mathrm{Lor.prim.}}$.

For a pair of fluxes $G_1^{(4)}$ and $G_2^{(4)}$ in $[H^4(X;\mathbb{Z})]_{\mathrm{shift}}^{\mathrm{Lor.prim.}}$ to preserve the same symmetry group within the 7-brane gauge group R, their difference needs to satisfy

$$i_{\hat{\mathcal{C}}_i}^* \left(G_1^{(4)} - G_2^{(4)}\right) = 0 \in H^4(\hat{\mathcal{C}}_i;\mathbb{Z}), \tag{2.3}$$

where $i_{\hat{\mathcal{C}}_i} : \hat{\mathcal{C}}_i \hookrightarrow X$ is the embedding of the Cartan divisors (generators) $\{\hat{\mathcal{C}}_i\}_{i=1,\cdots,\mathrm{rank}(R)}$. Thus, we formulate an ensemble of fluxes leading to effective theories with a common unbroken symmetry group as

$$\left\{G_{\mathrm{tot}}^{(4)} = G_{\mathrm{scan}}^{(4)} + G_{\mathrm{fix}}^{(4)} \mid G_{\mathrm{scan}}^{(4)} \in H_{\mathrm{scan}}\right\}; \tag{2.4}$$

we choose $G_{\mathrm{fix}}^{(4)}$ and H_{scan} such that $G_{\mathrm{scan}}^{(4)} = 0$ is contained in H_{scan}. $G_{\mathrm{fix}}^{(4)}$ must be in $[H^4(X;\mathbb{Z})]_{\mathrm{shift}}^{\mathrm{Lor.prim.}}$, while H_{scan} needs to be a sub-*set* of the cohomology group $H^4(X;\mathbb{Z})$ satisfying all the conditions (2.1), (2.2), (2.3). Because all of these conditions[3] are linear in $G^{(4)}$, we always take H_{scan} to be a sub-*group* of $H^4(X;\mathbb{Z})$.

We now argue that the real primary horizontal subspace $H_H^4(X;\mathbb{R}) \subset H^4(X;\mathbb{R})$ satisfies all of the conditions (2.1), (2.2), (2.3) modulo $\otimes\mathbb{R}$, and we can hence take H_{scan} to

[2]Here, 'type R' singular fibre means that at a generic point in S, the dual graph of the fibre is given by the extended Dynkin diagram of R.

[3]The condition from D3-brane tadpole is treated separately from the conditions discussed above.

JHEP01(2015)047

contain all of $H^4_H(X;\mathbb{R}) \cap H^4(X;\mathbb{Z})$. To see this, we take a little moment to provide a brief review on the definition of $H^4(X;\mathbb{C})$, and to make clear what we mean by the *real* primary horizontal subspace. For any point $p \in \mathcal{M}^R_*$, we can define a subspace

$$\begin{aligned}&\mathrm{Span}_{\mathbb{C}}\left\{\Omega_{X_p}, D\Omega_{X_p}, D^2\Omega_{X_p}, D^3\Omega_{X_p}, D^4\Omega_{X_p}\right\} \\ &= H^{4,0}(X_p,\mathbb{C}) \oplus H^{3,1}(X_p;\mathbb{C}) \oplus H^{2,2}_H(X_p;\mathbb{C}) \oplus H^{1,3}(X_p;\mathbb{C}) \oplus H^{0,4}(X_p;\mathbb{C}) \subset H^4(X;\mathbb{C}).\end{aligned} \tag{2.5}$$

The cohomology group $H^4(X;\mathbb{C}) = \mathbb{C} \otimes H^4(X;\mathbb{Z})$ is topological; there is a canonical identification between $H^4(X_p;\mathbb{C})$ and $H^4(X_{p'};\mathbb{C})$ for p, p' in a small neighbourhood in $\mathcal{M}_*$ — called flat structure — and the reference to $p \in \mathcal{M}_*$ is suppressed in the expression above. The (p,q)-Hodge components with the canonical identification relative to $H^4(X;\mathbb{C})$, however, vary over $p \in \mathcal{M}^R_*$. The fact that the Picard-Fuchs equations on the period integral are closed in the subspace specified above, however, implies that the space (2.5) remains the same in $H^4(X;\mathbb{C})$ for every $p \in \mathcal{M}_*$ (at least locally) under the canonical identification (flat structure). A reference to $p \in \mathcal{M}^R_*$ is hence suppressed and the invariant subspace is called the primary horizontal subspace $H^4_H(X;\mathbb{C})$. The remaining component in the decomposition (1.2), $H^{2,2}(X_p;\mathbb{C})$, should therefore be independent of $p \in \mathcal{M}_*$ under the canonical identification. This is why reference to $p \in \mathcal{M}_*$ is completely dropped in (1.2); the decomposition (1.2) is topological.

The four-form flux in M-theory/F-theory compactification is real-valued, while the primary horizontal subspace $H^4_H(X;\mathbb{C})$ is complex-valued. Noting, however, that the complex conjugation operation is compatible with the canonical identification (topological tracking) of $H^4(X_p;\mathbb{C})$ for $p \in \mathcal{M}_*$, we also have a decomposition of the real part $H^4(X;\mathbb{R})$:

$$H^4(X;\mathbb{R}) = H^4_H(X;\mathbb{R}) \oplus H^{2,2}_{RM}(X;\mathbb{R}) \oplus H^{2,2}_V(X;\mathbb{R}), \tag{2.6}$$

just like in (1.2). The "primary horizontal subspace" component of $H^4(X;\mathbb{R})$ is what we call the real primary horizontal subspace $H^4_H(X;\mathbb{R})$.

Now, let us see that the four-forms in the real primary horizontal subspace $H^4_R(X;\mathbb{R})$ satisfy all the conditions (2.1), (2.2), (2.3) modulo $\otimes\mathbb{R}$. First, noting that $\sigma \cdot \eta$ and $\eta_1 \cdot \eta_2$ in (2.1) form only a subset of generators of the vertical four-cycles, and that all of the elements of the horizontal component are orthogonal to those in the vertical component in (1.2), it is straightforward to see that the four-forms in $H^4_H(X;\mathbb{R})$ satisfy (2.1).

In order to verify the primitiveness condition, consider the $(h^{3,1}+1) = (m+1)$-dimensional variety occupied by the complex line $\mathbb{C}[\Omega_{X_p}]$ (this is a $\mathbb{C}^\times$-cone over the period domain). Any four-form G in this variety satisfies the condition (2.2), because G is a $(4,0)$-form for some choice $p \in \mathcal{M}_*$ of complex structure on X, and $J \wedge G$ would have become a $(5,1)$-form under that complex structure, if it were non-zero. The absence of such a Hodge component in a Calabi-Yau fourfold X implies that $J \wedge G = 0$. Since all kinds of four-forms in $H^4_H(X;\mathbb{C})$ are obtained by taking derivatives of such G with respect to the local coordinates in $\mathcal{M}_*$, we find that all the four-forms in the (real) horizontal primary subspace satisfy the primitiveness condition (2.2).

Finally, we can make a similar argument to show that the four-forms in $H^4_H(X;\mathbb{R})$ satisfy the condition (2.3). Consider again the set of four-forms realized in the form of Ω_{X_p}

JHEP01(2015)047

for some $p \in \mathcal{M}_*$. Its pull-back to any one of Cartan divisors $\hat{\mathcal{C}}_i$ must be a $(4,0)$-form on a complex *three*-fold $\hat{\mathcal{C}}_i$ under the complex structure of $p \in \mathcal{M}_*$ induced on $\hat{\mathcal{C}}_i \subset X_p$. Thus, the pull-back of such a four-form vanishes in $H^4(\hat{\mathcal{C}}_i;\mathbb{C})$. Taking derivatives with respect to the local coordinates of $\mathcal{M}_*$, we find that the four-forms in $H^4_H(X;\mathbb{R})$ satisfy the condition (2.3).

References [14, 15, 29] studied how the flux vacua are distributed in the complex structure moduli space for ensembles of fluxes of the form (2.4). One of the two key ideas is to replace the vacuum distribution by the vacuum index distribution

$$d\mu_I := d^{2m}z \sum_{G^{(4)}_{\rm scan} \in H_{\rm scan}} \delta^{2m}(DW, \overline{DW}) \det \begin{bmatrix} DDW & D\overline{DW} \\ \overline{D}DW & \overline{DDW} \end{bmatrix}_{2m\times 2m} \Theta\left(L_* - \frac{1}{2}(G^{(4)}_{\rm tot})^2\right), \tag{2.7}$$

so that the problem becomes easier. $(z,\bar{z})$ are local coordinates of $\mathcal{M}_*$, $W \propto \int_X \Omega_{X_p} \wedge G^{(4)}$ and L_* is the upper bound of the D3-brane charge allowed for the fluxes $G^{(4)}_{\rm tot}$. The other idea is to make a continuous approximation to $H_{\rm scan}$, which is to treat the subgroup $H_{\rm scan} \subset H^4(X;\mathbb{Z})$ as a vector space $H_{\rm scan} \otimes \mathbb{R}$, and to replace the sum by an integral over the vector space $H_{\rm scan} \otimes \mathbb{R}$. Under the continuous approximation, the vacuum index density $d\mu_I$ is of the form [14, 15] ($L_* \gg K$)

$$d\mu_I \simeq \frac{(2\pi L_*)^{K/2}}{\Gamma(K/2)}\, \rho_I, \qquad K := \dim_{\mathbb{R}} (H_{\rm scan} \otimes \mathbb{R}), \tag{2.8}$$

where ρ_I is an (m,m) form on $\mathcal{M}_*$. It is given as the Euler class of some real $\mathrm{rank}_{\mathbb{R}} = 2m$ vector bundle on $\mathcal{M}_*$ [29], and can be put in the explicit form

$$\rho_I = c_m(T\mathcal{M}_* \otimes \mathcal{L}^{-1}) = \det\left[-\frac{R}{2\pi i} + \frac{\omega}{2\pi}\mathbf{1}_{m\times m}\right], \tag{2.9}$$

where ω is the Kähler form on $\mathcal{M}_*$ derived from $K = -\ln[\int \Omega \wedge \overline{\Omega}]$, and $\mathcal{L}$ a line bundle satisfying $c_1(\mathcal{L}^{-1}) = \omega/(2\pi)$, whenever the vector space $H_{\rm scan}\otimes\mathbb{R}$ contains the real primary horizontal subspace $H^4_H(X;\mathbb{R})$ [14–16, 29].

Having reminded ourselves of how $H_{\rm scan}$ is used, let us return to the question of how we should take $G^{(4)}_{\rm fix}$ and $H_{\rm scan}$. The problem we set in this article (and also in [16, 22]) is to classify the fluxes in $[H^4(X;\mathbb{Z})]^{\rm Lor.prim.}_{\rm shift}$ into sub-ensembles of the form (2.4) so that each subensemble corresponds to the ensemble of low-energy effective theories with a given set of algebraic (or algebraic and topological) information. $G^{(4)}_{\rm fix}$ is used as a tag of the subensemble. Apart from [16], the $H^{2,2}_{RM}(X;\mathbb{R})$ component has not been carefully discussed (at least from the perspective of the geometry of Calabi-Yau fourfolds) in the context of F-theory phenomenology to our knowledge. In order to address this problem, therefore, it is necessary to reopen the case and understand carefully how the low-energy effective theories are controlled by the fluxes in each one of the components of the decomposition (2.6).

First of all, it is already known that $h^{2,2}_{RM}$ can be non-zero in a family of $X = \mathrm{K3} \times \mathrm{K3}$ [16], as we have already reviewed in the introduction. We will prove in section 5 that the class of families of elliptic fibred Calabi-Yau fourfolds for F-theory compactification with SU(5) unification results in $h^{2,2}_{RM} \neq 0$ precisely in the cases that are well-motivated

JHEP01(2015)047

for a mechanism of SU(5) symmetry breaking in [20, 21]. Despite the presence of the $H^{2,2}_{RM}(X;\mathbb{R})$ component in the middle cohomology, however, we have confirmed (see also the detailed discussion in the appendix A.4 of this article) that the matter surfaces for $\mathbf{10}+\overline{\mathbf{10}}$ representations and also $\bar{\mathbf{5}}+\mathbf{5}$ representations of SU(5) belong to topological classes of $H^{2,2}_{V}(X;\mathbb{Q})$, confirming [25]. This means that the net chirality of these representations is controlled by the flux in the $H^{2,2}_{V}(X;\mathbb{R})$ component.

It has also been indicated that fluxes in $H^{2,2}_{RM}(X;\mathbb{R})$ may break the symmetry of the 7-brane gauge group R based on the family $X = \text{K3} \times \text{K3}$ [16]. Certainly this family is not suitable for realistic compactifications of F-theory in that all the matter fields in the relatively light spectrum are in the adjoint representation of R; this family may also be somehow special in that $h^{2,0}(X) \neq 0$. However, we have confirmed that the flux in the $H^{2,2}_{RM}(X;\mathbb{R})$ component may indeed break the symmetry R; the hypercharge flux of [20, 21] turns out to be precisely in this category.

Given all the observations above we conclude that $H_{\text{scan}} \otimes \mathbb{R}$ should be chosen such that it contains all of the horizontal component $H^4_H(X;\mathbb{R})$ and possibly a part of $H^{2,2}_{RM}(X;\mathbb{R})$. Clearly, $H_{\text{scan}} \otimes \mathbb{R}$ should not contain the entire $H^{2,2}_{RM}(X;\mathbb{R})$ for sub-ensemble of fluxes (2.4) to correspond to an ensemble of effective theories with a given set of algebraic and topological information. An example of the family of $X = \text{K3} \times \text{K3}$ suggests strongly that we should choose $(H_{\text{scan}} \otimes \mathbb{R})$ to be precisely the horizontal component, because any flux in $H^{2,2}_{RM}(X;\mathbb{R})$ breaks some of the 7-brane gauge group and Higgses away vector bosons from the low-energy spectrum in this example. We remain inconclusive about the case of families for realistic F-theory compactification with $(B_3, [S], R)$ (with $R = A_4, D_5$ etc.), however, because the discussion in sections 3 and 5 provides only a partial understanding of the geometry of the $H^{2,2}_{RM}(X;\mathbb{R})$ component. This material is enough, however, to conclude that the formula (2.8), (2.9) of [14, 15] can be used for the ensemble of effective theories with a given algebraic and topological information. In the examples of elliptic fourfolds for F-theory compactification studied in section 4.4 of this paper, the remaining component $H^{2,2}_{RM}(X;\mathbb{R})$ is absent, so that the horizontal component can be identified with $H_{\text{scan}} \otimes \mathbb{R}$.

We have so far assumed that smooth Calabi-Yau fourfolds X with flat elliptic fibration are used for F-theory compactifications with fluxes; it should be rememebered, however, that it is a belief rather than a fact that such smooth models X should be used instead of the Weierstrass models X_s, which are singular for compactifications leading to effective theories with unbroken non-Abelian gauge groups. There may be alternative and/or equivalent formulations of fluxes that lead to the same physics end results. Even when we pursue the direction of using smooth models X, there can be more than one choice of such a smooth model X. All of those different resolutions, however, should describe the low-energy physics of the same vacuum with an unbroken unified symmetry. Thus, no matter how fluxes in F-theory are formulated, all the observable physics consequences should not depend on the choice of resolutions. The dimension of the primary horizontal component ($(H_{\text{scan}} \otimes \mathbb{R})$ to be more precise) should be regarded as one of such physical consequences of F-theory, and hence $K = \dim_{\mathbb{R}}[H^4_H(X;\mathbb{R})]$ must not depend on the choice of the smooth model X for a singular X_s.

JHEP01(2015)047

There is a general argument that is good enough to make us consider that the dimensions of $h_V^{2,2}(X;\mathbb{R})$, $h_H^{2,2}(X;\mathbb{R})$ and $h_{RM}^{2,2}(X;\mathbb{R})$ are resolution independent. It seems reasonable to assume that, for a singular Calabi-Yau fourfold (X_s), any crepant resolution (X) gives rise to the same complex structure moduli space. If this holds, the dimension of the space of primary horizontal (2, 2) cycles, $h_H^{2,2}(X;\mathbb{R})$, as well as $h^{3,1}(X)$ cannot depend on the resolution. By mirror symmetry, the same statement must be true also for the space of primary vertical (2, 2) cycles $h_V^{2,2}(X;\mathbb{R}) = h_H^{2,2}(X_m;\mathbb{R})$, and $h^{1,1}(X) = h^{3,1}(X_m)$, where we assume that all the different resolutions X for X_s share some mirror geometries X_m with a common complex structure moduli space. If furthermore the Euler characteristic is invariant under which resolution is used, it follows that also $h^{2,2}$ cannot be resolution dependent. This is because $h^{2,2}$ is not an independent Hodge number but related to all others by (3.62). From the independence of $h_H^{2,2}(X;\mathbb{R})$ and $h_V^{2,2}(X;\mathbb{R})$ on which resolution is used, it then follows that also $h_{RM}^{2,2}(X;\mathbb{R})$ is independent of the resolution.

The two assumptions we have made are obvious for a Calabi-Yau manifold X given as a hypersurface (or, more generally, complete intersection) in a toric ambient space: for a fixed singular Calabi-Yau manifold, different crepant resolutions correspond to different triangulations of the N-lattice polytope whereas all Hodge numbers, and, in particular the complex structure moduli space depend on the combinatorics of the N- and M-lattice polytopes, but not on triangulations. We will give a more specific proof of this for the expressions we derive in the hypersurface case in section 3.6.3.

More generally, our assumptions follow if different resolutions correspond to different cones in the extended Kähler moduli space, so that they are connected by flop transitions, which are known to leave both the complex structure moduli space and the Euler characteristic invariant. This state of affairs is realized in the geometries which are the main motivation for the present work: F-theory on Calabi-Yau fourfolds supporting non-abelian gauge groups [30–35].

Let us leave a few remarks at the end of this section in order to clarify what the vacuum index density distribution $d\mu_I$ is for, as well as what it is not (yet) for. These are more or less known things, and we include this discussion in this article only as reminder.

The first remark is that a family $\pi : \mathcal{X} \longrightarrow \mathcal{M}_*^R$ for some choice of symmetry R and topology of $(B_3, [S])$ is used to describe the distribution of a subensemble of flux vacua that is *inclusive* in nature. Even though the scanning component of the flux, $G_{\text{scan}}^{(4)}$, is chosen from the real primary *horizontal* component $H_H^4(\hat{Z};\mathbb{R}) \subset H^4(\hat{Z};\mathbb{R})$, it may eventually end up with the Poincaré dual of a algebraic cycle as a result of dynamical relaxation of the complex structure moduli due to the superpotential $W \propto \int \Omega \wedge G^{(4)}$. The delta function $\delta^{2m}(DW, \overline{DW})$ for a given $G_{\text{scan}}^{(4)}$ eventually has a support on a point p in a Noether-Lefschetz locus of $\mathcal{M}_*^R$; see [16, 18, 24] and references therein. For some choice of $G_{\text{scan}}^{(4)}$ (and its corresponding $p \in \mathcal{M}_*^R$) not only the rank of $H^{2,2}(X_p;\mathbb{R}) \cap H^4(X_p;\mathbb{Z})$, but even the rank of $H^{1,1}(X_p;\mathbb{R}) \cap H^2(X_p;\mathbb{Z})$ may be enhanced.[4] For the effective theory corresponding

[4]Depending on what conditions to impose mathematically on behaviour of the family $\mathcal{X} \longrightarrow \mathcal{M}_*^R$ at special loci, the enhancement of the rank of $\text{Pic}(X_p)$ may be phrased differently. The mathematical conditions to impose should ultimately be determined by the (yet unknown) microscopic formulation of F-theory.

JHEP01(2015)047

to such a choice of $G^{(4)}_{\rm scan}$, this can result in an enhanced gauge symmetry forming a hidden sector in addition to the gauge group R, or the symmetry R is enhanced to another R' containing R. Such a subensemble of fluxes with $(H_{\rm scan}\otimes\mathbb{R}) = H^4_H(X;\mathbb{R})$ for $(B_3,[S],R)$ therefore contains not just effective theories with the 7-brane gauge group being precisely R, but also those with an extra factor of gauge group, or those with the 7-brane gauge group larger than R. In this sense, the subensemble (and the distribution $d\mu_I$) captured on the moduli space $\mathcal{M}^R_*$ is an *inclusive* ensemble. With the expectation that only a very small fraction of such an inclusive ensemble has a hidden sector or enhanced symmetry, however, we will refer to vacua in such an ensemble as those with symmetry R; the fraction of such vacua can be estimated by using the discussion in section 6 and the appendix B, and we see the fraction is exponentially small indeed.

Secondly, let us record our understanding of the issue of potential instabilities. Given a topological flux $G^{(4)}_{\rm tot} = G^{(4)}_{\rm scan} + G^{(4)}_{\rm fix}$, we may not be able to find a solution to $DW = 0$ within the restricted moduli space $\mathcal{M}^R_*$. Such a flux, if there is any, has been removed automatically from the ensemble by the time the continuous approximation $H_{\rm scan} \longrightarrow H_{\rm scan}\otimes\mathbb{R}$ is introduced and the distribution $d\mu_I$ is cast into the form of (2.8). When the flux space integral is carried out, the delta-function picks up contributions only from fluxes that satisfy $DW = 0$ somewhere in $\mathcal{M}^R_*$. This argument may be, however, only about the instability issue associated with $DW = 0$ for moduli along $\mathcal{M}^R_*$, i.e., R-singlet moduli. Instability associated with physical "moduli" transverse to $\mathcal{M}^R_*$ may be captured by the effective superpotential $W = \int_S \mathrm{tr}[\varphi\wedge F]$ of [36, 37].

Thirdly and finally, the Kähler moduli have been (and will be) treated in this work as if they were given by hand, but their stabilization of course also has to be studied separately. The distribution (2.8), (2.9) on the moduli space of complex structure $\mathcal{M}_*$ needs to be convoluted with other data, including stabilization of Kähler moduli and dynamical evolution of cosmology in the early universe. There is nothing to add in this article to this well-known zoom-out picture, aside from reminding ourselves that it may make sense to study the distribution over the complex structure moduli space separately from Kähler moduli stabilization when there is a separation of scales between the stabilization of two distinct sets of moduli. In this case the two problems can be treated separately and then be combined, rather than facing the mixed problem.

3 $H^{2,2}$ of a Calabi-Yau fourfold hypersurface of a toric variety

Suppose that $\hat{Z}$ is a smooth variety and $\{\hat{Y}_i\}$ a set of its divisors. We can introduce the following stratification to $\hat{Z}$:

$$\hat{Z} = (\hat{Z}\setminus\cup_i\hat{Y}_i)\amalg\Big(\cup_i\hat{Y}_i\setminus(\cup_{kj}\hat{Y}_k\cap\hat{Y}_j)\Big)\amalg\cdots\,. \tag{3.1}$$

The first stratum, $Z := \hat{Z}\setminus\cup_i\hat{Y}_i$, is the only one that has the same dimension as $\hat{Z}$; we call it the primary stratum. For the pair $\hat{Z}$ and $Y := \hat{Z}\setminus Z$, there is the long exact sequence (3.11). It was with this exact sequence in combination with the mixed Hodge structure on these cohomology groups that ref. [19] derived a formula of $h^{1,1}(\hat{Z})$ and $h^{n-2,1}(\hat{Z})$ for a Calabi-Yau $(n-1)$-fold hypersurface of a toric n-fold and showed the beautiful mirror correspondence.

JHEP01(2015)047

We find that the same combination of methods — stratification (3.1) and mixed Hodge structure — is also very useful in studying various properties of algebraic cycles in $\hat{Z}$ even when $\hat{Z}$ is not necessarily realized as a hypersurface of a toric variety. Section 5 of this article uses this combination to study the space of vertical cycles of general fourfolds $\hat{Z}$, whereas we can derive stronger results in the case $\hat{Z}$ is a Calabi-Yau $(n-1)$-fold hypersurface of a toric n-fold. In the latter case, which is discussed in the present section, the Hodge-Deligne numbers of the cohomology of the primary stratum can be easily computed by following [38].

By carefully examining the contributions to $H^{2,2}(\hat{Z})$ and using mirror symmetry, we are able to isolate the pieces $h^{2,2}_V(\hat{Z}) = h^{2,2}_H(\hat{Z}_m)$, $h^{2,2}_H(\hat{Z}) = h^{2,2}_V(\hat{Z}_m)$ and $h^{2,2}_{RM}(\hat{Z}) = h^{2,2}_{RM}(\hat{Z}_m)$. The results are given in section 3.6.

3.1 General setup and known results

Let us start by fixing our notation and reviewing some helpful facts; subtleties associated with singularity resolution are summarized in section 3.1.1. Helpful reviews on toric geometry may be found in [39, 40].

A toric variety $\mathbb{P}^n_\Sigma$ can be constructed from a fan Σ, which is composed of strictly convex polyhedral cones in $\mathbb{R}^n$ for a lattice $N := \mathbb{Z}^{\oplus n}$. The dual lattice is denoted by $M = \mathbb{Z}^{\oplus n}$ and the pairing between them for $\nu \in N$ and $\tilde{\nu} \in M$ is denoted by $\langle \nu, \tilde{\nu} \rangle \in \mathbb{Z}$. We also use the notation $N_\mathbb{R} := N \otimes \mathbb{R}$ and $M_\mathbb{R} := M \otimes \mathbb{R}$. For a given fan Σ, $\Sigma(k)$ stands for the collection of all the k-dimensional cones. $\Sigma(0) = \{\vec{0} \in N\}$. We denote the k-skeleton $\cup_{i=0}^k \Sigma(i)$ by $\Sigma[k]$.

By definition, an n-dimensional toric variety contains an open algebraic torus $(\mathbb{C}^*)^n = \mathbb{T}^n$. From this perspective, a fan Σ gives information on how $\mathbb{T}^n$ is compactified. In particular, the fan determines a stratification into algebraic tori of lower dimension: simplicial cones of Σ are in one-to-one correspondence with strata of $\mathbb{P}^n_\Sigma$ such that a k-dimensional cone $\sigma \in \Sigma(k)$ corresponds to a stratum of $\mathbb{P}^n_\Sigma$ isomorphic to $(\mathbb{T})^{n-k}$. For cone σ, we denote the corresponding stratum by $\mathbb{T}_\sigma$.

A lattice polytope is the convex hull in $N_\mathbb{R}$ (or $M_\mathbb{R}$) of a number of lattice points of the lattice N (or M). For a lattice polytope Δ in M the polar (or dual) polytope $\widetilde{\Delta}$ (in N) is defined as

$$\widetilde{\Delta} := \{v \in N_\mathbb{R} | \langle v, w \rangle \geq -1 \quad \forall w \in \Delta\}\,. \tag{3.2}$$

If $\widetilde{\Delta}$ is a lattice polytope as well, it follows that Δ is also the polar of $\widetilde{\Delta}$ and the two are called a reflexive pair. An elementary property which follows from reflexivity is that the origin is the only integral point which is internal to the polytope. Faces of an n-dimensional polytope Δ are denoted by their dimensions[5] as $\Theta^{[n-k]}$. For a pair of reflexive polytopes Δ in $M_\mathbb{R}$ and $\widetilde{\Delta}$ in $N_\mathbb{R}$, there is a one-to-one correspondence between faces $\Theta^{[n-k]}$ of Δ and faces $\widetilde{\Theta}^{[k-1]}$ of $\widetilde{\Delta}$. We frequently use $(\widetilde{\Theta}^{[n-k]}, \Theta^{[k-1]})$ to indicate such a pair of dual faces. Note that an n-dimensional polytope can be considered as its own n-dimensional face. We indicate that a face Θ_a is on a face Θ_b by writing $\Theta_a \leq \Theta_b$. We let $\ell(\Theta)$ stand for the

[5] Faces of a polytope Δ are often referred to in the literature by their codimensions. Codimension-1 faces of Δ are called facets, for example. So, we reserve a notation $\Theta^{(k)} = \Theta^{[n-k]}$ for codimension-k faces, although we are not using this notation in the present article.

JHEP01(2015)047

number of integral points on a face Θ and $\ell^*(\Theta)$ for the number of integral points interior to Θ. The p-skeleton of Δ, i.e. the union of all faces of Δ which have dimension p or less is denoted by $\Delta_{\leq p}$.

Given a reflexive polytope $\widetilde{\Delta}$ we can easily construct a fan Σ by forming the cones over all faces of $\widetilde{\Delta}$. The one-to-one correspondence between $(k-1)$-dimensional faces $\{\widetilde{\Theta}^{[k-1]}\}$ and k-dimensional cones $\Sigma(k)$ in $N_{\mathbb{R}}$ (resp. between $\{\Theta^{[k-1]}\}$ and $\widetilde{\Sigma}(k)$ in $M_{\mathbb{R}}$) is described in the form of a map $\sigma : \{\widetilde{\Theta}^{[k-1]}\} \longrightarrow \Sigma(k)$ (resp. $\tilde{\sigma} : \{\Theta^{[k-1]}\} \longrightarrow \widetilde{\Sigma}(k)$).

Well-known formulae [19, 41, 42] for the Hodge numbers of a Calabi-Yau $(n-1)$-fold hypersurface $\hat{Z}$ are recorded here in the notation adopted above:

$$h^{1,1}(\hat{Z}) = \ell(\widetilde{\Delta}) - (n+1) - \sum_{\widetilde{\Theta}^{[n-1]}} \ell^*(\widetilde{\Theta}^{[1]}) + \sum_{(\widetilde{\Theta}^{[n-2]},\Theta^{[1]})} \ell^*(\widetilde{\Theta}^{[n-2]})\ell^*(\Theta^{[1]})\,, \tag{3.3}$$

$$h^{n-2,1}(\hat{Z}) = \ell(\Delta) - (n+1) - \sum_{\Theta^{[n-1]}} \ell^*(\Theta^{[n-1]}) + \sum_{(\Theta^{[n-2]},\widetilde{\Theta}^{[1]})} \ell^*(\Theta^{[n-2]})\ell^*(\widetilde{\Theta}^{[1]})\,, \tag{3.4}$$

$$h^{m,1}(\hat{Z}) = \sum_{(\widetilde{\Theta}^{[n-m-1]},\Theta^{[m]})} \ell^*(\widetilde{\Theta}^{[n-m-1]})\ell^*(\Theta^{[m]}) \quad \text{for} \quad n-2 > m > 1. \tag{3.5}$$

3.1.1 Triangulations, smoothness and projectivity

The polytope Δ in $M_{\mathbb{R}}$ is regarded as the Newton polyhedron of the defining equation of a Calabi-Yau hypersurface Z_s in $\mathbb{P}^n_\Sigma$. Because Z_s is not smooth, in general, we are interested in its projective crepant resolution; $\hat{Z}$ in (3.3)–(3.5) stands for such a resolution. Such resolutions may always be constructed from the data of the polytope for $n \leq 4$ [19]. For Calabi-Yau hypersurfaces of complex dimension 4 (or dimensions larger than that), this is not the case, so that we need to explicitly check in each example.

Constructing a fan Σ over the faces of a polytope $\widetilde{\Delta}$, the resulting cones may be non-simplicial or have (lattice-) volume[6] greater than one. Consequently, the toric variety $\mathbb{P}^n_\Sigma$ has singularities. We may, however, subdivide the fan Σ to cure such singularities. We denote the corresponding map between fans by $\phi : \Sigma' \longrightarrow \Sigma$. For $\sigma' \in \Sigma'$, $\phi(\sigma')$ is given by the σ'-containing cone $\sigma \in \Sigma$ with the smallest dimension. The map ϕ (resp. $\tilde{\phi}$) induces a toric morphism $\mathbb{P}^n_{\Sigma'} \longrightarrow \mathbb{P}^n_\Sigma$ of (partial) singularity resolution.

Such a morphism will preserve the Calabi-Yau condition of a hypersurface if all of the one-dimensional cones introduced are generated by points on the polytope $\widetilde{\Delta}$ (remember that the origin is the only internal point for a reflexive polytope). A (partial) crepant desingularization of Z_s is hence equivalent to finding a triangulation of the polytope $\widetilde{\Delta}$ in which every n-simplex contains the origin. This is called a star triangulation and the origin is the star point. A maximal desingularization of $\mathbb{P}^n_\Sigma$ keeping Z_s Calabi-Yau is found by using all points[7] on $\widetilde{\Delta}$. A triangulation using all points of a polytope is called a fine triangulation.

[6] The "lattice volume" of a cone in $\partial\Delta$ is defined by multiplying $k!$ to the volume of a k-dimensional cone cut-off at $\partial\Delta$. The smallest lattice k-simplex has the lattice volume 1.

[7] In fact, it makes sense to relax this requirement, as points which lie in the interior of facets of $\widetilde{\Delta}$ do not lead to divisors intersecting a Calabi-Yau hypersurface. This can be seen as follows: for any facet F we can find a normal vector n_F such that $< n_F, \nu_i > = 1$ for all vectors ν_i on F. This means that the intersection

JHEP01(2015)047

When subdividing cones in Σ, we want the ambient space $\mathbb{P}^n_{\Sigma'}$ to be a projective variety (i.e. it should be a Kähler manifold), which implies projectivity of the Calabi-Yau hypersurface; the Kählerian nature combined with the trivial canonical bundle implies Ricci-flatness. For an n-dimensional toric variety $\mathbb{P}^n_\Sigma$ given in terms of a fan Σ, a Weil divisor $D = \sum_i a_i D_i$ is also Cartier iff we can find a support function ψ_D with the following properties:

- ψ_D is linear on each cone
- For a given cone of maximal dimension, $\sigma \in \Sigma(n)$, ψ_D can be described by an element m_σ of M satisfying
$$\psi_D|_\sigma = < m_\sigma, \nu_i > = -a_i \tag{3.9}$$
for all one-dimensional cones (determined by the primitive vectors ν_i) in σ.

In this language, the cone of ample curves (or, equivalently, the Kähler cone) is described as the set of divisors for which ψ_D is strongly convex. This means that $\psi_D|_\sigma > -a_j$ for all one-dimensional cones *not* in σ and implies that $m_\sigma \neq m_{\sigma'}$ for two different cones σ and σ' in $\Sigma(n)$. If this cone of ample curves is non-empty, we can find a line bundle which is very ample, i.e. it defines an embedding of the toric variety $\mathbb{P}^n_\Sigma$ into $\mathbb{P}^m$ for some m. Conversely, if no strongly convex support function exists, the corresponding toric variety cannot be projective.

A strongly convex support function ψ_D defines a 'lift' of $\tilde{\Delta}$ into $\mathbb{R}^{n+1}$ by assigning the value of ψ_D to each point on $\tilde{\Delta}$. The triangulation can then be seen as the upper facets of the resulting polyhedron in $\mathbb{R}^{n+1}$. Note that strong convexity means that no $n+2$ points of $\tilde{\Delta}$ are mapped to a hyperplane in $\mathbb{R}^{n+1}$, i.e. faces of $\tilde{\Delta}$ which are subdivided into more than one simplex by a triangulation are not coplanar after this lift. Conversely, any triangulation which descends from a triangulation of a lift of $\tilde{\Delta}$ (with the property that no $n+2$ points are on a common non-vertical plane) to $\mathbb{R}^{n+1}$ can be used to construct a projective toric variety. Triangulations with this property are called regular triangulations.

---

ring contains a linear relation of the form

$$\sum_{\nu_i \in F} D_i + \sum_{j \text{ not} \in F} a_j D_j = 0\,, \tag{3.6}$$

with includes some contribution of divisors whose corresponding primitive vectors ν_j are not in F but lie on other facets. Let us now assume we have refined Σ such that there is a point ν_p interior to the facet F. The associated divisor D_p can only have a non-zero intersection with divisors D_k for which ν_k also lies in F, as all others necessarily lie in different cones of the fan Σ. This means that the above relation implies

$$D_p \cdot \sum_{\nu_i \in F} D_i = 0\,, \tag{3.7}$$

where we sum over all toric divisors coming from points on F. The Calabi-Yau hypersurface is given as the zero-locus of a section of $-K_{\mathbb{P}^n_\Sigma} = \sum_j D_j$, where we sum over all toric divisors. We now find

$$D_p \cdot \sum_j D_j = D_p \cdot \sum_{\nu_i \in F} D_i = 0\,, \tag{3.8}$$

by using the same argument again. Hence D_p does not meet a generic Calabi-Yau hypersurface. Correspondingly, a refinement of Σ introducing ν_p does not have any influence.

JHEP01(2015)047

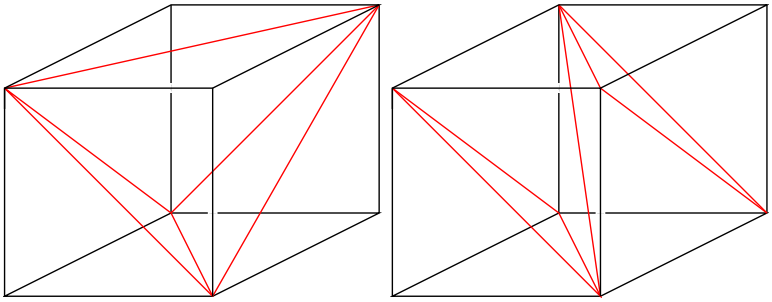

Figure 1. Two fine regular triangulations of a three-dimensional cube. The 'central' 3-simplex of the triangulation on the left has lattice volume 2. As there are no extra lattice points, this triangulation cannot be further refined to become unimodular. Of course the cube shown above does have a unimodular triangulation, as shown on the right. It may happen, however, that the central simplex of the triangulation shown on the left arises as a face of a polytope, in which case no unimodular triangulation can exist.

A maximal projective crepant desingularization (referred to as an *MPCP* of Z_s in [19]) is hence achieved by finding a fine regular star triangulation of $\widetilde{\Delta}$. If all cones of such a triangulation have lattice volume unity the ambient space, and hence the Calabi-Yau hypersurface, become completely smooth and the map $\phi : \Sigma' \to \Sigma$ can rightfully be called a resolution. Triangulations of this type are called unimodular. We will also call simplices of volume unity and cones over such simplices unimodular.

It turns out that unimodular triangulations do not necessarily exist for polytopes of dimension $n \geq 4$. This is only relevant for Calabi-Yau manifolds of dimension ≥ 4 though, as one may always find a triangulation which is 'good enough' in the case of Calabi-Yau threefolds [19]. While any fine triangulation is also unimodular in two dimensions, a simplex can fail to be unimodular in three dimensions or more, even if it does not contain any points besides its vertices. A standard example for this is given in figure 1. For a star triangulation of a reflexive polytope, the lattice volume[8] of any simplex is given by the volume of its 'outward' face, i.e. the face which lies on a facet of $\tilde{\Delta}$. For a polytope of dimension three or less, the facets are at most two-dimensional, so that any fine triangulation is automatically unimodular and the ambient space is smooth. For a Calabi-Yau threefold, the facets of $\tilde{\Delta}$ are three-dimensional. Hence even for a fine triangulation we are not guaranteed a smooth ambient space, as there might be a simplex S with volume greater than unity. However, the singularities which are induced by such cones are point-like: they are located at the intersection of the four divisors spanning S. These points do not meet a generic hypersurface, so that a fine triangulation is still enough to ensure smoothness for Calabi-Yau threefolds. In the case of Calabi-Yau fourfolds, there can be singularities along curves of $\mathbb{P}^n_{\Sigma'}$ which are induced by faces which are not unimodular in a fine triangulation. These generically meet a hypersurface in points, so that smoothness is no longer automatic. For Calabi-Yau fourfolds, we thus need to check explicitly if a triangulation giving a resolution exists.

[8]This is commonly expressed by saying that facets of reflexive polyhedra are at lattice distance one from the origin.

JHEP01(2015)047

In the following, we will assume that we have found a fine regular star triangulation which makes $\mathbb{P}^n_{\Sigma'}$ a smooth projective toric variety and leads to a smooth Calabi-Yau fourfold hypersurface $\hat{Z}$. This means we fix a fan Σ' and a map $\phi : \Sigma' \to \Sigma$. We will come back to the issues discussed in this section, when we look at examples in section 4.

3.2 Computing $h^{2,2}$ via decomposition

Let $\hat{Z}$ be a non-singular compact Calabi-Yau $(n-1)$-fold defined as a hypersurface of a smooth toric ambient space $\mathbb{P}^n_{\Sigma'}$. Let $\{\nu_i\}_{i=1,\cdots,|\Sigma'(1)|}$ be the primitive vectors for all the 1-dimensional cones of the toric fan Σ'. For each one of them, there is a toric divisor D_i given by $\{X_i = 0\} \subset \mathbb{P}^n_{\Sigma'}$. The restriction of D_i to the hypersurface $\hat{Z}$ is denoted by $\hat{Y}_i$. This set of toric divisors $\left\{\hat{Y}_i\right\}$ is used to introduce a stratification (3.1). The primary stratum can be regarded as a hypersurface of $\mathbb{T}^n$,

$$Z := \hat{Z}\backslash Y = \hat{Z} \cap (\mathbb{P}^n_\Sigma \backslash \cup_i D_i) = \hat{Z} \cap (\mathbb{T}^n \subset \mathbb{P}^n_{\Sigma'}) \,, \tag{3.10}$$

and its complement is denoted by $Y := \cup_i \hat{Y}_i$.

For a compact non-singular irreducible algebraic variety $\hat{Z}$ and a divisor Y with normal crossings in $\hat{Z}$ (such that $Z = \hat{Z}\backslash Y$ is non-singular), we can write a long exact sequence

$$\begin{array}{c} \cdots \longrightarrow H_c^{k-1}(Z) \longrightarrow H_c^{k-1}(\hat{Z}) \longrightarrow H_c^{k-1}(Y) \longrightarrow \\ \longrightarrow H_c^{k}(Z) \longrightarrow H_c^{k}(\hat{Z}) \longrightarrow H_c^{k}(Y) \longrightarrow \cdots \end{array} \tag{3.11}$$

for the cohomology groups with compact support. Since $\hat{Z}$ and Y are both compact, $H^k(\hat{Z})$ and $H^k(Y)$ are the same as $H^k_c(\hat{Z})$ and $H^k_c(Y)$. All the morphisms in this exact sequence are morphisms of mixed Hodge structure[9] of type $(0,0)$.

In order to use the exact sequence (3.11), we first note [38] that $H^i_c(Z)$ vanishes for $i = 0, \cdots, n-2$, and

$$\begin{aligned} h^{p,q}\left[H_c^{k>(n-1)}(Z)\right] &= h^{p+1,q+1}\left[H_c^{k+2}(\mathbb{T}^n)\right] = \begin{cases} \binom{n}{k+2-n} & p = q = k+1-n \,, \\ 0 & \text{otherwise} \end{cases} \,. \\ h^{p,q}\left[H_c^{n-1}(Z)\right] &= 0 \quad \text{if } p+q > n-1 \,. \end{aligned} \tag{3.12}$$

More information about the non-vanishing parts of $H^{n-1}_c(Z)$ will be provided later.

The main focus in this article is to study $H^4(\hat{Z})$ for a Calabi-Yau fourfold $\hat{Z}$ in a toric ambient space of dimension $n = 5$. In this case, only the weight-4 components of $H^4_c(Z)$, $H^4_c(\hat{Z})$ and $H^4_c(Y)$ are relevant to determining $H^4(\hat{Z})$, and we learn from (3.11) that they satisfy

$$0 \longrightarrow \left[H^4_c(Z)\right]^{4,0} \longrightarrow \left[H^4_c(\hat{Z})\right]^{4,0} \longrightarrow 0, \tag{3.13}$$

[9] For mixed Hodge structure and Hodge-Deligne numbers, see [43] or an easy example discussed in [44]. For an algorithm of computing the Hodge-Deligne numbers, see [38]. We do not intend to provide a systematic exposition on this (well-understood) issue; we just focus on deriving new results such as (3.50) and (3.61). The example presented in section 4.1, however, is best suited to getting accustomed to such concepts.

JHEP01(2015)047

$$0 \longrightarrow \left[H_c^4(Z)\right]^{3,1} \longrightarrow \left[H_c^4(\hat{Z})\right]^{3,1} \longrightarrow \left[H_c^4(Y)\right]^{3,1} \longrightarrow 0, \tag{3.14}$$

$$0 \longrightarrow \left[H_c^4(Z)\right]^{2,2} \longrightarrow \left[H_c^4(\hat{Z})\right]^{2,2} \longrightarrow \left[H_c^4(Y)\right]^{2,2} \longrightarrow 0, . \tag{3.15}$$

Let us first focus on $\left(H_c^4(Y)\right)$. Y is not necessarily non-singular, but it can be written as $Y = \cup_i \hat{Y}_i$ where each $\hat{Y}_i$ is a non-singular divisor of $\hat{Z}$. Note that each $\hat{Y}_i$ is not necessarily irreducible. This can happen when ν_i is in a codimension-2 face of $\widetilde{\Delta}$. The (co)homology groups of such geometries can be computed by using the Mayer-Vietoris spectral sequence, and one finds that

$$H^4(Y) = \text{Kernel}\left(\left[\oplus_i H^4(\hat{Y}_i)\right] \longrightarrow \left[\oplus_{i<j} H^4(\hat{Y}_i \cap \hat{Y}_j)\right]\right). \tag{3.16}$$

As each $\hat{Y}_i$ is a smooth hypersurface of a toric variety, its $h^{1,0} = h^{3,1}$ vanishes (see e.g. [38]). Hence $H^4(Y)$ contributes only to the $(H_c^4(\hat{Z}))^{2,2}$ component in (3.13)–(3.15). Furthermore, keeping in mind that all divisors of $\hat{Z}$ occur as components of toric divisors, it is obvious from (3.16) that all vertical $(2,2)$-forms of $\hat{Z}$ are contained in the $H^4(Y)$ quotient of $H^4(\hat{Z})$.

We will discuss later how to compute $h^{2,2}(\hat{Y}_i) = h^{1,1}(\hat{Y}_i)$ and $h^{2,2}(\hat{Y}_i \cap \hat{Y}_j) = h^{0,0}(\hat{Y}_i \cap \hat{Y}_j)$ by using toric data. In order to determine $h^4(Y) = h^{2,2}[H^4(Y)]$ from (3.16), we further need to know the dimension of the cokernel of the homomorphisms in (3.16). We claim that the homomorphism in (3.16) has a cokernel of dimension $n(n-1)/2$.

In order to verify the claim, one needs to note that the kernel of (3.16) is $E_\infty^{0,4} = E_2^{0,4} = \text{Ker}[d_1^{0,4} : E_1^{0,4} \longrightarrow E_1^{1,4}]$ in the Mayer-Vietoris sequence calculation of $H^\bullet(Y)$. The cokernel of the same homomorphism therefore corresponds to

$$\text{Coker}[d_1^{0,4} : E_1^{0,4} \longrightarrow E_1^{1,4}] = E_2^{1,4} = E_\infty^{1,4}, \tag{3.17}$$

which gives rise to the $[H^5(Y)]^{2,2}$ component. It can be determined by exploiting other parts of the long exact sequence (3.11). Focusing on the weight-4 components, we find that the following is exact:

$$0 \longrightarrow \left[H^5_{(c)}(Y)\right]^{2,2} \longrightarrow \left[H_c^6(Z)\right]^{2,2} \longrightarrow 0. \tag{3.18}$$

Using (3.12), $h^{2,2}[H_c^{n+1}(Z)] = h^{n-3,n-3}[H^{n-3}(Z)] = n(n-1)/2$, so we find that

$$\dim\left(\text{Coker}\left[\oplus_i H^4(\hat{Y}_i) \longrightarrow \oplus_{i<j} H^4(\hat{Y}_i \cap \hat{Y}_j)\right]\right) = h^{2,2}\left[H^5_{(c)}(Y)\right] = \frac{n(n-1)}{2}. \tag{3.19}$$

as stated before.

3.3 Stratification and geometry of divisors

For the purpose of capturing $H_c^4(Y)$ and $H^4(Z)$ in terms of combinatorial data of the toric ambient space, we take a moment to digress. To start off, we describe stratifications of Calabi-Yau hypersurfaces $\hat{Z}$ of a toric ambient space $\mathbb{P}^n_{\Sigma'}$. There are two distinct stratifications to which we pay attention: one is associated with the toric fan Σ, and the other with its refinement[10] Σ'.

[10]Remember that by assumption, Σ' is determined by a regular star triangulation turning $\hat{Z}$ into a smooth hypersurface, whereas Σ is a fan over faces of the polytope $\widetilde{\Delta}$.

JHEP01(2015)047

The stratification induced by Σ' is easier to describe, it descends from that on $\mathbb{P}^n_{\Sigma'}$ straightforwardly: each stratum of $\hat{Z}$ is of the form $Z_\sigma = \hat{Z} \cap \mathbb{T}_\sigma$ for $\sigma \in \Sigma'$.

The stratification corresponding to Σ is

$$\hat{Z} = (Z_\Delta) \amalg \left(\amalg_{\Theta^{[n-1]} \leq_\Delta} Z_{\Theta^{[n-1]}}\right) \amalg \amalg_{2 \leq k \leq n-1} \left(\amalg_{(\widetilde{\Theta}^{[k-1]}, \Theta^{[n-k]})} [E_{\widetilde{\Theta}^{[k-1]}} \times Z_{\Theta^{[n-k]}}]\right); \quad (3.20)$$

here, the strata are labelled by the faces of Δ, namely, Δ itself, codimension-1 faces $\Theta^{[n-1]}$'s, and all other faces $\Theta^{[n-k]}$'s of codimension $2 \leq k \leq n-1$. It is understood in the expression above, and also in expressions later, that $(\widetilde{\Theta}^{[k-1]}, \Theta^{[n-k]})$ is a dual pair of faces. Due to the one-to-one correspondence between faces of Δ, the faces of $\widetilde{\Delta}$ and the cones in Σ, the strata in (3.20) are in one-to-one correspondence with the cones of the fan Σ. The primary stratum, Z_Δ, corresponds to the 0-dimensional cone $\vec{0} \in \Sigma$, and the $Z_{\Theta^{[n-1]}}$ to the individual 1-dimensional cones in $\Sigma(1)$.

The geometry of $E_{\widetilde{\Theta}^{[k-1]}}$ can be read out from the $(k-1)$-dimensional face $\widetilde{\Theta}^{[k-1]}$ of $\widetilde{\Delta}$. $E_{\widetilde{\Theta}^{[k-1]}}$ has a stratification associated with the maximal simplicial subdivision Σ',

$$E_{\widetilde{\Theta}^{[k-1]}} = \left[(\mathbb{T}^{k-1}\text{'s}) \amalg (\mathbb{T}^{k-2}\text{'s}) \amalg \cdots \amalg \text{points}\right], \quad (3.21)$$

where the number of $\mathbb{T}^{k-1-p}$ in this decomposition is equal to the number of p-simplices in $\widetilde{\Theta}^{[k-1]}$ which are not contained in the boundary of $\widetilde{\Theta}^{[k-1]}$.

The geometries of Z_Δ $(k=0)$ and all the other of $Z_{\Theta^{[n-k]}}$ are given by hypersurfaces of $\mathbb{T}^{\dim_{\mathbb{C}}(\Theta)=(n-k)}$. For each one of the Z_Θ, only the terms in the Newton (Laurent) polynomial corresponding to $\Theta^{[n-k]} \cap M$ are relevant in determining $Z_{\Theta^{[n-k]}} \subset \mathbb{T}^{n-k}$ (which also means all terms originating from $\Delta \cap M$ are relevant in determining $Z_\Delta \subset \mathbb{T}^n$). Obviously the primary stratum Z_Δ is the same as $Z := \hat{Z} \backslash Y$ introduce before.

The stratification for the fan Σ', $\hat{Z} = \amalg_{\sigma \in \Sigma'} Z_\sigma$, is therefore obtained by decomposing the stratification (3.20) under (3.21). Put differently,

$$\left[E_{\widetilde{\Theta}^{[k-1]}} \times Z_{\Theta^{[n-k]}}\right] = \amalg_{\sigma' \in \phi^{-1} \cdot \sigma(\widetilde{\Theta}^{[k-1]})} Z_{\sigma'}, \quad (3.22)$$

where $\phi : \Sigma' \longrightarrow \Sigma$ is the map of toric fans (mapping cones to cones) associated with the subdivision refining Σ to Σ' and $\sigma(\widetilde{\Theta}^{[k-1]})$ is the map identifying a cone of Σ with a face $\widetilde{\Theta}^{[k-1]}$ of $\widetilde{\Delta}$. One can think of $E_{\widetilde{\Theta}^{[k-1]}}$ as the exceptional geometry appearing in a resolution of singularities of $\mathbb{P}^n_\Sigma$ associated with the k-dimensional cone $\sigma(\widetilde{\Theta}^{[k-1]})$.

3.4 Combinatorial formula for $h^{2,2}[H^4_{(c)}(Y)] = [h^{n-3,n-3}[H^{2n-6}_c(Y)]]_{n=5}$

Just like various Hodge numbers of a Calabi-Yau toric hypersurface $\hat{Z}$ are computed by using the stratification and the Hodge-Deligne numbers of the strata [19, 38], Hodge numbers of divisors $\hat{Y}_i$'s of a Calabi-Yau toric hypersurface $\hat{Z}$ can also be computed essentially with the same technique. Once $h^{2,2}(\hat{Y}_i)$'s are computed, it is almost straightforward (as already explained) to determine $h^{2,2}[H^4_c(Y)]$.

The 'Euler characteristics' of Hodge-Deligne numbers of compact support cohomology groups (for some geometry X) are

$$e^{p,q}_c(X) := \sum_k (-)^k h^{p,q}[H^k_c(X)]. \quad (3.23)$$

JHEP01(2015)047

These numbers have the following three nice properties, which were exploited heavily in [19, 38], and will also be in the following.

The first two are additivity,

$$e_c^{p,q}(X_1 \amalg X_2) = e_c^{p,q}(X_1) + e_c^{p,q}(X_2), \tag{3.24}$$

and multiplicativity,

$$e_c^{p,q}(E \times Z) = \sum_{p'+p''=p} \sum_{q'+q''=q} e_c^{p',q'}(E) e_c^{p'',q''}(Z). \tag{3.25}$$

Finally, when an algebraic variety X (of complex dimension $n-1$) is compact and smooth, i.e the mixed Hodge structure on cohomology groups is pure,

$$e_c^{p,q}(X) = (-)^{p+q} h_c^{p,q}(X) = (-)^{p+q} h^{p,q}(X) = (-)^{p+q} h^{n-1-p,n-1-q}(X) \tag{3.26}$$

In a slight abuse of language, we will frequently refer to the $e^{p,q}$ as Hodge-Deligne numbers in the text.

Each divisor component $\hat{Y}_i$ (corresponding to $\rho_i \in \Sigma'(1)$) of a Calabi-Yau $(n-1)$-fold $\hat{Z}$ is compact and smooth, and hence $h^{n-3,n-3}(\hat{Y}_i) = h^{1,1}(\hat{Y}_i)$ is the same as[11] $e_c^{n-3,n-3}(\hat{Y}_i)$. The compact geometry $\hat{Y}_i$ has a stratification associated with Σ', or to be more specific,

$$\hat{Y}_i = \left(\amalg_{\rho_i \leq \sigma \in \Sigma'} Z_\sigma\right) \subset \hat{Z}. \tag{3.27}$$

Because of additivity, $e_c^{n-3,n-3}(\hat{Y}_i)$ is obtained by summing up $e_c^{n-3,n-3}(Z_\sigma)$ ($\sigma \geq \rho_i$). Using multiplicativity, this calculation is further boiled down to the computation of $e_c^{p,q}(Z_\Theta)$ of various faces $\Theta \leq \Delta$, for which the algorithm of [38] (in combination with (3.12)) can be used.

Here, we record a few crucial formulas from [38] for Hodge-Deligne numbers of the strata Z_Θ. For a face of dimension f there is the 'sum rule'

$$(-1)^{f-1} \sum_q e^{p,q}(Z_\Theta) = (-1)^p \binom{f}{p+1} + \varphi_{f-p}(\Theta)\,, \tag{3.28}$$

where f is the dimension of the face Θ. Here, the functions φ_k are defined as

$$\varphi_k(\Theta) := \sum_{j \geq 1} (-1)^{k-j} \binom{f+1}{k-j} \ell^*(j\Theta)\,, \tag{3.29}$$

where $j\Theta$ stands for the polytope which is obtained by scaling all vertices of the face Θ by j and then taking the convex hull. We introduce the notation

$$\bar{e}_c^{p,q}(Z_\Theta) := e_c^{p,q}(Z_\Theta) - \delta_{p,q} (-1)^{f-1-p} \binom{f}{p+1}\,, \tag{3.30}$$

[11] A completely parallel story holds for any cone $\rho \in \Sigma'(\ell)$ (not in the interior of a facet of $\widetilde{\Delta}$), and for any one of its Hodge numbers.

JHEP01(2015)047

in this article. $bare_c^{p,q}(Z_\Theta)$ is equal to $(-1)^{f-1}h^{p,q}[H^{f-1}(Z_\Theta)]$ except when $(p,q)=(0,0)$. Obviously the sum rule (3.28) can be written as

$$\sum_q \bar{e}_c^{p,q}(Z_\Theta) = (-1)^{f-1}\varphi_{f-p}(\Theta). \tag{3.31}$$

Furthermore, the Hodge numbers obey [38]

$$e^{p,0}(Z_\Theta) = (-1)^f \sum_{\Gamma\leq\Theta,\dim\Gamma=p+1} \ell^*(\Gamma)\,, \tag{3.32}$$

for any $p>0$. For a face of dimension $f\geq 4$ we also have that

$$e^{f-2,1}(Z_\Theta) = (-1)^{f-1}\left(\varphi_2(\Theta) - \sum_{\Gamma\leq\Theta,\dim\Gamma=f-1}\varphi_1(\Gamma)\right). \tag{3.33}$$

3.4.1 Computation of $h^{1,1}(\hat{Y}_i) = h^{n-3,n-3}(\hat{Y}_i)$ for $n\geq 5$ cases

We are primarily interested in $h^{2,2}(\hat{Y}_i)$, where $\hat{Y}_i$ is of $(n-2)=3$-dimensions in a Calabi-Yau $(n-1)=4$-fold $\hat{Z}$, embedded in a toric ambient space $\mathbb{P}^{n=5}_{\Sigma'}$. This can be regarded, however, as a special case of the more general problem of determining $h^{n-3,n-3}(\hat{Y}_i)$ of a divisor $\hat{Y}_i$ of a Calabi-Yau $(n-1)$-fold embedded in a toric ambient space $\mathbb{P}^n_{\Sigma'}$. We shall study the more general version of the problem for $n\geq 5$.

For any 1-dimensional cone ρ_i generated by a primitive vector ν_i in the lattice N, there is a divisor $\hat{Y}_i$ of $\hat{Z}$. Depending on which face contains ν_i in its interior, the computation $h^{n-3,n-3}(\hat{Y}_i)$ has to be treated separately. The divisor $\hat{Y}_i$ is empty if ν_i is interior to an $n-1$-dimensional face of $\widetilde{\Delta}$. Let $\phi(\rho_i)\in\Sigma(k_0)$, i.e., ν_i is an interior point of a (k_0-1)-dimensional face $\widetilde{\Theta}_i^{[k_0-1]}\leq\widetilde{\Delta}$. The cases we have to study are then

- $k_0=1$: i.e., ν_i is one of vertices of $\widetilde{\Delta}$.
- $1<k_0<n-3$: (this case is absent if $n=5$.)
- $k_0=n-3$: i.e., ν_i is an interior point of a codimension-4 face (an edge, if $n=5$).
- $k_0=n-2$: i.e., ν_i is an interior point of a codimension-3 face (a 2dim face, if $n=5$).
- $k_0=n-1$: i.e., ν_i is an interior point of a codimension-2 face. (a 3dim face, if $n=5$)

We work on those five cases one-by-one from now.

The case $k_0=1$. Here, $\nu_i=\widetilde{\Theta}_i^{[0]}$ is a vertex of $\widetilde{\Delta}$. $\hat{Y}_i$ is composed of the following strata:

$$Z_{\Theta_i^{[n-1]}},\qquad [\mathrm{pt}\times Z_{\Theta^{[n-2]}}]_{(\widetilde{\Theta}^{[1]},\Theta^{[n-2]})},\quad [(\mathbb{T}\text{'s}+\mathrm{pts})\times Z_{\Theta^{[n-3]}}]_{(\widetilde{\Theta}^{[2]},\Theta^{[n-3]})}\,,$$
$$\cdots\cdots,\quad \left[\left(\mathbb{T}^{n-3}\text{'s}\sim\mathrm{points}\right)\times Z_{\Theta^{[1]}}\right]_{(\widetilde{\Theta}^{[n-2]},\Theta^{[1]})}. \tag{3.34}$$

Note that a stratum $Z_\sigma\subset[E_{\widetilde{\Theta}^{[k-1]}}\times Z_{\Theta^{[n-k]}}]$ contributes to $\hat{Y}_i$ only when $\widetilde{\Theta}^{[k-1]}$ contains the vertex ν_i, i.e. $\widetilde{\Theta}^{[k-1]}\geq\widetilde{\Theta}_i^{[0]}$ (equivalently $\Theta^{[n-k]}\leq\Theta_i^{[n-1]}$). Furthermore, $\mathbb{T}^{k-1-p}\subset E_{\widetilde{\Theta}^{[k-1]}}$

JHEP01(2015)047

only contributes when the corresponding p-simplex in $\widetilde{\Theta}^{[k-1]}$ contains ν_i as one of its faces. This is why, for example, only one point $\mathbb{T}^0$ (one 1-simplex) from $E_{\widetilde{\Theta}^{[1]}}$ of a given dual pair $(\widetilde{\Theta}^{[1]}, \Theta^{[n-2]})$ contributes to $\hat{Y}_i$. Such strata combined are denoted by $[E_{\widetilde{\Theta}^{[k-1]}} \times Z_{\Theta^{[n-k]}}]^{\rho_i \leq}$ in this article.

From the first stratum,

$$e_c^{n-3,n-3}(Z_{\Theta_i^{[n-1]}}) = -\binom{n-1}{n-2} = -(n-1) \tag{3.35}$$

picking up the contribution from $h^{n-3,n-3}[H_c^{2n-3}(Z_{\Theta_i^{[n-1]}})]$.

From the k-th group of strata ($k = 2, \cdots, (n-2)$), each pair $(\widetilde{\Theta}^{[k-1]}, \Theta^{[n-k]})$ gives rise to

$$\begin{aligned} e_c^{n-3,n-3}\left([E_{\widetilde{\Theta}^{[k-1]}} \times Z_{\Theta^{[n-k]}}]^{\rho_i \leq}\right) &= \left[{}_{\nu_i}\ell_1^*(\widetilde{\Theta}^{[k-1]}) \times e_c^{k-2,k-2}(\mathbb{T}^{k-2})\right] \times [e_c^{n-k-1,n-k-1}(Z_{\Theta^{[n-k]}})] \\ &= {}_{\nu_i}\ell_1^*(\widetilde{\Theta}^{[k-1]})\,. \end{aligned} \tag{3.36}$$

Here, we have introduce the notation ${}_{\nu_i}\ell_1^*(\widetilde{\Theta})$ for the number of internal 1-simplices in the face $\widetilde{\Theta}$ which end on ν_i or, in other words, have ν_i as a face. In the language of cones

$${}_{\nu_i}\ell_1^*(\widetilde{\Theta}) := \left|\left\{\sigma \in \Sigma'(2) \cap \phi^{-1} \cdot \sigma(\widetilde{\Theta}) \mid \rho_i \leq \sigma\right\}\right| \tag{3.37}$$

We also introduce ${}_{\nu_i}\ell_1(\widetilde{\Delta}_{\leq p})$ for the number of 1-simplices (again containing ν_i as a face) contained in the p-skeleton (faces of dimension p or less) of $\widetilde{\Delta}$.

The contribution from the last group of strata, $k = n-1$, is the same as above, except that $e_c^{n-k-1,n-k-1}(Z_{\Theta^{[n-k]}})$ is not necessarily 1. $Z_{\Theta^{[1]}}$ consists of

$$e_c^{n-k-1,n-k-1}(Z_{\Theta^{[n-k]}}) = e_c^{0,0} = 1 + \ell^*(\Theta^{[1]}), \tag{3.38}$$

points, which is not necessarily 1. Hence the contribution to $e_c^{n-3,n-3}$ is $e_c^{0,0}(Z_{\Theta^{[1]}})$ times larger than that of (3.36). We thus finally obtain

$$h^{1,1}(\hat{Y}_i)|_{\text{if } k_0=1} = {}_{\nu_i}\ell_1(\widetilde{\Delta}_{\leq n-2}) - (n-1) + \sum_{(\widetilde{\Theta}^{[n-2]}, \Theta^{[1]})} {}_{\nu_i}\ell_1^*(\widetilde{\Theta}^{[n-2]}) \times \ell^*(\Theta^{[1]}). \tag{3.39}$$

This formula for the divisors $\hat{Y}_i$ of $\hat{Z}$ is quite like that of $\hat{Z}$ in (3.3). The first two terms originate from toric divisors (divisors of the ambient space $\mathbb{P}^n_{\Sigma'}$ of $\hat{Z}$ and the linear equivalence restricted to $\hat{Y}_i$). The correction term at the end of (3.39) also looks quite similar to the last term of (3.3); we will come back in section 3.6 to discuss the geometric interpretation of this term in more detail.

The three cases $1 < k_0 < (n-3)$, $k_0 = (n-3)$ and $k_0 = (n-2)$. The stratification of $\hat{Y}_i$ is described schematically by

$$[E_{\widetilde{\Theta}_i^{[k_0-1]}} \times Z_{\Theta_i^{[n-k_0]}}]^{\rho_i \leq}, \quad \cdots, \left[E_{\widetilde{\Theta}^{[k-1]}} \times Z_{\Theta^{[n-k]}}\right]^{\rho_i \leq}, \cdots, \left[E_{\widetilde{\Theta}^{[n-2]}} \times Z_{\Theta^{[1]}}\right]^{\rho_i \leq}. \tag{3.40}$$

In all the three cases, the contributions to $e_c^{n-3,n-3}$ from all but the first group of strata remain the same as in the $k_0 = 1$ case. The first group of strata gives rise to

$$e_c^{n-3,n-3}([E_{\widetilde{\Theta}_i^{[k_0-1]}} \times Z_{\Theta_i^{[n-k_0]}}]^{\geq \rho_i}) = e_c^{k_0-1,k_0-1}(E^{\geq \rho_i}_{\widetilde{\Theta}_i^{[k_0-1]}}) e_c^{n-k_0-2,n-k_0-2}(Z_{\Theta_i^{[n-k_0]}})$$

JHEP01(2015)047

$$+e_c^{k_0-2,k_0-2}(E^{\geq\rho_i}_{\widetilde{\Theta}_i^{[k_0-1]}})e_c^{n-k_0-1,n-k_0-1}(Z_{\Theta_i^{[n-k_0]}}). \quad (3.41)$$

In all the three cases, $1 < k_0 < n-3$, $k_0 = n-3$ and $k_0 = n-2$, we have that

- $e_c^{k_0-1,k_0-1}(E^{\geq\rho_i}_{\widetilde{\Theta}_i^{[k_0-1]}}) = 1$, because the only contribution comes from $\mathbb{T}^{k_0-1}$ corresponding to the 0-plex ν_i itself
- $e_c^{n-k_0-1,n-k_0-1}(Z_{\Theta_i^{[n-k_0]}}) = 1$
- $e_c^{k_0-2,k_0-2}(E^{\geq\rho_i}_{\widetilde{\Theta}_i^{[k_0-1]}}) = -(k_0-1) + {}_{\nu_i}\ell_1^*(\widetilde{\Theta}^{[k_0-1]})$

The expression for the factor $e_c^{n-k_0-2,n-k_0-2}(Z_{\Theta^{[n-k_0]}})$, however, is different in all the three cases. If $1 < k_0 < n-3$, then $2(n-k_0-2) > (n-k_0-1)$, so that

$$e_c^{n-k_0-2,n-k_0-2}(Z_{\Theta_i^{[n-k_0]}}) = -\binom{n-k_0}{n-k_0-1} = -(n-k_0). \quad (3.42)$$

For the two other cases, $k_0 = (n-3)$ and $k_0 = (n-2)$, however, there is an extra term in $e_c^{n-k_0-2,n-k_0-2}(Z_{\Theta^{[n-k_0]}})$, which we denote by $\bar{e}_c^{n-k_0-2,n-k_0-2}(Z_{\Theta^{[n-k_0]}})$ hereafter.

Therefore, it turns out that $h^{1,1}(\hat{Y}_i)$ remains the same as in (3.39) for $\hat{Y}_i$ with $1 < k_0 < (n-3)$, while

$$\begin{aligned} h^{1,1}(\hat{Y}_i)|_{\text{if } k_0=(n-3),(n-2)} &= {}_{\nu_i}\ell_1(\widetilde{\Delta}_{\leq n-2}) - (n-1) + \sum_{(\widetilde{\Theta}^{[n-2]},\Theta^{[1]})} {}_{\nu_i}\ell_1^*(\widetilde{\Theta}^{[n-2]}) \times \ell^*(\Theta^{[1]}) \\ &\quad + \bar{e}_c^{n-k_0-2,n-k_0-2}(Z_{\Theta_i^{[n-k_0]}}). \end{aligned} \quad (3.43)$$

The correction term in the last line of (3.43) is determined by using the sum rule in [38], (3.28). In the case $k_0 = n-3$, $Z_{\Theta_i^{[n-k_0=3]}}$ is a surface given by a Laurent polynomial in $\mathbb{T}^3$. Therefore,

$$\bar{e}_c^{n-k_0-2,n-k_0-2}(Z_{\Theta_i^{[n-k_0]}}) = \bar{e}_c^{1,1}(Z_{\Theta_i^{[3]}}) = \varphi_2(\Theta_i^{[3]}) - \sum_{\Theta^{[2]}\leq\Theta_i^{[3]}} \varphi_1(\Theta^{[2]}), \quad (3.44)$$

$$= \ell^*(2\Theta_i^{[3]}) - 4\ell^*(\Theta_i^{[3]}) - \sum_{\Theta^{[2]}\leq\Theta_i^{[3]}} \ell^*(\Theta^{[2]}). \quad (3.45)$$

In the case $k_0 = n-2$, $Z_{\Theta_i^{[n-k_0]}}$ is a curve given by a Laurent polynomial in $\mathbb{T}^2$. Thus,

$$\bar{e}_c^{n-k_0-2,n-k_0-2}(Z_{\Theta_i^{[n-k_0]}}) = \bar{e}_c^{0,0}(Z_{\Theta_i^{[2]}}) = -\varphi_2(\Theta_i^{[2]}) + \varphi_1(\Theta_i^{[2]}), \quad (3.46)$$

$$= -\ell^*(2\Theta_i^{[2]}) + 4\ell^*(\Theta_i^{[2]}). \quad (3.47)$$

Again, the first two lines of (3.43) are understood as toric divisors of $\hat{Z}$ restricted on $\hat{Y}_i$. The $(n-1)$-dimensional redundancy among them is simply given by the number of toric linear equivalences. The geometric interpretation of the correction term $\bar{e}_c^{n-k_0-3,n-k_0-3}(Z_{\Theta^{[n-k_0]}})$ is discussed in detail in section 3.6.

JHEP01(2015)047

The cases $k_0 = n-1$. Finally, let us work out $h^{1,1}(\hat{Y}_i)$ for $k_0 = n-1$, where ν_i is in the interior of an codimension-2 face $\widetilde{\Theta}_i^{[n-2]}$ of $\widetilde{\Delta}$. The dual face of Δ is of dimension 1 and denoted by $\Theta_i^{[1]}$. The divisor $\hat{Y}_i$ of the Calabi-Yau $(n-1)$-fold $\hat{Z}$ consists of $e_c^{0,0}(Z_{\Theta_i^{[1]}}) = [1+\ell^*(\Theta_i^{[1]})]$ irreducible components, each of which is a toric variety $E^{\geq\rho_i}_{\widetilde{\Theta}_i^{[n-2]}}$ given by p-simplices $\widetilde{\Theta}_i^{[n-2]}$ containing ν_i as a face. Therefore,

$$e_c^{n-3,n-3}(E^{\geq\rho_i}_{\widetilde{\Theta}_i^{[n-2]}}) = \nu_i \ell_1^*(\widetilde{\Theta}^{[n-2]}) - (n-2)\,. \tag{3.48}$$

Note that the "number of linear equivalences" is different from that in all the other cases where $k_0 < (n-1)$: it is now $n-2$ instead of $n-1$. Finally, $h^{1,1}(\hat{Y}_i) = h^{n-3,n-3}(\hat{Y}_i)$ is obtained by multiplying the above expression with $e_c^{0,0}(Z_{\Theta_i^{[1]}}) = [1+\ell^*(\Theta_i^{[1]})]$.

3.4.2 The result

Combining the results of (3.34), (3.43), (3.45), (3.47), (3.48), $h^{n-3,n-3}[H_c^{2n-6}(Y)] = h^{2,2}[H_c^4(Y)]$ is determined. As we have already explained,

$$\begin{aligned} h^{n-3,n-3}[H_c^{2n-6}(Y)] &= \sum_i h^{n-3,n-3}(\hat{Y}_i) \\ &\quad - \left[\sum_{i<j} \left|\left\{\text{irr. nonempty components of } \hat{Y}_i \cap \hat{Y}_j\right\}\right| - \frac{n(n-1)}{2}\right]. \end{aligned} \tag{3.49}$$

Noting that all one-simplices on the $n-3$-skeleton of $\widetilde{\Delta}$ contribute twice in the first line of (3.49) and by (-1) in the second line, and that all one-simplices internal to a $n-2$-dimensional face of $\widetilde{\Delta}$ do so by a factor of $[2+(-1)]\times[1+\ell^*(\Theta^{[1]})]$, we find that

$$\begin{aligned} h^{n-3,n-3}[H_c^{2n-6}(Y)] &= \ell_1(\widetilde{\Delta}_{\leq n-2}) + \frac{n(n-1)}{2} \\ &\quad -(n-1)\left[\ell(\widetilde{\Delta}) - \sum_{\widetilde{\Theta}^{[n-1]}\leq\widetilde{\Delta}} \ell^*(\widetilde{\Theta}^{[n-1]}) - \sum_{\widetilde{\Theta}^{[n-2]}\leq\widetilde{\Delta}} \ell^*(\widetilde{\Theta}^{[n-2]}) - 1\right] \\ &\quad -(n-2)\sum_{(\widetilde{\Theta}^{[n-2]},\Theta^{[1]})} \ell^*(\widetilde{\Theta}^{[n-2]})\left[1+\ell^*(\Theta^{[1]})\right], \\ &\quad + \sum_{(\widetilde{\Theta}^{[n-2]},\Theta^{[1]})} \ell_1^*(\widetilde{\Theta}^{[n-2]})\times\ell^*(\Theta^{[1]}), \\ &\quad - \sum_{(\widetilde{\Theta}^{[n-3]},\Theta^{[2]})} \ell^*(\widetilde{\Theta}^{[n-3]})\times\left\{\ell^*(2\Theta^{[2]}) - 4\ell^*(\Theta^{[2]})\right\}. \\ &\quad + \sum_{(\widetilde{\Theta}^{[n-4]},\Theta^{[3]})} \ell^*(\widetilde{\Theta}^{[n-4]})\times\left\{\ell^*(2\Theta^{[3]}) - 4\ell^*(\Theta^{[3]}) - \sum_{\Theta^{[2]}\leq\Theta^{[3]}} \ell^*(\Theta^{[2]})\right\}. \end{aligned} \tag{3.50}$$

Here, $\ell_1(\widetilde{\Delta}_{\leq p})$ denotes the number of 1-simplices on the p-skeleton of $\widetilde{\Delta}$ and $\ell_1^*(\widetilde{\Theta})$ the number of internal 1-simplices on a face $\widetilde{\Theta}$.

JHEP01(2015)047

3.5 Combinatorial formula for $h^{2,2}[H_c^4(Z_\Delta)] = [h^{n-3,2}[H_c^{n-1}(Z_\Delta)]]_{n=5}$

Using the sum rule (3.31) of [38] we immediately find that,

$$\sum_{q=0}^{2} h^{n-3,q}\left[H_c^{n-1}(Z_\Delta)\right] = \varphi_3(\Delta), \tag{3.51}$$

$$\sum_{q=0}^{1} h^{n-3,q}\left[H_c^{n-2}(Z_{\Theta^{[n-1]}})\right] = \varphi_2(\Theta^{[n-1]}), \tag{3.52}$$

$$h^{n-3,0}\left[H_c^{n-3}(Z_{\Theta^{[n-2]}})\right] = \varphi_1(\Theta^{[n-2]}). \tag{3.53}$$

There are six unknowns in the left-hand sides, so that we need three more conditions in order to determine $h^{n-3,2}[H_c^{n-1}(Z)]$, i.e. $h^{2,2}[H_c^4(Z)]$ $(n=5)$. They come from the fact that all of the Hodge numbers of components where neither $p=q$, nor $p+q=n-1$ are tightly constrained for a compact smooth hypersurface of a toric variety. For $p=0$ (or $q=0$) such Hodge numbers even vanish. Thus, for the closure of $Z_{\Theta^{[n-1]}}$ (satisfying the condition above), it follows that

$$-h^{n-3,0}[H_c^{n-2}(Z_{\Theta^{[n-1]}})] + \sum_{\Theta^{[n-2]}\le\Theta^{[n-1]}} h^{n-3,0}[H_c^{n-3}(Z_{\Theta^{[n-2]}})] = 0 \tag{3.54}$$

for any facets $\Theta^{[n-1]}$ of Δ. Similarly for the closure of $Z_\Delta = \hat{Z}$, we obtain

$$\begin{aligned} 0 &= h^{n-3,0}(\hat{Z}) \\ &= h^{n-3,0}[H_c^{n-1}(Z_\Delta)] - \sum_{\Theta^{[n-1]}\le\Delta} h^{n-3,0}[H_c^{n-2}(Z_{\Theta^{[n-1]}})] + \sum_{\Theta^{[n-2]}\le\Delta} h^{n-3,0}[H_c^{n-3}(Z_{\Theta^{[n-2]}})]\times 1, \end{aligned} \tag{3.55}$$

where the factor 1 is due to $e^{0,0}(E_{\widetilde{\Theta}^{[2]}}) = (-)^{2+1}[\chi(\text{2d ball}) - \chi(S_1)] = 1$ (see e.g., [38]).

The $(n-3,1)$ component (i.e. $h^{2,1}$ for the case $n=5$) does not vanish, but is given by the formula (3.5) (see [41], with a correction in [9, 12]):

$$\begin{aligned} (-)\sum_{(\widetilde{\Theta}^{[2]},\Theta^{[n-3]})} \ell^*(\widetilde{\Theta}^{[2]})\times\ell^*(\Theta^{[n-3]}) &= (-)^{n-1}e_c^{n-2,2}(\hat{Z}) = (-)^{n-1}e_c^{n-3,1}(\hat{Z}) \\ &= h^{n-3,1}[H_c^{n-1}(Z_\Delta)] - \sum_{\Theta^{[n-1]}\le\Delta} h^{n-3,1}[H_c^{n-2}(Z_{\Theta^{[n-1]}})] \\ &\quad + \sum_{(\widetilde{\Theta}^{[1]},\Theta^{[n-2]})} h^{n-4,0}[H_c^{n-3}(Z_{\Theta^{[n-2]}})]\times e_c^{1,1}(E_{\widetilde{\Theta}^{[1]}}) \\ &\quad - \sum_{(\widetilde{\Theta}^{[2]},\Theta^{[n-3]})} h^{n-4,0}[H_c^{n-4}(Z_{\Theta^{[n-3]}})]\times e_c^{1,1}(E_{\widetilde{\Theta}^{[2]}}). \end{aligned} \tag{3.56}$$

On the right hand side, $e_c^{1,1}(E_{\widetilde{\Theta}^{[1]}}) = \ell^*(\widetilde{\Theta}^{[1]})$, and $e_c^{1,1}(E_{\widetilde{\Theta}^{[2]}})$ is given by $-2\ell^*(\widetilde{\Theta}^{[2]}) + \ell_1^*(\widetilde{\Theta}^{[2]})$.

In order to solve the six unknowns by using the six conditions above, we need to determine $h^{n-4,0}[H_c^{n-3}(Z_{\Theta^{[n-2]}})]$ and $h^{n-4,0}[H_c^{n-4}(Z_{\Theta^{[n-3]}})]$ appearing in the last condition.

JHEP01(2015)047

As for $h^{n-4,0}[H_c^{n-3}(Z_{\Theta^{[n-2]}})]$, using a similar condition for the closure of $Z_{\Theta^{[n-2]}}$,

$$h^{n-4,0}[H_c^{n-3}(Z_{\Theta^{[n-2]}})] = \sum_{\Theta^{[n-3]}\leq\Theta^{[n-2]}} h^{n-4,0}[H_c^{n-4}(Z_{\Theta^{[n-3]}})] = \sum_{\Theta^{[n-3]}\leq\Theta^{[n-2]}} \varphi_1(\Theta^{[n-3]}). \tag{3.57}$$

For $h^{n-4,0}[H_c^{n-4}(Z_{\Theta^{[n-3]}})]$, we can simply use $h^{n-4,0}[H_c^{n-4}(Z_{\Theta^{[n-3]}})] = \varphi_1(\Theta^{[n-3]})$.

Now we can solve (3.51):

$$h^{n-3,0}[H_c^{n-2}(Z_{\Theta^{[n-1]}})] = \sum_{\Theta^{[n-2]}\leq\Theta^{[n-1]}} \varphi_1(\Theta^{[n-2]}), \tag{3.58}$$

$$h^{n-3,0}[H_c^{n-1}(Z_\Delta)] = \sum_{\Theta^{[n-1]}\leq\Delta} \sum_{\Theta^{[n-2]}\leq\Theta^{[n-1]}} \varphi_1(\Theta^{[n-2]}) - \sum_{\Theta^{[n-2]}\leq\Delta} \varphi_1(\Theta^{[n-2]}) = \sum_{\Theta^{[n-2]}\leq\Delta} \varphi_1(\Theta^{[n-2]}), \tag{3.59}$$

where we used the fact that any $\Theta^{[n-2]}$ is codimension-1 in the boundary of Δ, so that it is shared by precisely two faces $\Theta^{[n-1]}$; those two results (3.58), (3.59) are examples of (3.32).[12] Let us continue with

$$\begin{aligned} h^{n-3,1}[H_c^{n-1}(Z_\Delta)] = & \sum_{\Theta^{[n-1]}\leq\Delta} \varphi_2(\Theta^{[n-1]}) - \sum_{\Theta^{[n-1]}\leq\Delta} \sum_{\Theta^{[n-2]}\leq\Theta^{[n-1]}} \varphi_1(\Theta^{[n-2]}) \\ & - \sum_{(\widetilde{\Theta}^{[1]},\Theta^{[n-2]})} \ell^*(\widetilde{\Theta}^{[1]}) \times \sum_{\Theta^{[n-3]}\leq\Theta^{[n-2]}} \ell^*(\Theta^{[n-3]}), \\ & + \sum_{(\widetilde{\Theta}^{[2]},\Theta^{[n-3]})} \left(-2\ell^*(\widetilde{\Theta}^{[2]}) + \ell_1^*(\widetilde{\Theta}^{[2]})\right) \times \ell^*(\Theta^{[n-3]}) \\ & - \sum_{(\widetilde{\Theta}^{[2]},\Theta^{[n-3]})} \ell^*(\widetilde{\Theta}^{[2]})\ell^*(\Theta^{[n-3]}). \end{aligned} \tag{3.60}$$

Therefore, we arrive at a the formula

$$\begin{aligned} h^{n-3,2}[H_c^{n-1}(Z_\Delta)] = & \varphi_3(\Delta) - \sum_{\Theta^{[n-1]}\leq\Delta} \varphi_2(\Theta^{[n-1]}) + \sum_{\Theta^{[n-2]}\leq\Delta} \varphi_1(\Theta^{[n-2]}) \\ & + \sum_{(\widetilde{\Theta}^{[1]},\Theta^{[n-2]})} \ell^*(\widetilde{\Theta}^{[1]}) \times \sum_{\Theta^{[n-3]}\leq\Theta^{[n-2]}} \ell^*(\Theta^{[n-3]}) \\ & + \sum_{(\widetilde{\Theta}^{[2]},\Theta^{[n-3]})} \left(3\ell^*(\widetilde{\Theta}^{[2]}) - \ell_1^*(\widetilde{\Theta}^{[2]})\right) \times \ell^*(\Theta^{[n-3]}). \end{aligned} \tag{3.61}$$

3.6 Vertical, horizontal and the remaining components

Due to the exact sequence (3.15), we can now compute $h^{2,2}(\hat{Z})$ by summing $h^{2,2}[H^4(Y)]$ in (3.50) and $h^{2,2}(\hat{Z})$ in (3.61). In fact, this is how ref. [19] derived the formula (3.3), (3.4) for $h^{1,1}$ and $h^{3,1}$ of a Calabi-Yau hypersurface fourfold $\hat{Z}$, and it is a straightforward generalization to use (3.15) to determine $h^{2,2}(\hat{Z})$ in this way. The dimension of the $H^{2,2}$

[12] Prop. 5.8 of [38] obtained the formula (3.32) by using the algorithm reviewed here.

JHEP01(2015)047

component, however, does not have to be determined in this way: for a smooth fourfold $\hat{Z}$, the formula [9, 12]

$$h^{2,2}(\hat{Z}) = 44 + 4\left(h^{1,1}(\hat{Z}) + h^{3,1}(\hat{Z})\right) - 2h^{2,1}(\hat{Z})\,. \tag{3.62}$$

makes it possible to determine $h^{2,2}(\hat{Z})$ from the three other Hodge numbers that are already determined through (3.3)–(3.5).

The exact sequence (3.15) is still very useful for the purpose of studying the decomposition (1.2). This is because all the independent divisors of a hypersurface Calabi-Yau fourfold $\hat{Z} \subset \mathbb{P}^5_{\Sigma'}$ appear in the form of irreducible components of toric divisors $\hat{Y}_i$ of $\hat{Z}$. We can therefore take a set of generators of the vertical component $H^{2,2}_V(\hat{Z})$ within $[H^4(Y)]^{2,2}$. Homological equivalence among the generators has already been taken care of in the study of $[H^4(Y)]^{2,2}$ in section 3.4. In this section, we start off with identifying which subspace of $[H^4(Y)]^{2,2}$ corresponds to the vertical component $H^{2,2}_V(\hat{Z})$. Mirror symmetry is then used to identify the horizontal component $H^{2,2}_H(\hat{Z};\mathbb{C}) := H^4_H(\hat{Z};\mathbb{C}) \cap H^{2,2}(\hat{Z};\mathbb{C})$. We will comment on the geometry associated with the remaining component $H^{2,2}_{RM}(\hat{Z};\mathbb{C})$ at the end.

3.6.1 The vertical component

Let us discuss which subspace of $H^{1,1}(\hat{Y}_i)$ is generated by vertical cycles for the cases with $k_0 = 1$, $n-3 = 2$, $n-2 = 3$ and $n-1 = 4$. We begin with a divisor $\hat{Y}_i$ corresponding to a vertex ν_i of $\widetilde{\Delta}$ (i.e., $k_0 = 1$). The formula (3.39) can be rewritten as

$$h^{1,1}(\hat{Y}_i) = {}_{\nu_i}\ell_1(\widetilde{\Delta}_{\leq n-2}) - (n-1) + \sum_{(\widetilde{\Theta}^{[n-2]},\Theta^{[1]})} \left[{}_{\nu_i}\ell_1^{*\circ}(\widetilde{\Theta}^{[n-2]}) + {}_{\nu_i}\ell_1^{*\bullet}(\widetilde{\Theta}^{[n-2]})\right] \times \ell^*(\Theta^{[1]}), \tag{3.63}$$

where ${}_{\nu_i}\ell_1^{*\circ}(\widetilde{\Theta}^{[n-2]})$ is the number of 1-simplices whose endpoints are ν_i and one of the interior points of a face $\widetilde{\Theta}^{[n-2]}$, and ${}_{\nu_i}\ell_1^{*\bullet}(\widetilde{\Theta}^{[n-2]})$ is the number of 1-simplices which run through the interior of $\widetilde{\Theta}^{[n-2]}$, but have both end points on the boundary of $\widetilde{\Theta}^{[n-2]}$. The first two terms account for the dimension of the space of algebraic cycles obtained as the intersection of $\hat{Y}_i$ with another toric divisor (i.e., a divisor of $\hat{Z}$ that descends from the toric ambient space $\mathbb{P}^{n=5}_{\Sigma'}$). When the intersection of a pair of toric divisors of the form $\hat{Y}_i \cap \hat{Y}_j$ corresponds to a 1-simplex counted in ${}_{\nu_i}\ell_1^{*\circ}(\widetilde{\Theta}^{[n-2]})$, however, the toric divisor $\hat{Y}_j$ corresponding to an interior point of a codimension-two face of $\widetilde{\Delta}$ consists of $\ell^*(\Theta^{[1]}) + 1$ irreducible components, each one of which are independent in $H^{1,1}(\hat{Z})$. Therefore each one of $\hat{Y}_i \cap [\hat{Y}_j]_{\rm irr}$'s can be taken as an independent generator of the vertical algebraic cycles. The term ${}_{\nu_i}\ell_1^{*\circ}(\widetilde{\Theta}^{[n-2]})\ell^*(\Theta^{[1]})$ should therefore be counted as a part of the vertical component $H^{2,2}(\hat{Z})$.

1-simplices counted in ${}_{\nu_i}\ell_1^{*\bullet}(\widetilde{\Theta}^{[n-2]})$, however, correspond to algebraic cycles of the form $\hat{Y}_i \cap \hat{Y}_j$, with $\hat{Y}_j$ corresponding to a point in a face of codimension-three or higher. In such cases, $\hat{Y}_i \cap \hat{Y}_j$ consists of $\ell^*(\Theta^{[1]}) + 1$ irreducible components, but only one linear combination of those irreducible components, $\hat{Y}_i \cap \hat{Y}_j$, should be regarded as a vertical cycle. Thus, there are algebraic but non-vertical cycles left over in $h^{1,1}(\hat{Y}_i)$ if and only if

$${}_{\nu_i}\ell_1^{*\bullet}(\widetilde{\Theta}^{[n-2]})\ell^*(\Theta^{[1]}) \neq 0. \tag{3.64}$$

JHEP01(2015)047

Let us move on to $H^{1,1}(\hat{Y}_i)$ for a toric divisor $\hat{Y}_i$ corresponding to an interior point of $\widetilde{\Theta}^{[1]}$ (i.e., $k_0 = n-3 = 2$). The first line of (3.43) is rewritten just like in (3.63), and the same interpretation applies also in this case. The remaining correction term $\bar{e}_c^{1,1}(Z_{\Theta^{[3]}})$ in (3.43) in the $k_0 = n-3$ case is not regarded as part of the vertical component either. To see this, let us use a long exact sequence like (3.11), decomposing $\hat{Y}_i$ into the primary stratum $Z_{\rho_i} = \mathbb{T}^{k_0-1} \times Z_{\Theta_i^{[3]}}$ and the rest $\hat{Y}_i \backslash Z_{\rho_i} = \amalg_{\rho_i < \sigma \in \Sigma'} Z_\sigma$.

$$\begin{aligned} &\cdots \longrightarrow H_c^{2n-6}(Z_{\rho_i}) \longrightarrow H_c^{2n-6}(\hat{Y}_i) \longrightarrow H_c^{2n-6}(\hat{Y}_i \backslash Z_{\rho_i}) \longrightarrow \\ &\qquad \longrightarrow H_c^{2n-5}(Z_{\rho_i}) \longrightarrow H_c^{2n-5}(\hat{Y}_i) \longrightarrow H_c^{2n-5}(\hat{Y}_i \backslash Z_{\rho_i}) \longrightarrow \cdots . \end{aligned} \tag{3.65}$$

We focus on the $(n-3, n-3)$ components in this sequence in order to study $h^{n-3,n-3}[H_c^{2n-6}(\hat{Y}_i)]$. The cohomology groups $H_c^k(Z_{\rho_i})$ for $k = 2n-6$ and $2n-5$ are determined by

$$[H_c^{2n-6}(\mathbb{T}^{n-4} \times Z_{\Theta_i^{[3]}})]^{n-3,n-3} = [H_c^{2n-8}(\mathbb{T}^{n-4})]^{n-4,n-4} \otimes [H_c^2(Z_{\Theta_i^{[3]}})]^{1,1}, \tag{3.66}$$

$$\begin{aligned} [H_c^{2n-5}(\mathbb{T}^{n-4} \times Z_{\Theta_i^{[3]}})]^{n-3,n-3} &= [H_c^{2n-9}(\mathbb{T}^{n-4})]^{n-5,n-5} \otimes [H_c^4(Z_{\Theta_i^{[3]}})]^{2,2} \\ &\quad \oplus [H_c^{2n-8}(\mathbb{T}^{n-4})]^{n-4,n-4} \otimes [H_c^3(Z_{\Theta_i^{[3]}})]^{1,1}, \end{aligned} \tag{3.67}$$

and (3.12). Thus we find

$$h^{n-3,n-3}[H_c^{2n-6}(Z_{\rho_i})] = \bar{e}_c^{1,1}(Z_{\Theta_i^{[3]}}), \qquad h^{n-3,n-3}[H_c^{2n-5}(Z_{\rho_i})] = (n-4)+3. \tag{3.68}$$

As for $H_c^{2n-6}(\hat{Y}_i \backslash Z_{\rho_i})$, it is enough to note that all of the irreducible components (strata) in $\hat{Y}_i \backslash Z_{\rho_i}$ are at most of complex dimension $(n-3)$, so that it suffices to count the number of such irreducible components, which is in turn determined by ${}_{\nu_i}\ell_1(\widetilde{\Delta}_{\leq n-3}) + \sum {}_{\nu_i}\ell_1(\widetilde{\Theta}^{[n-2]}) \left(\ell(\Theta^{[1]}) + 1\right)$. Therefore, the kernel of $[H_c^{2n-6}(\hat{Y}_i \backslash Z_{\rho_i})]^{n-3,n-3} \longrightarrow [H_c^{2n-5}(Z_{\rho_i})]^{n-3,n-3}$ accounts for the first line of (3.43). The correction term — the second line of (3.43) — comes from $[H^{2n-6}(Z_{\rho_i})]^{n-3,n-3}$. All the vertical components in $[H_c^{2n-6}(\hat{Y}_i)]^{n-3,n-3}$ are contained within $[H_c^{2n-6}(\hat{Y}_i \backslash Z_{\rho_i})]^{n-3,n-3}$, and hence the correction term $\bar{e}_c^{1,1}(Z_\Theta^{[3]})$ does not belong to the vertical component.

In the case $k_0 = n-2$, ν_i is an interior point of a two-dimensional face. The vertical component in $H^{1,1}(\hat{Y}_i)$ is identified in the same way as far as the first line of (3.43) is concerned; the term ${}_{\nu_i}\ell_1^{*\bullet}(\widetilde{\Theta}^{[3]})\ell^*(\Theta^{[1]})$ corresponds to cycles that are algebraic, but not vertical. The interpretation of the correction term $\bar{e}_c^{0,0}(Z_{\Theta_i^{[2]}})$ in (3.43), on the other hand, is quite different from the one in the $k_0 = n-3$ case.

Note first that in this case, $\hat{Y}_i$ is an $(n-2)$-fold which can be regarded as a flat family of toric $(n-3) = (k_0-1)$-dimensional varieties over a curve $\Sigma_{\Theta_i^{[2]}}$, which is the closure of $Z_{\Theta_i^{[2]}} \subset \mathbb{T}^2$. The fibre over any point in $Z_{\Theta_i^{[2]}}$ is given by toric data (ν_i-containing simplices within the face $\widetilde{\Theta}^{[k_0-1]}$). The second thing to note is that $Z_{\Theta_i^{[2]}}$ is a Riemann surface (of

JHEP01(2015)047

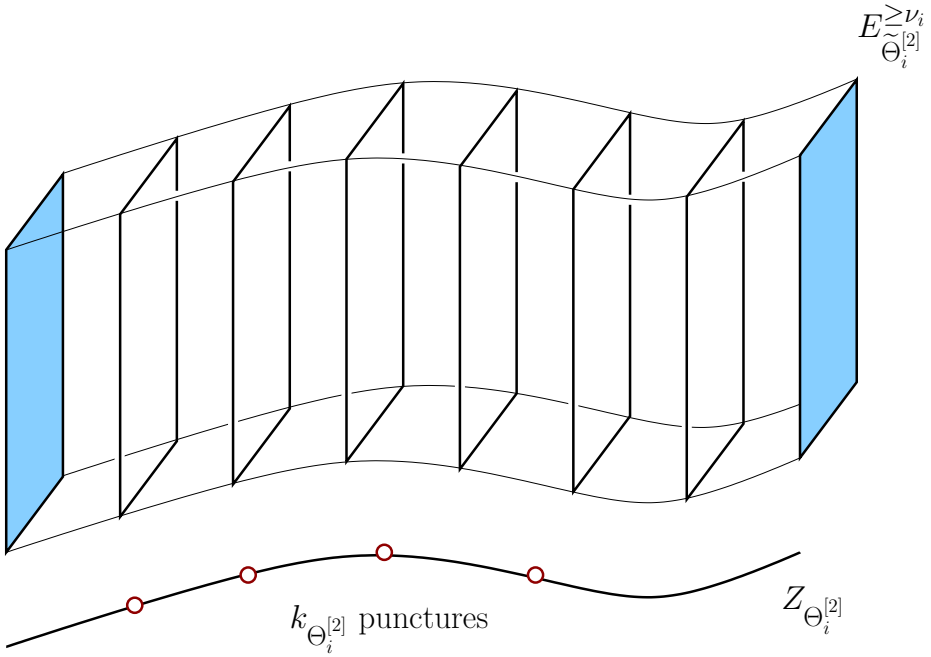

Figure 2. $\hat{Y}_i$ as a fibration of $E^{\geq\nu_i}_{\widetilde{\Theta}^{[2]}_i}$ over the curve $Z_{\Theta^{[2]}_i}$ with $k_{\Theta^{[2]}_i}$ punctures. Divisors of a generic fibre correspond to divisors of $\hat{Y}_i$ by sweeping them over the whole base.

genus $\ell^*(\Theta^{[2]}_i)$) with a finite number of punctures. The number of punctures (denoted by $k_{\Theta^{[2]}_i}$) is given by

$$k_{\Theta^{[2]}_i} - 1 = [H^1_c(Z_{\Theta^{[2]}_i})]^{0,0} = 2 - \bar{e}^{0,0}_c(Z_{\Theta^{[2]}_i})\,. \tag{3.69}$$

The compact Riemann surface $\Sigma_{\Theta^{[2]}_i}$ is obtained by filling these $k_{\Theta^{[2]}_i}$ punctures in $Z_{\Theta^{[2]}_i}$. Any one of those punctures is assigned to one of the 1-dimensional faces $\Theta^{[1]} \leq \Theta^{[2]}_i$ (see also footnote 14), and the toric $k_0 - 1$-dimensional fibre geometry is determined by the ν_i-containing simplices in the face $\widetilde{\Theta}^{[k_0]} \geq \widetilde{\Theta}^{[k_0-1]}_i$ dual to $\Theta^{[1]}$. From this point of view, the first line of (3.43), with $-(n-1)$ replaced by $-(k_0-1)$, accounts for the number of irreducible divisors of $\hat{Y}_i$ modulo the toric linear equivalence acting in the fibre direction (see figure 2). The remaining contribution to (3.43) is precisely $\bar{e}^{0,0}_c(Z_{\Theta^{[2]}_i}) - (n-k_0) = 1 - k_{\Theta^{[2]}_i}$. This correction term is now understood as counting only the generic fibre class for an independent divisor in $\hat{Y}_i$, while removing the total fibre class at each one of the $k_{\Theta^{[2]}_i}$ points in $\Sigma_{\Theta^{[2]}_i}$ from the formula of $h^{1,1}(\hat{Y}_i)$. This subtraction is necessary because the total fibre class over any point in $\Sigma_{\Theta^{[2]}_i}$ is algebraically equivalent (see figure 3).

The correction term $\bar{e}^{0,0}_c(Z_{\Theta^{[2]}_i}) = 3 - k_{\Theta^{[2]}_i}$ should always be negative, because this term accounts for the algebraic equivalence relations among the generators of $H^{2,2}_c(\hat{Y}_i)$. It is not hard to see this. For a dual pair of faces $(\widetilde{\Theta}^{[2]}_i, \Theta^{[2]}_i)$ and an interior point ν_i of $\widetilde{\Theta}^{[2]}_i$, list up all the dual pairs of faces $\{(\widetilde{\Theta}^{[3]}_a, \Theta^{[1]}_a) \mid a \in A_i\}$ labelled by $a \in A_i$ such that

$$\widetilde{\Theta}^{[3]}_a \geq \widetilde{\Theta}^{[2]}_i \qquad \text{and} \qquad \Theta^{[1]}_a \leq \Theta^{[2]}_i.$$

JHEP01(2015)047

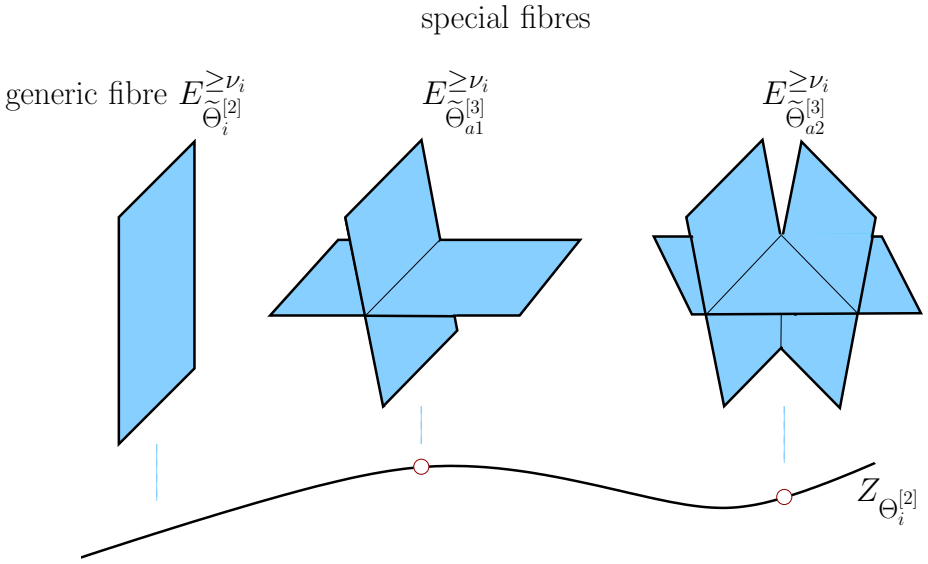

Figure 3. Over specific points, the fibre degenerates and becomes reducible. All fibres are algebraically (and hence homologically) equivalent, however.

Each one of those pairs leaves $\ell(\Theta^{[1]}_a) = [1 + \ell^*(\Theta^{[1]}_a)]$ points in $\Sigma_{\Theta^{[2]}_i}$ for which the fibre of $\hat{Y}_i \longrightarrow \Sigma_{\Theta^{[2]}_i}$ is a (not necessarily irreducible) complex surface $E^{\geq\nu_i}_{\widetilde{\Theta}^{[3]}_a}$ rather than the generic fibre $E^{\geq\nu_i}_{\Theta^{[2]}_i}$. Therefore

$$\bar{e}_c^{0,0}(Z_{\Theta^{[2]}_i}) = 3 - k_{\Theta^{[2]}_i} = 3 - \sum_{\Theta^{[1]}_a \leq \Theta^{[2]}_i} [1 + \ell^*(\Theta^{[1]}_a)] = 3 - \#\{\Theta^{[1]}_a \leq \Theta^{[2]}_i\} - \sum_{\Theta^{[1]}_a \leq \Theta^{[2]}_i} \ell^*(\Theta^{[1]}_a). \tag{3.70}$$

The last term is obviously negative as the number of edges of a two-dimensional face $\Theta^{[2]}$ is always greater than or equal to 3. Thus, $\bar{e}_c^{0,0}(Z_{\Theta^{[2]}_i}) \leq 0$.

The algebraic equivalence relations encoded in $\bar{e}_c^{0,0}(Z_{\Theta^{[2]}_i})$ are sometimes among algebraic cycles in the vertical component, and sometimes among cycles in the non-vertical component. Figure 4 is a schematic picture of the singular fibres of $\hat{Y}_i \longrightarrow \Sigma_{\Theta^{[2]}_i}$ at the $\ell^*(\Theta^{[1]}_a) + 1$ punctures associated with a given face $\Theta^{[1]}_a \leq \Theta^{[2]}_i$. There is always at least one combination of the total fibre classes that is in the vertical component; such a combination of the total fibre classes is in fact even in the space of vertical cycles generated by toric divisors. Such a fibre class is algebraically equivalent to the generic fibre class of $\hat{Y}_i \longrightarrow \Sigma_{\Theta^{[2]}}$, and is subtracted by the algebraic equivalence on $\Sigma_{\Theta^{[2]}_i}$ corresponding to the $(3 - \#\{\Theta^{[1]}_a \leq \Theta^{[2]}_i\})$ term in $\bar{e}_c^{0,0}(Z_{\Theta^{[2]}_i})$ above.

Suppose that the dual face pair $(\widetilde{\Theta}^{[3]}_a, \Theta^{[1]}_a)$ for an $a \in A_i$ is such that *all* the 1-simplices counted in ${}_{\nu_i}\ell^*_1(\widetilde{\Theta}^{[3]}_a)$ end at interior points of $\widetilde{\Theta}^{[3]}_a$. This means that all the $[1 + \ell^*(\Theta^{[1]}_a)]$ total fibre classes of $\hat{Y}_i \longrightarrow \Sigma_{\Theta^{[2]}_i}$ belong to the space of vertical cycles (see figure 4). Let Av_i be the subset of the labels $a \in A_i$ satisfying the condition above, and $(\widetilde{\Theta}^{[3]}_{\rm v}, \Theta^{[1]}_{\rm v})$ be such a

JHEP01(2015)047

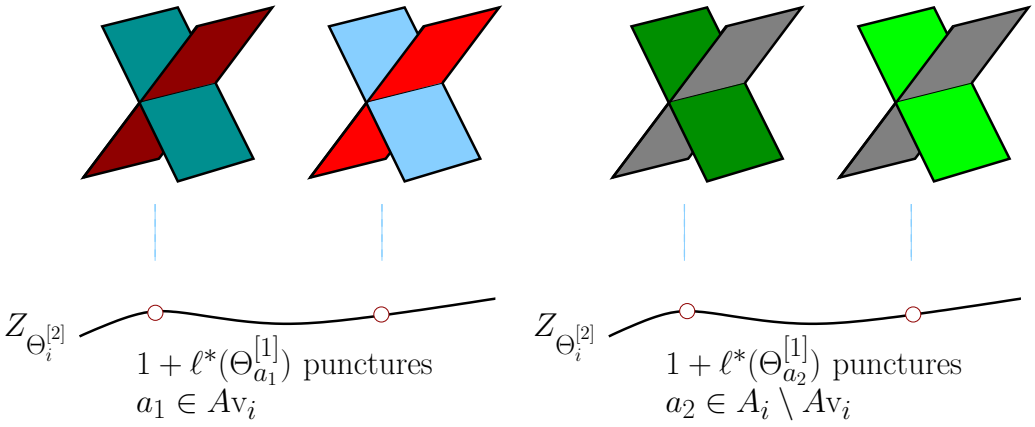

Figure 4. (colour online) Fibre components corresponding to points ν_i contributing to $\Theta_v^{[3]}$ (left hand side) and $\Theta_{nv}^{[3]}$ (right hand side). The fibre components drawn in red, blue and green correspond to fibre components which are obtained by intersecting appropriate divisors. These components arise from one-simplices connecting ν_i to an interior point of the face $\widetilde{\Theta}_a^{[3]}$. When there is a one-simplex connecting ν_i to a point on the boundary of $\widetilde{\Theta}_a^{[3]}$, only the sum of several components of different fibres, drawn in grey, arises from an intersection of divisors (so that it should be considered vertical). Again, the two degenerate fibres on the left hand side are algebraically equivalent, as are the two degenerate fibres on the right hand side.

dual pair of faces. The space of vertical but non-toric cycles originating from $H^{1,1}(\hat{Y}_i)$ is reduced by $-\sum_{\Theta_{\rm v}^{[1]}\leq\Theta^{[2]}}\ell^*(\Theta_{\rm v}^{[1]})$ due to the algebraic equivalence.

A dual pair of faces $(\widetilde{\Theta}_a^{[3]},\Theta_a^{[1]})$ otherwise (i.e., $a\in A_i\setminus A\mathrm{v}_i$) has at least one 1-simplex counted in ${}_{\nu_i}\ell_1^*(\widetilde{\Theta}_a^{[3]})$ whose boundary other than ν_i is not in the interior of $\widetilde{\Theta}^{[3]}$. Such pairs of faces are denoted by $(\widetilde{\Theta}_{\rm nv}^{[3]},\Theta_{\rm nv}^{[1]})$. The remaining $-\sum_{\Theta_{\rm nv}^{[1]}\leq\Theta_i^{[2]}}\ell^*(\Theta_{\rm nv}^{[1]})$ independent algebraic equivalences reduce the dimension of the space of algebraic, but non-vertical four-cycles. To summarize,

$$\begin{aligned}
V^{\rm alg}(\hat{Z}) &= \sum_{(\widetilde{\Theta}^{[2]},\Theta^{[2]})}\ell^*(\widetilde{\Theta}^{[2]})\left\{-\ell^*(2\Theta^{[2]})+4\ell^*(\Theta^{[2]})\right\},\\
&= \sum_{(\widetilde{\Theta}^{[2]},\Theta^{[2]})}\ell^*(\widetilde{\Theta}^{[2]})(3-k_{\Theta^{[2]}}) = V^{\rm alg}_{\rm tor}(\hat{Z})+V^{\rm alg}_{\rm cor}(\hat{Z})+V^{\rm alg}_{\rm rm}(\hat{Z}); \qquad (3.71)\\
V^{\rm alg}_{\rm tor}(\hat{Z}) &:= \sum_{(\widetilde{\Theta}^{[2]},\Theta^{[2]})}\ell^*(\widetilde{\Theta}^{[2]})\left(3-\#\{\Theta^{[1]}\leq\Theta^{[2]}\}\right),\\
V^{\rm alg}_{\rm cor}(\hat{Z}) &:= -\sum_{(\widetilde{\Theta}^{[2]},\Theta^{[2]})}\ell^*(\widetilde{\Theta}^{[2]})\sum_{\Theta_{\rm v}^{[1]}\leq\Theta^{[2]}}\ell^*(\Theta_{\rm v}^{[1]}),\\
V^{\rm alg}_{\rm rm}(\hat{Z}) &:= -\sum_{(\widetilde{\Theta}^{[2]},\Theta^{[2]})}\ell^*(\widetilde{\Theta}^{[2]})\sum_{\Theta_{\rm nv}^{[1]}\leq\Theta^{[2]}}\ell^*(\Theta_{\rm nv}^{[1]}). \qquad (3.72)
\end{aligned}$$

All the three terms are negative.

Finally, in the cases of $k_0=n-1$, it is easy to see that all of the generators of the space $\oplus_{\rm irr}H_c^{2,2}([\hat{Y}_i]_{\rm irr})$ are vertical cycles. The space of vertical cycles generated by

JHEP01(2015)047

the toric divisors, however, has a dimension given by (3.48) without being multiplied by $e_c^{0,0}(Z_{\Theta_i^{[1]}}) = [1 + \ell^*(\Theta_i^{[1]})]$.

Having seen which subspace of $H_c^{2,2}(\hat{Y}_i)$ is identified with a part of the vertical component $H^{2,2}(\hat{Z})$, we are now ready to determine the dimension of the vertical component in $H_V^{2,2}(\hat{Z})$. Setting aside the components in $[H^4(Y)]^{2,2}$ that have turned out to be non-vertical, we have

$$h^{2,2}[H^4(Y)] = h_V^{2,2}(\hat{Z}) + \left[RM_a(\hat{Z}) + V_{\rm rm}^{\rm alg}(\hat{Z})\right] + NV_1(\hat{Z}), \tag{3.73}$$

$$h_V^{2,2}(\hat{Z}) = \left[V_{\rm tor}(\hat{Z}) + V_{\rm tor}^{\rm alg}(\hat{Z})\right] + \left[V_{\rm cor}(\hat{Z}) + V_{\rm cor}^{\rm alg}(\hat{Z})\right], \tag{3.74}$$

where

$$\begin{aligned}
V_{\rm tor}(\hat{Z}) :=\ & \ell_1(\widetilde{\Delta}_{\leq n-2}) + \frac{n(n-1)}{2} \\
& -(n-1)\left[\ell(\widetilde{\Delta}) - \sum_{\widetilde{\Theta}^{[n-1]} \leq \widetilde{\Delta}} \ell^*(\widetilde{\Theta}^{[n-1]}) - \sum_{\widetilde{\Theta}^{[n-2]} \leq \widetilde{\Delta}} \ell^*(\widetilde{\Theta}^{[n-2]}) - 1\right] \\
& -(n-2) \sum_{\widetilde{\Theta}^{[n-2]}} \ell^*(\widetilde{\Theta}^{[n-2]}) \\
V_{\rm cor}(\hat{Z}) :=\ & \sum_{(\widetilde{\Theta}^{[3]}, \Theta^{[1]})} \left[\ell_1^{*\circ}(\widetilde{\Theta}^{[3]}) - 3\ell^*(\widetilde{\Theta}^{[3]})\right] \times \ell^*(\Theta^{[1]}), \\
RM_a(\hat{Z}) =\ & \sum_{(\widetilde{\Theta}^{[3]}, \Theta^{[1]})} \ell_1^{*\bullet}(\widetilde{\Theta}^{[3]}) \ell^*(\Theta^{[1]}), \\
NV_1(\hat{Z}) :=\ & \sum_{(\widetilde{\Theta}^{[1]}, \Theta^{[3]})} \ell^*(\widetilde{\Theta}^{[1]}) \times \left(\ell^*(2\Theta^{[3]}) - 4\ell^*(\Theta^{[3]}) - \sum_{\Theta^{[2]} \leq \Theta^{[3]}} \ell^*(\Theta^{[2]})\right).
\end{aligned} \tag{3.75}$$

Here, $\ell_1^{*\circ}(\widetilde{\Theta}^{[3]})$ is the number of 1-simplices that run through the interior of a face $\widetilde{\Theta}^{[3]}$ and have at least one boundary point in the interior of $\widetilde{\Theta}^{[3]}$. $\ell_1^{*\bullet}(\widetilde{\Theta}^{[3]})$ is the number of all other 1-simplices that run through the interior of the face $\widetilde{\Theta}^{[3]}$; it only counts those one-simplices which start and end on the boundary of the face $\widetilde{\Theta}^{[3]}$.

The Chow group $Ch^2(\hat{Z})$ is obtained by taking a quotient of the space of algebraic (complex)-two-cycles by rational equivalence, whereas we have also exploited algebraic equivalence in studying the cohomology group $H^{2,2}(\hat{Z})$. The Deligne cohomology $H_D^4(\hat{Z}; \mathbb{Z}(2))$ and the closely related Chow group $Ch^2(\hat{Z})$ not only contain information on the flux field strength $G^{(4)}$ for F-theory, but also on the three-form potential $C^{(3)}$. Truly of interest in the context of physics application, though, will be $H_D^4(\hat{Z}_p; \mathbb{Z}(2))$ for $\hat{Z}_p$ corresponding to a point $p \in \mathcal{M}_*$ in some Noether-Lefschetz locus, rather than that of $\hat{Z}_p$ at a generic point $p \in \mathcal{M}_*$. Fluxes which are in the primary horizontal subspace may also become algebraic in a Noether-Lefschetz locus, where we are expected to end up from the superpotential $W \propto \int_{\hat{Z}} G^{(4)} \wedge \Omega$. Ignoring the original context of physics applications, however, let us leave an interesting observation on $Ch^2(\hat{Z})$ for $\hat{Z}$ corresponding to a generic point $p \in \mathcal{M}_*$. The relevance of the refined data contained in $Ch^2(\hat{Z})$ (compared with

JHEP01(2015)047

homology) to F-theory fluxes has recently been discussed in [45] (see also the literatures therein).

For $\hat{Z}_p$ at a generic point in complex structure moduli space $p \in \mathcal{M}_*$, algebraic cycles generate a subspace of $H^{2,2}(\hat{Z})$ with a dimension no less than

$$V_{\rm tor}(\hat{Z}) + V_{\rm cor}(\hat{Z}) + RM_a(\hat{Z}) + V^{\rm alg}(\hat{Z}),$$

and possibly larger than this by at most $NV_1(\hat{Z})$. Only the first term descends from algebraic cycles of the toric ambient space. Apart from the last term, all the equivalence relations that have been exploited are linear (rational) equivalence. The last term, $V^{\rm alg}(\hat{Z})$, introduces algebraic equivalence relations among those cycles as we have already seen. They are associated with divisors $\hat{Y}_i$ of $\hat{Z}$ corresponding to interior points ν_i of two-dimensional faces $\widetilde{\Theta}^{[2]} \leq \widetilde{\Delta}$. The threefolds $\hat{Y}_i$ can be seen as flat fibrations of surfaces over curves $\Sigma_{\Theta^{[2]}}$ with genus $g = \ell^*(\Theta^{[2]})$. The fibre classes over any two points in $\Sigma_{\Theta^{[2]}}$ are mutually algebraically equivalent, and they are identified in the cohomology group. Under rational equivalence, however, they form a family of *inequivalent* classes parametrized by $g = \ell^*(\Theta^{[2]})$ complex parameters. This is analogous to divisors (points) on the curve $\Sigma_{\Theta^{[2]}}$, which are classified under linear equivalence by $\mathrm{Pic}(\Sigma_{\Theta^{[2]}})$, which has $g = \dim_{\mathbb{C}}[\mathrm{Pic}^0(\Sigma^{[2]}_\Theta)]$ complex parameters more than the discrete data (the first Chern class) counted in $H^{1,1}(\Sigma_{\Theta^{[2]}})$. Noting that

$$h^{2,1}(\hat{Z}) = \sum_{(\widetilde{\Theta}^{[2]},\Theta^{[2]})} \ell^*(\widetilde{\Theta}^{[2]})\ell^*(\Theta^{[2]}) = \sum_{(\widetilde{\Theta}^{[2]},\Theta^{[2]})} \ell^*(\widetilde{\Theta}^{[2]}) g(\Sigma_{\Theta^{[2]}}), \tag{3.76}$$

we see that the $Ch^2(\hat{Z})$ group contains $h^{2,1}(\hat{Z})$ more complex parameters than the cohomology group, and that this difference comes from divisors $\hat{Y}_i$ of $\hat{Z}$ that are regarded as flat surface fibration over curves with $g > 0$.

3.6.2 Horizontal and remaining components

Since the vertical component $H^{2,2}_V(\hat{Z})$ has been identified within $[H^4(Y)]^{2,2}$, the horizontal and the remaining components in the decomposition (1.2) should live in $[H^4(Z_\Delta)]^{2,2}$ and the remaining space within $[H^4(Y)]^{2,2}$. We are going to use mirror symmetry to identify the horizontal component $H^{2,2}_H(\hat{Z})$ in $[H^4_c(Z_\Delta)]^{2,2}$.

To this end, it is convenient to verify a couple of relations among the combinatorial data first. Let us introduce the following decomposition in order to facilitate the discussion:

$$h^{2,2}[H^4(Z_\Delta)] := H_{\rm mon}(\hat{Z}) + H^{\rm red}(\hat{Z}) + NV_3(\hat{Z}), \tag{3.77}$$

where

$$\begin{aligned} H_{\rm mon}(\hat{Z}) &:= \varphi_3(\Delta) - \sum_{\Theta^{[4]}} \varphi_2(\Theta^{[4]}) + \sum_{\Theta^{[3]}} \varphi_1(\Theta^{[3]}), \\ H^{\rm red}(\hat{Z}) &:= \sum_{(\widetilde{\Theta}^{[2]},\Theta^{[2]})} \left(3\ell^*(\widetilde{\Theta}^{[2]}) - \ell^*_1(\widetilde{\Theta}^{[2]})\right) \times \ell^*(\Theta^{[2]}), \end{aligned}$$

JHEP01(2015)047

$$NV_3(\hat{Z}) := \sum_{(\widetilde{\Theta}^{[1]},\Theta^{[3]})} \sum_{\Theta^{[2]}\leq\Theta^{[3]}} \ell^*(\widetilde{\Theta}^{[1]}) \times \ell^*(\Theta^{[2]})\,. \tag{3.78}$$

We claim that

$$H_{\rm mon}(\hat{Z}) = V_{\rm tor}(\hat{Z}_m), \quad H^{\rm red}(\hat{Z}) = V^{\rm alg}(\hat{Z}_m), \quad NV_1(\hat{Z}) + NV_3(\hat{Z}) = V_{\rm cor}(\hat{Z}_m) + RM_a(\hat{Z}_m). \tag{3.79}$$

This also means that the following relation holds:

$$h^{2,2}[H^4_c(Z_\Delta)] + NV_1(\hat{Z}) = V_{\rm tor}(\hat{Z}_m) + V_{\rm cor}(\hat{Z}_m) + RM_a(\hat{Z}_m) + V^{\rm alg}(\hat{Z}_m). \tag{3.80}$$

Let us verify the relations (3.79) one by one. As for the first one, note that

$$\begin{aligned}
&H_{\rm mon}(\hat{Z}) \\
&= [\ell(2\Delta) - (n+1)\ell(\Delta) + \frac{n(n+1)}{2}] \qquad (3.81)\\
&\quad - \sum_{\Theta^{[n-1]}\leq\Delta} [\ell^*(2\Theta^{[n-1]}) - n\ell^*(\Theta^{[n-1]})] + \sum_{\Theta^{[n-2]}\leq\Delta} \ell^*(\Theta^{[n-2]}), \\
&= [\ell(2\Delta) - \ell(\Delta) - \sum_{\Theta^{[n-1]}} \ell^*(2\Theta^{[n-1]})] \qquad (3.82)\\
&\quad - n[\ell(\Delta) - \sum_{\Theta^{[n-1]}} \ell^*(\Theta^{[n-1]})] + \frac{n(n+1)}{2} + \sum_{\Theta^{[n-2]}\leq\Delta} \ell^*(\Theta^{[n-2]}), \\
&= [\ell(2\Delta) - \ell(\Delta) - \sum_{\Theta^{[n-1]}} \ell^*(2\Theta^{[n-1]})] - [\ell(\Delta) - 1 - \sum_{\Theta^{[n-1]}} \ell^*(\Theta^{[n-1]})], \qquad (3.83)\\
&\quad + \left[-n + \frac{n(n+1)}{2}\right], \\
&\quad - \left[(n-1)\left[\ell(\Delta) - 1 - \sum_{\Theta^{[n-1]}} \ell^*(\Theta^{[n-1]}) - \sum_{\Theta^{[n-2]}} \ell^*(\Theta^{[n-2]})\right] + (n-2)\sum_{\Theta^{[n-2]}} \ell^*(\Theta^{[2]}),\right].
\end{aligned}$$

Obviously one only needs to verify that (3.83) is equal to $\ell_1(\Delta_{\leq n-2})$ in order to prove that $H_{\rm mon}(\hat{Z}) = V_{\rm tor}(\hat{Z}_m)$. Secondly, we see that the first term in (3.83) counts the number of lattice points in M at the "lattice-distance-2" that are not in the interior of n-dimensional cones, while the second term in (3.83) counts lattice points at the "lattice distance 1". Now remember that we assume existence of a fine unimodular triangulation of the polytope Δ (so that both $\hat{Z}_m$ and the ambient toric variety $\mathbb{P}^n_\Sigma$ are smooth). For a cone whose base at the lattice-distance 1 is a minimum volume k-simplex, lattice points at the distance 1 are the $k+1$ vertices of the k-simplex, while those at the distance 2 consist of $\binom{k+1}{1} + \binom{k+1}{2} = \binom{k+2}{2} =: N_{k,2}$ points corresponding to the vertices and 1-simplices on the k-simplex (see figure 5).[13] Because any cone of the fan $\widetilde{\Sigma}$ can be decomposed into such cones of the fan $\widetilde{\Sigma}'$,

$$\ell(2\Theta) = \ell(\Theta) + \ell_1(\Theta) \tag{3.84}$$

[13] The slice of such a cone at the distance h becomes a k-dimensional pyramid of height h (see footnote 16). The number of interior points of such a pyramid is $N_{k,h-k-1} = (h-k)_k/k!$, which becomes positive only when $h > k$. That is, a lattice point corresponding to a k-simplex is found only at the lattice distance $h > k$. At the distance 2, $\partial(2\widetilde{\Delta})$, the lattice points correspond only to vertices or 1-simplices on $\partial\widetilde{\Delta}$.

JHEP01(2015)047

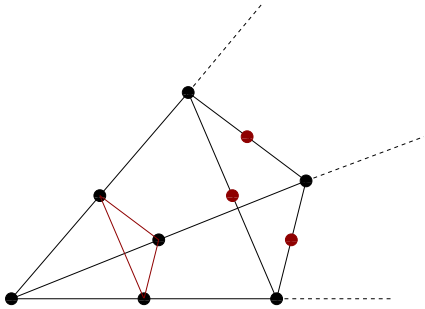

Figure 5. (colour online) The lattice points at the distance-2 layer are in one-to-one correspondence with the lattice points and 1-simplices at the distance-1 layer.

for any faces $\Theta < \Delta$. Using recursion with respect to the faces of Θ, similar relations can be derived for the number of internal one-simplices, $\ell_1^*(\Theta)$. This proves the equality between $\ell_1(\Delta_{\leq n-2})$ and (3.83) and also the first relation $H_{\rm mon}(\hat{Z}) = V_{\rm tor}(\hat{Z}_m)$ in (3.79).

The second one of the relations (3.79) $H^{\rm red}(\hat{Z}) = V^{\rm alg}(\hat{Z}_m)$ can be verified for each one of dual pairs, $(\widetilde{\Theta}^{[2]}, \Theta^{[2]})$. Using the relation (3.84) for the 2-dimensional face $\widetilde{\Theta}^{[2]} < \widetilde{\Delta}$, we find that[14]

$$\bar{e}_c^{0,0}(Z_{\widetilde{\Theta}^{[2]}}) = -\ell^*(2\widetilde{\Theta}^{[2]}) + 4\ell^*(\widetilde{\Theta}^{[2]}) = \left(3\ell^*(\widetilde{\Theta}^{[2]}) - \ell_1^*(\widetilde{\Theta}^{[2]})\right). \tag{3.89}$$

The third relation in (3.79) is equivalent to

$$\ell^*(2\Theta^{[3]}) - 4\ell^*(\Theta^{[3]}) = \ell_1^*(\Theta^{[3]}) - 3\ell^*(\Theta^{[3]}) \tag{3.90}$$

for each one of the faces $\Theta^{[3]} < \Delta$. This relation also follows from (3.84).

Toric divisors on $\hat{Z}_m$ are mirror to monomial deformations of the defining equation of the hypersurface $\hat{Z}$. It is thus reasonable to consider that the space spanned by mutual intersections of toric divisors — a $V_{\rm tor}(\hat{Z}_m)$-dimensional subspace of the primary vertical subspace of $\oplus_p H^{p,p}(\hat{Z}_m)$ — is mirror to second order monomial deformations of $\hat{Z}$, which must be a subspace of the primary horizontal subspace of $\oplus_p H^{p,n-1-p}(\hat{Z})$. This subspace

[14]The relation (3.69), (3.70) between $\bar{e}_c^{0,0}(Z_{\widetilde{\Theta}^{[2]}}) = -\ell^*(2\widetilde{\Theta}^{[2]}) + 4\ell^*(\widetilde{\Theta}^{[2]})$ and the number of punctures $k_{\widetilde{\Theta}^{[2]}}$ can also be derived purely combinatorially, without looking at the geometry of the curve and punctures on it. To see this, note first that $k_{\widetilde{\Theta}^{[2]}} = V_B$, where V_B is the number of lattice points appearing on the boundary of a two-dimensional simplicial complex $\widetilde{\Theta}^{[2]}$. Now, let T be the number of 2-simplices in $\widetilde{\Theta}^{[2]}$, E_I and E_B the number of 1-simplices in the interior and boundary of $\widetilde{\Theta}^{[2]}$, and V_I and V_B the number of points in the interior and boundary of $\widetilde{\Theta}^{[2]}$. The topology of $\widetilde{\Theta}^{[2]}$ and $\partial\widetilde{\Theta}^{[2]}$ indicates that

$$0 = V_B - E_B, \tag{3.85}$$

$$1 = (V_B + V_I) - (E_B + E_I) + T, \tag{3.86}$$

$$3T = 2E_I + E_B. \tag{3.87}$$

From this, we find that

$$3V_I - E_I = 3 - V_B = 3 - k_{\Theta^{[2]}}. \tag{3.88}$$

The left-hand side is precisely the right-hand side of (3.89), and is hence equal to $\bar{e}_c^{0,0}(Z_{\widetilde{\Theta}^{[2]}})$ combinatorially. This completes a combinatorial proof of the relation (3.69), (3.70), which also follows from the geometry of the curve $Z_{\widetilde{\Theta}^{[2]}}$).

JHEP01(2015)047

should have a dimension $H_{\rm mon}(\hat{Z}) = V_{\rm tor}(\hat{Z}_m)$ because of mirror symmetry. This reasoning seems to work very well: the first line of the expression (3.83) of $H_{\rm mon}(\hat{Z})$ counts the number of lattice points $2\Delta \cap M$ of the form $\tilde{\nu}_\alpha + \tilde{\nu}_\beta$ where $\tilde{\nu}_\alpha$ and $\tilde{\nu}_\beta$ have corresponding monomial deformations $D_\alpha \Omega_{\hat{Z}}$ and $D_\beta \Omega_{\hat{Z}}$, and there is a 1-simplex joining the lattice points $\tilde{\nu}_\alpha$ and $\tilde{\nu}_\beta$. It is quite reasonable to identify the point $\tilde{\nu}_\alpha + \tilde{\nu}_\beta$ in $2\Delta \cap M$ with the quadratic complex structure deformation $D_\alpha D_\beta \Omega_{\hat{Z}}$ (or $(\Omega^{-1} D_\alpha \Omega) \cdot (\Omega^{-1} D_\beta \Omega)$ in $H^2(\hat{Z}; \wedge^2 T\hat{Z})$ of [4]).

According to mirror symmetry, the subspace of non-vertical components with the dimension $NV_1(\hat{Z}) + NV_3(\hat{Z})$ must be decomposed into

$$\begin{aligned} H_{\rm cor}(\hat{Z}) &:= V_{\rm cor}(\hat{Z}_m) = \sum_{(\widetilde{\Theta}^{[1]}, \Theta^{[3]})} \ell^*(\widetilde{\Theta}^{[1]}) \times \left[\ell_1^{*\circ}(\Theta^{[3]}) - 3\ell^*(\Theta^{[3]}) \right], \\ RM_a^m(\hat{Z}) &:= RM_a(\hat{Z}_m) = \sum_{(\widetilde{\Theta}^{[1]}, \Theta^{[3]})} \ell^*(\widetilde{\Theta}^{[1]}) \ell_1^{*\bullet}(\Theta^{[3]}) \,. \end{aligned} \tag{3.91}$$

The space generated by $H_{\rm cor}$ generators must also be part of the primary horizontal subspace. The $H_{\rm cor}$-dimensional subspace of the primary horizontal component must correspond to $D^2\Omega_{\hat{Z}}$ which involve at least one deformation that is not represented by a monomial, i.e. the last term of (3.4). It is reasonable that the expression of $H_{\rm cor}(\hat{Z})$ above vanishes when there is no pair of dual faces where $\ell^*(\widetilde{\Theta}^{[1]}) \ell^*(\Theta^{[3]}) \neq 0$, because there should be no non-monomial deformation of complex structure in that case.

The correction term $H^{\rm red}(\hat{Z})$ in (3.77) is mirror to the $V^{\rm alg}(\hat{Z}_m)$ algebraic equivalences, and hence will represent some redundancy in the description of the quadratic deformations of complex structure by $H_{\rm mon}(\hat{Z}) + H_{\rm cor}(\hat{Z})$ generators and $RM_a^m(\hat{Z})$ for the non-horizontal non-vertical components. $H^{\rm red}(\hat{Z})$ can be split into three, just like we did for $V^{\rm alg}(\hat{Z})$. The dimensions of those three pieces are denoted by $H^{\rm red}_{\rm mon}(\hat{Z})$, $H^{\rm red}_{\rm cor}(\hat{Z})$ and $H^{\rm red}_{\rm rm}(\hat{Z})$.

By using mirror symmetry, we finally arrive at the following formula for the vertical, horizontal and remaining components of $H^{2,2}(\hat{Z})$ of a Calabi-Yau fourfold $\hat{Z}$ obtained as a hypersurface of a toric variety $\mathbb{P}^5_{\Sigma'}$.

$$h^{2,2}(\hat{Z}) = h^{2,2}_V(\hat{Z}) + h^{2,2}_{RM}(\hat{Z}) + h^{2,2}_H(\hat{Z}), \tag{3.92}$$

$$h^{2,2}_H(\hat{Z}) = \left[H_{\rm mon}(\hat{Z}) + H^{\rm red}_{\rm mon}(\hat{Z}) \right] + \left[H_{\rm cor}(\hat{Z}) + H^{\rm red}_{\rm cor}(\hat{Z}) \right], \tag{3.93}$$

$$h^{2,2}_{RM}(\hat{Z}) = \left[RM_a(\hat{Z}) + V^{\rm alg}_{\rm rm}(\hat{Z}) \right] + \left[RM_a^m(\hat{Z}) + H^{\rm red}_{\rm rm}(\hat{Z}) \right]. \tag{3.94}$$

This result shows under which circumstances the remaining component is present. It is quite reasonable from the perspective of mirror symmetry, though, that the remaining component $H^{2,2}_{RM}(\hat{Z})$ has a dimension that is symmetric under the exchange of Δ and $\widetilde{\Delta}$.

The term $RM_a(\hat{Z})$ describes the space of algebraic cycles on divisors $\hat{Y}_i$ of $\hat{Z}$ that are not obtained by restriction of divisors of $\hat{Z}$; that is, they come from

$$\mathrm{Coker} \left[i^*_{\hat{Y}_i \hookrightarrow \hat{Z}} : NS(\hat{Z}) \longrightarrow NS(\hat{Y}_i) \right]. \tag{3.95}$$

We do not have a robust theory on the component with the dimension $RM_a^m(\hat{Z})$ at this moment. Some of this component come from $NV_1(\hat{Z})$-dimensional subspace of $[H^4(Y)]^{2,2}$,

JHEP01(2015)047

but some may also come from the $NV_3(\hat{Z})$-dimensional subspace of $[H_c^4(Z_\Delta)]^{2,2}$. There are some examples where (a part of) the $RM_a^m(\hat{Z})$-dimensional space also represents algebraic but non-vertical cycles characterized by (3.95), as we will see in section 4.3. Not all of the components in this $RM_a^m(\hat{Z})$-dimensional space may be of this form for general choices of Δ and $\widetilde{\Delta}$, however. We just simply do not know at this moment.

3.6.3 Triangulation (resolution) independence

As we have already explained in section 2, formulating F-theory compactification on resolved fourfolds only makes sense if the dimensions of the vertical, horizontal and the remaining components (i.e., $h_V^{2,2}$, $h_H^{2,2}$ and $h_{RM}^{2,2}$) of a Calabi-Yau fourfold $\hat{Z}$ are independent of the choice of crepant resolution of singularities of Z_s (fine regular unimodular triangulation of $\widetilde{\Delta}$).[15] As we have discussed, this follows from the independence of the complex structure moduli space on which resolution is chosen.

In this section we supplement this general argument with a more specific discussion of triangulation independence for the construction discussed in this section, i.e. for resolutions $\hat{Z}$ of Z_s obtained by fine unimodular triangulations of the polytope $\widetilde{\Delta}$.

It is easy to see, first, that $H_{\rm mon}(\hat{Z})$ and $V_{\rm tor}^{\rm alg}(\hat{Z})$ do not depend on the triangulation of Δ (or $\widetilde{\Delta}$), because their expressions only involve the numbers of lattice points in polytopes. Since $V_{\rm tor}(\hat{Z})$ and $H_{\rm mon}^{\rm red}(\hat{Z})$ are mirror to $H_{\rm mon}(\hat{Z}_m)$ and $V_{\rm tor}^{\rm alg}(\hat{Z}_m)$, they are also independent of the triangulation of $\widetilde{\Delta}$ (or Δ); although the expression of $V_{\rm tor}(\hat{Z})$ involves a number of 1-simplices explicitly, we have seen by using (3.84) that $V_{\rm tor}(\hat{Z})$ is equal to $H_{\rm mon}(\hat{Z}_m)$, and the number of 1-simplices used in $V_{\rm tor}(\hat{Z})$ does not depend on the choice of triangulation. This means that both

$$\left[V_{\rm tor}(\hat{Z}) + V_{\rm tor}^{\rm alg}(\hat{Z})\right] \quad \text{and} \quad \left[H_{\rm mon}(\hat{Z}) + H_{\rm mon}^{\rm red}(\hat{Z})\right]$$

are independent of triangulations.

The dimensions of other components such as $V_{\rm cor}(\hat{Z})$, $V_{\rm cor}^{\rm alg}(\hat{Z})$, $RM_a(\hat{Z})$, etc., however, involve counting the number of 1-simplices with much more specific restrictions, and it is not obvious at first sight how we see triangulation-independence. Let us look at (3.94), however, where four terms are grouped into two. The first two terms do not depend on the triangulation of Δ, but they may depend on the triangulation of $\widetilde{\Delta}$; the last two terms, on the other hand, do not depend on the triangulation of $\widetilde{\Delta}$, but they may depend on the triangulation of Δ. The dimension of $h_{RM}^{2,2}(\hat{Z})$, however, has no chance of depending on the choice of triangulation of Δ by construction. This means that the last two terms of (3.94) combined — $[RM_a^m(\hat{Z}) + H_{\rm rm}^{\rm red}(\hat{Z})]$ — should not depend on the choice of a triangulation of Δ, and not just on the triangulation of $\widetilde{\Delta}$. Taking its mirror, we see that the combination

[15] To be more precise, the formulation of F-theory suggests this resolution independence only for Calabi-Yau fourfolds where Z_s is given by a Weierstrass-model elliptic fibration over B_3, and $\hat{Z}$ is a crepant resolution of Z_s such that $\hat{Z} \longrightarrow B_3$ remains a flat fibration. Thus, the statement here is stretching the "suggestion" a bit too far by not demanding a flat elliptic fibration, and also restricting the range of validity by focusing on $\hat{Z}$ which are obtained as hypersurfaces of toric fivefolds. Thus, an attempt of formulating flux in F-theory using resolved models $\hat{Z}$ will still survive, even when the dimensions $h_V^{2,2}$, $h_H^{2,2}$ and $h_{RM}^{2,2}$ may turn out to depend on resolutions for some Calabi-Yau fourfolds Z_s which do not admit elliptic fibrations.

JHEP01(2015)047

of the first two terms,

$$[RM_a(\hat{Z}) + V_{\rm rm}^{\rm alg}(\hat{Z})],$$

also does not depend on the triangulation of $\widetilde{\Delta}$. This proves that $h_{RM}^{2,2}(\hat{Z})$ is independent of which (fine, regular, unimodular) triangulation is chosen.

In order to prove that $h_V^{2,2}(\hat{Z})$ is also independent of the triangulation of $\widetilde{\Delta}$, note that $V^{\rm alg}(\hat{Z})$ and $NV_1(\hat{Z}_m) + NV_3(\hat{Z}_m)$ are independent of triangulation; they depend only on numbers of lattice points, not on 1-simplices. This means that the combination $V_{\rm cor}^{\rm alg}(\hat{Z}) + V_{\rm rm}^{\rm alg}(\hat{Z})$ is also independent of triangulation, because $V_{\rm tor}^{\rm alg}(\hat{Z})$ is, and so is the combination $[V_{\rm cor}(\hat{Z}) + RM_a(\hat{Z})]$ because of the relation (3.79). From all above, we see that the combination

$$\left[V_{\rm cor}(\hat{Z}) + V_{\rm cor}^{\rm alg}(\hat{Z})\right],$$

the second group of terms in (3.74), is also independent of triangulation. Obviously the independence of $[H_{\rm cor}(\hat{Z}) + H_{\rm cor}^{\rm red}(\hat{Z})]$ also follows from mirror symmetry.

We have therefore seen that the six groups of terms in (3.74), (3.93), (3.94) are separately independent of the choice of triangulations of $\widetilde{\Delta}$ and Δ in a toric-*hypersurface* realization of a smooth $\hat{Z}$ and singular Z_s. This statement is almost the same as the similar statement in section 2, although the argument in section 2 is about arbitrary crepant resolutions $\hat{Z}$ of Z_s, i.e. $\hat{Z}$ does not have to be a toric hypersurface. When a Calabi-Yau fourfold hypersurface $\hat{Z}$ of a toric fivefold is also realized as a complete intersection in an ambient space of higher dimensions, the separation between $[V_{\rm tor} + V_{\rm tor}^{\rm alg}]$ and $[V_{\rm cor} + V_{\rm cor}^{\rm alg}]$ may not remain the same, in general. One can also see that the argument for triangulation-independence given here exploits some combinatorics of toric data, (3.84), but still relies partially on mirror symmetry. This means that there must be some triangulation independent relations involving such numbers as $\ell_1^{*\bullet}(\Theta^{[3]})$, $\ell_1^*(\widetilde{\Theta}^{[1]})$ etc.

4 Examples

A couple of examples of toric-hypersurface Calabi-Yau fourfolds are presented in this section. We begin with the pair of sextic $(6) \subset \mathbb{P}^5$ and its mirror in section 4.1, where the geometry is so simple that we can compute everything by hand. It serves well for the purpose of digesting such notions as stratification and mixed Hodge structure. We will see how things work together nicely so that the long exact sequence (3.11) holds. For more complicated toric-hypersurface Calabi-Yau fourfolds, however, we need to use the computer packages `TOPCOM` [46] and `sage` [47] partially in the computation (see section 4.2). Examples in section 4.3 bring the formulae (3.74), (3.93), (3.94) and (3.72), (3.75), (3.78), (3.91) to life. We chose examples where various terms have non-zero contributions, so that we can test our geometric interpretation developed in the previous section. In section 4.4, we work on examples to be used in F-theory compactification for unified theories, and compute $h_V^{2,2}$, $h_H^{2,2}$ and $h_{RM}^{2,2}$. The results in this section are used as an input in section 6, along with additional results from appendices C and B, to study how the number of flux vacua depends on the number of generations $N_{\rm gen}$ or on the choice of the unification group of low-energy effective theories.

JHEP01(2015)047

4.1 The sextic and its mirror

As a first canonical example, let us discuss the sextic fourfold $\hat{Z}_6$, a degree-six hypersurface of $\mathbb{P}^5$, and its mirror manifold denoted by $\hat{Z}_{6,m}$. With this definition, it is easy to find (using index theorems and the Lefschetz hyperplane theorem) that the Hodge numbers of $\hat{Z}_6$ are

$$h^{p,q}(\hat{Z}_6) = \begin{array}{|ccccc|} \hline 1 & & & & 1 \\ & 426 & 0 & 1 & \\ & 0 & 1752 & 0 & \\ & 1 & 0 & 426 & \\ 1 & & & & 1 \\ \hline \end{array} \,. \tag{4.1}$$

In this presentation of the Hodge numbers, p starts from 0 and increases to the right, while q begins with 0 and increases upward. We will use the same presentation style in this article, when we write down the numbers $e_c^{p,q}$. For the sextic, $h^{1,1}(\hat{Z}_6) = 1$ is generated by $H|_{\hat{Z}_6}$, restriction of the hyperplane class of $\mathbb{P}^5$. The vertical component $H_V^{2,2}(\hat{Z})$ is generated by $H^2|_{\hat{Z}_6}$, and we expect $h_V^{2,2}(\hat{Z}) = 1$. Mirror symmetry also indicates that $h_H^{2,2}(\hat{Z}_{6,m}) = 1$. We compute $h_H^{2,2}(\hat{Z}_6) = h_V^{2,2}(\hat{Z}_{6,m})$ and $h_{RM}^{2,2}(\hat{Z}_6) = h_{RM}^{2,2}(\hat{Z}_{6,m})$ in section 4.1.3. Sections 4.1.1 and 4.1.2 are only meant to be warming up exercise for readers unfamiliar with such notions as mixed Hodge structure or toric stratification.

As a toric variety, $\mathbb{P}^5$ can be described by a fan over the faces of a polytope $\tilde{P}_6$, whose six vertices in $\mathbb{Z}^{\oplus 5}$ are given by

$$\begin{pmatrix} -1 & 0 & 0 & 0 & 0 & 1 \\ -1 & 0 & 0 & 0 & 1 & 0 \\ -1 & 0 & 0 & 1 & 0 & 0 \\ -1 & 0 & 1 & 0 & 0 & 0 \\ -1 & 1 & 0 & 0 & 0 & 0 \end{pmatrix} . \tag{4.2}$$

The dual polytope P_6 has six vertices in $\mathbb{Z}^{\oplus 5}$:

$$\begin{pmatrix} -1 & -1 & -1 & -1 & -1 & 5 \\ -1 & -1 & -1 & -1 & 5 & -1 \\ -1 & -1 & -1 & 5 & -1 & -1 \\ -1 & -1 & 5 & -1 & -1 & -1 \\ -1 & 5 & -1 & -1 & -1 & -1 \end{pmatrix} , \tag{4.3}$$

and one quickly recognizes that the fan Σ over the faces of P_6 gives rise to an orbifold of $\mathbb{P}^5$.

4.1.1 Geometry of the sextic: mixed Hodge structure of its subvarieties

The sextic $\hat{Z}_6$ has six toric divisors $\hat{Y}_i$, $i = 1, \cdots, 6$, corresponding to the six vertices of $\tilde{P}_6$. These toric divisors $\hat{Y}_i$ are all $(6) \subset \mathbb{P}^4$. Similarly, $\hat{Y}_i \cap \hat{Y}_j$ are surfaces $(6) \subset \mathbb{P}^3$, while $\hat{Y}_i \cap \hat{Y}_j \cap \hat{Y}_k$ are curves $(6) \subset \mathbb{P}^2$ and $\hat{Y}_i \cap \hat{Y}_j \cap \hat{Y}_k \cap \hat{Y}_l$ are six points in $\mathbb{P}^1$. These

JHEP01(2015)047

facts can be read out from the fact that the k-dimensional faces $\Theta^{[k]}$ of the polytope P_6 are k-dimensional pyramids of height-6 (7 points in one edge),[16] which are regarded as the complete linear system of the divisor $6H$ of $\mathbb{P}^k$. Exploiting e.g. index theorems in combination with the Picard-Lefschetz hyperplane theorem one easily finds that

$$h^{p,q}(\hat{Y}_i) = \begin{vmatrix} 5 & & & 1 \\ & 255 & 1 & \\ & 1 & 255 & \\ 1 & & & 5 \end{vmatrix} \qquad h^{p,q}(\hat{Y}_i \cap \hat{Y}_j) = \begin{vmatrix} 10 & & 1 \\ & 86 & \\ 1 & & 10 \end{vmatrix}$$

$$h^{p,q}(\hat{Y}_i \cap \hat{Y}_j \cap \hat{Y}_k) = \begin{vmatrix} 10 & 1 \\ 1 & 10 \end{vmatrix} \qquad h^{p,q}(\hat{Y}_i \cap \hat{Y}_j \cap \hat{Y}_k \cap \hat{Y}_l) = \begin{vmatrix} 6 \end{vmatrix} . \tag{4.4}$$

We begin with the direct computation of $H^k(Y)$ using the explicit results (4.4) and the Mayer-Vietoris spectral sequence, where $Y = \cup_i \hat{Y}_i$ is the complement of the primary stratum Z_{P_6} in $\hat{Z}_6$. The compact support cohomology groups of Z_{P_6}, on the other hand, are obtained by following the algorithm of [38] (which we have reviewed partially in the previous section). Those computations allow us to see that the long exact sequence (3.11) nicely reproduces the Hodge diamond (4.1); see (4.12).

It is important in the sum rule (3.28), (3.31) and the algorithm of [38] that they can be applied to polytopes that do not necessarily correspond to the complete linear system defining a family of Calabi-Yau hypersurfaces; the sum rule (3.31) has been used in (3.52), (3.53), for example. Thus, we will compute $e_c^{p,q}(Z_{\Theta^{[k]}})$ from the Hodge diamonds of the subvarieties (4.4), and confirm that the sum rule (3.28), (3.31) is indeed satisfied at the end of this section.

The cohomology group of the compact (but singular) geometry $Y = \cup_i \hat{Y}_i$ is computed by the Mayer-Vietoris spectral sequence. At the stage of $d_1^{pq} : E_1^{p,q} \longrightarrow E_1^{p+1,q}$, we have

$6 \times (1)$ 0			
$6 \times (0,1,0)$ $6 \times (5,255,255,5)$	$\longrightarrow$ $15 \times (1)$ $\longrightarrow$ 0		
$6 \times (0,1,0)$ 0	$\longrightarrow$ $15 \times (10,86,10)$ $\longrightarrow$ 0	$\longrightarrow$ $20 \times (1)$ $\longrightarrow$ $20 \times (10,10)$	
$6 \times (1)$	$\longrightarrow$ $15 \times (1)$	$\longrightarrow$ $20 \times (1)$	$\longrightarrow$ $15 \times (6)$

, (4.5)

where $\dim(E_1^{p,q})$ is shown in the $(p+1)$-th column from the left and the $(q+1)$-th row from the bottom, in a form maintaining the information of the Hodge filtration. To proceed to the stage $E_2^{p,q}$ in the spectral sequence calculation, we need to know the morphisms

[16] A k-dimensional pyramid of height-h is (anything lattice-isomorphic to) the minimal k-dimensional simplex in a lattice $\mathbb{Z}^{\oplus k}$ enlarged by a positive integer h. The number of lattice points on such a pyramid is $N_{k,h} := [(h+1)(h+2)\cdots(h+k)]/k!$, while the number of interior points is given by $N_{k,h-k-1}$.

JHEP01(2015)047

$d_1^{pq} : E_1^{p,q} \longrightarrow E_1^{p+1,q}$. In the case of the sextic, the morphism $d_1 : E_1^{0,q} \longrightarrow E_1^{1,q}$ has a 5-dimensional image for $q = 0, 2, 4$, while $d_1 : E_1^{1,q} \longrightarrow E_1^{2,q}$ has a 10-dimensional image for $q = 0, 2$. The morphism $d_1 : E_1^{2,0} \longrightarrow E_1^{3,0}$ has a 10-dimensional image. Combining all of the above, we have that

$$\dim(E_2^{p,q}) = \begin{array}{|c|c|c|c|} \hline (6) & & & \\ \hline (0,1,0) & (10) & & \\ (30,1530,1530,30) & & & \\ \hline (0,1,0) & (150,1275,150) & (10) & \\ & & (200,200) & \\ \hline (1) & (0) & (0) & (80) \\ \hline \end{array} . \tag{4.6}$$

We conclude from this that

$$h^{3,3}[H^6(Y)] = 6, \quad h^{2,2}[H^5(Y)] = 10, \quad h^{0,0}[H^0(Y)] = 1, \quad h^{1,1}[H^2(Y)] = 1, \tag{4.7}$$

and all other Hodge-Deligne numbers of the cohomology groups $H^k(Y)$ with $k = 0, 1, 2, 5, 6$ vanish. As for $H^k(Y)$ with $k = 3, 4$,

$$h^{p,q}[H^3(Y)] = \begin{vmatrix} 30 & & & \\ 150 & 1530 & & \\ 200 & 1275 & 1530 & \\ 80 & 200 & 150 & 30 \end{vmatrix} , \qquad h^{p,q}[H^4(Y)] = \begin{vmatrix} 0 & & \\ 0 & 1 & \\ 10 & 0 & 0 \end{vmatrix} . \tag{4.8}$$

Let us now move on to the computation the Hodge-Deligne numbers of the cohomology group of the top (primary) stratum $Z_6 = \hat{Z}_6 \setminus Y = Z_{P_6}$. They are determined by the algorithm of §5 in [38], which is precisely the one we adopted in section 3.5. We only need the values of the functions φ_i for the polytope P_6,

$$\varphi_1(P_6) = 1, \quad \varphi_2(P_6) = 456, \quad \varphi_3(P_6) = 3431, \quad \varphi_4(P_6) = 3431, \quad \varphi_5(P_6) = 456, \tag{4.9}$$

in order to use the algorithm.[17] It turns out that

$$h^{p,q}[H_c^4(Z_{P_6})] = \begin{vmatrix} 1 & & & & \\ 30 & 426 & & & \\ 150 & 1530 & 1751 & & \\ 200 & 1275 & 1530 & 426 & \\ 80 & 200 & 150 & 30 & 1 \end{vmatrix} . \tag{4.10}$$

[17] This task has already been carried out partially in section 3.5. $h^{2,1}$ of $H_c^4(Z_{P_6})$ is given by (3.60), while (3.61) determines $h^{2,2}$. The formulae (3.32), (3.58), (3.59) can be used to determine $h^{p,q}$'s of $H_c^4(Z_{P_6})$ with $p = 1, 2, 3, 4$, while $h^{3,1}$ is determined by (3.33), (3.4). The sum rule (3.28), (3.31) still has to be used along with (4.9), however, to determine two more Hodge-Deligne numbers $h^{1,1}$ and $h^{0,0}$ of $H_c^4(Z_{P_6})$.

JHEP01(2015)047

Using the Hodge-Deligne numbers of other cohomology groups $H_c^k(Z_{P_6})$ given in (3.12), we also see that

$$e_c^{p,q}(Z_{P_6}) = \begin{array}{|ccccc} 1 & & & & 1 \\ 30 & 426 & & -5 & \\ 150 & 1530 & 1761 & & \\ 200 & 1265 & 1530 & 426 & \\ 80 & 200 & 150 & 30 & 1 \end{array} . \tag{4.11}$$

With all the Hodge-Deligne numbers of the cohomology groups $H_c^k(Z_{P_6})$ and $H^k(Y)$ determined, we are now ready to see that the long exact sequence (3.11) reproduces the Hodge diamond of the sextic (4.1):

$$\begin{array}{ccccccccc} [H_c^4(Z_{P_6})] & \to & [H^4(\hat{Z})] & \to & [H^4(Y)] & \to & [H_c^5(Z_{P_6})] & \to & [H^5(\hat{Z})] \\ h^{2,2}=1751 & \to & h^{2,2}=1752 & \to & h^{2,2}=1 & \to & 0 & & \\ h^{3,1}=426 & \to & h^{3,1}=426 & \to & h^{3,1}=0 & & & & \\ h^{4,0}=1 & \to & h^{4,0}=1 & \to & h^{4,0}=0 & & & & \\ & & 0 & \to & h^{1,1}=10 & \to & h^{1,1}=10 & \to & 0 \end{array} ; \tag{4.12}$$

$h^{p,q}[H_c^4(Z_{P_6})]$ for (p,q) with $p+q<4$ are irrelevant here, because $h^{p,q}[H^3(Y)] = h^{p,q}[H_c^4(Z_{P_6})]$ for $p+q<4$, as one can see from (4.8) and (4.10).

The study above used the Mayer-Vietoris spectral sequence and the Hodge numbers of subvarieties (4.4) to determine the Hodge-Deligne numbers of $H^k(Y)$. This is doable by hand only for such a simple geometry as the sextic, however. The Hodge-Deligne numbers of $H^k(Y)$ in more complicated geometries are dealt with much more systematically under the approach using the toric stratification (3.1) and the algorithm and sum rule of [38]. We therefore confirm from here, toward the end of this section, that the sum rule (3.28) is satisfied indeed by $e_c^{p,q}(Z_{\Theta^{[k]}})$'s of various faces $\Theta^{[k]}$ of the polytope P_6.

The polytope P_6 has six vertices $\Theta^{[0]}$ in (4.3), $\binom{6}{2}=15$ faces $\Theta^{[1]}$ of dimension-1, $\binom{6}{3}=20$ faces $\Theta^{[2]}$ of dimension-2, $\binom{6}{4}=15$ faces $\Theta^{[3]}$ of dimension-3, and $\binom{6}{5}=6$ facets $\Theta^{[4]}$. All the faces of a given dimension k are lattice-isomorphic, thanks to the high symmetry of the sextic-mirror-sextic. Each one of the k-dimensional faces has $\binom{k+1}{1}$ facets $\Theta^{[k-1]}$ of dimension-$(k-1)$, $\binom{k+1}{2}$ faces $\Theta^{[k-2]}$ of dimension-$(k-2)$, etc., all the way to $\binom{k+1}{k}=(k+1)$ faces $\Theta^{[0]}$, i.e., vertices.

Let us begin with the face $\Theta^{[1]}$. The hypersurface $Z_{\Theta^{[1]}} \subset \mathbb{T}^1$ consists of six points, just like in the last entry of (4.4). This means that $e_c^{0,0}(Z_{\Theta^{[1]}})=6$, and $\bar{e}_c^{0,0}(Z_{\Theta^{[1]}})=5$. Because $\Theta^{[1]}$ is a 1-dimensional pyramid of height 6, $\ell^*(\Theta^{[1]})=N_{1,6-2}=5$ (see footnote 16), the sum rule (3.31) — which states that $\bar{e}_c^{0,0}(Z_{\Theta^{[1]}})=\varphi_1(\Theta^{[1]})=\ell^*(\Theta^{[1]})=5$ in this case — is satisfied indeed.

The next step is to verify the sum rule for $Z_{\Theta^{[2]}}$. It is a degree-6 curve of $\mathbb{P}^2=\mathbb{P}^2_{\Theta^{[2]}}$ (i.e., $g=10$ curve, $\hat{Y}_i\cap\hat{Y}_j\cap\hat{Y}_k$ in (4.4)), with 3 set of six points (i.e., $Z_{\Theta^{[1]}}$) removed. Using

JHEP01(2015)047

the additivity of $e_c^{p,q}$'s, we find that

$$e_c^{p,q}(Z_{\Theta^{[2]}}) = \begin{vmatrix} -10 & 1 \\ 1 & -10 \end{vmatrix} - 3 \begin{vmatrix} 6 \end{vmatrix} = \begin{vmatrix} -10 & 1 \\ -17 & -10 \end{vmatrix}, \qquad \bar{e}_c^{p,q}(Z_{\Theta^{[2]}}) = \begin{vmatrix} -10 \\ -15 & -10 \end{vmatrix}. \tag{4.13}$$

The sum $\sum_q \bar{e}_c^{p,q}$ is indeed equal to $-\varphi_{2-p}(\Theta^{[2]})$ given by $\varphi_1(\Theta^{[2]}) = \ell^*(\Theta^{[2]}) = N_{2,6-3} = 10$ and $\varphi_2(\Theta^{[2]}) = \ell^*(2\Theta^{[2]}) - 3\ell^*(\Theta^{[2]}) = N_{2,12-3} - 3 \cdot N_{2,6-3} = 25$.

A similar computation for $\Theta^{[3]}$ and $\Theta^{[4]}$ proceeds as follows:

$$e_c^{p,q}(Z_{\Theta^{[3]}}) = \begin{vmatrix} 10 & & 1 \\ & 86 & \\ 1 & & 10 \end{vmatrix} - 4 \begin{vmatrix} -10 & 1 \\ -17 & -10 \end{vmatrix} - 6 \begin{vmatrix} 6 \end{vmatrix} = \begin{vmatrix} 10 & & 1 \\ 40 & 82 & \\ 33 & 40 & 10 \end{vmatrix}, \tag{4.14}$$

$$e_c^{p,q}(Z_{\Theta^{[4]}}) = \begin{vmatrix} -5 & & & 1 \\ & -255 & 1 & \\ & 1 & -255 & \\ 1 & & & -5 \end{vmatrix} - 5 \begin{vmatrix} 10 & & 1 \\ 40 & 82 & \\ 33 & 40 & 10 \end{vmatrix} - 10 \begin{vmatrix} -10 & 1 \\ -17 & -10 \end{vmatrix} - 10 \begin{vmatrix} 6 \end{vmatrix}. \tag{4.15}$$

We thus find that

$$\bar{e}_c^{p,q}(Z_{\Theta^{[3]}}) = \begin{vmatrix} 10 & & \\ 40 & 85 & \\ 30 & 40 & 10 \end{vmatrix}, \qquad \bar{e}_c^{p,q}(Z_{\Theta^{[4]}}) = - \begin{vmatrix} 5 & & & \\ 50 & 255 & & \\ 100 & 425 & 255 & \\ 50 & 100 & 50 & 5 \end{vmatrix}, \tag{4.16}$$

which are consistent with the sum rule on $\sum_q \bar{e}_c^{p,q}(\Theta^{[k]})$ using the value of $\varphi_{k-p}(\Theta^{[k]})$ given by

$$\varphi_1(\Theta^{[3]}) = 10, \qquad \varphi_2(\Theta^{[3]}) = 125, \qquad \varphi_3(\Theta^{[3]}) = 80, \tag{4.17}$$

$$\varphi_1(\Theta^{[4]}) = 5, \qquad \varphi_2(\Theta^{[4]}) = 305, \qquad \varphi_3(\Theta^{[4]}) = 780, \qquad \varphi_4(\Theta^{[4]}) = 205. \tag{4.18}$$

As a final consistency check, one can compute $e_c^{p,q}(Y)$ by using the additivity of $e_c^{p,q}$ and the stratification of Y into non-compact and smooth subsets:

$$\begin{aligned} e_c^{p,q}(Y) &= \binom{6}{2} e_c^{p,q}(Z_{\Theta^{[1]}}) + \binom{6}{3} e_c^{p,q}(Z_{\Theta^{[2]}}) + \binom{6}{4} e_c^{p,q}(Z_{\Theta^{[3]}}) + \binom{6}{5} e_c^{p,q}(Z_{\Theta^{[4]}}) \\ &= \begin{vmatrix} -30 & & & 6 \\ -150 & -1530 & -9 & \\ -200 & -1264 & -1530 & \\ -79 & -200 & -150 & -30 \end{vmatrix}. \end{aligned} \tag{4.19}$$

One can see that this result is consistent with $e_c^{p,q}(Y)$ given directly from the Hodge-Deligne numbers of $H^k(Y)$ in (4.7), (4.8). Also, $e_c^{p,q}(Z_{P_6}) + e_c^{p,q}(Y)$ reproduces the Hodge diamond (4.1), as it should be.

JHEP01(2015)047

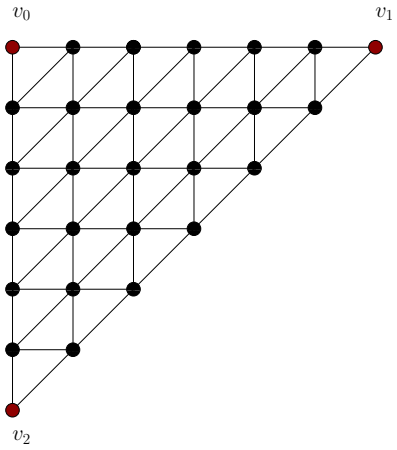

Figure 6. A 2-dimensional face of P_6, $\Theta^{[2]}$. We have shown vertices, integral points, and a simple triangulation.

4.1.2 Geometry of the mirror-sextic: toric stratification

Let us now use the mirror-to-sextic $\hat{Z}_{6,m}$ fourfold to have a close look at the stratification associated with the toric divisors $\left\{\hat{Y}_i\right\}$. The stratification of $\hat{Z}_6$ was very simple — $Z_6 + \binom{6}{1} Z_{\Theta^{[4]}} + \binom{6}{2} Z_{\Theta^{[3]}} + \cdots + \binom{6}{4} Z_{\Theta^{[1]}}$ — because all the faces $\widetilde{\Theta}^{[k]}$ of the polytope $\tilde{P}_6$ are lattice-isomorphic to the minimal simplex of k-dimension, so that any one of $E_{\widetilde{\Theta}^{[k]}}$'s consists of a single point. The faces $\Theta^{[k]}$ $(k < n = 5)$ of the polytope P_6 are not, however.

To the primary stratum of $\hat{Z}_{6,m}$, $\binom{6}{1} \times Z_{\widetilde{\Theta}^{[4]}}$ is added first. Each one of the $Z_{\widetilde{\Theta}^{[4]}}$'s is a $\mathbb{P}^3$ with five hyperplanes removed.

Coming next are the strata $\binom{6}{2} \times E_{\Theta^{[1]}} \times Z_{\widetilde{\Theta}^{[3]}}$. The geometry of $Z_{\Theta^{[3]}}$ is a $\mathbb{P}^2$ with four hyperplanes removed, while $E_{\Theta^{[1]}}$ is the exceptional locus of an A_4 singularity resolution. This exceptional locus $E_{\Theta^{[1]}}$ has a stratification that consists of five $\mathbb{T}^1$'s and six points, because $\ell^*(\Theta^{[1]}) = 5$ and $\ell_1^*(\Theta^{[1]}) = 6$.

Similarly, there are strata $\binom{6}{3} \times E_{\Theta^{[2]}} \times Z_{\widetilde{\Theta}^{[2]}}$. Each one of $Z_{\widetilde{\Theta}^{[2]}}$ is $\mathbb{P}^1$ with three points removed, while $E_{\Theta^{[2]}}$ has a stratification comprised of ten $\mathbb{T}^2$'s, $3 \times 15 = 45$ $\mathbb{T}^1$'s and thirty-six points. If a polytope $\Theta^{[2]}$ is given the triangulation shown in figure 6, then $E_{\Theta^{[2]}}$ contains ten compact complex surfaces isomorphic to dP_3.

The only remaining strata are $\binom{6}{4} \times Z_{\widetilde{\Theta}^{[1]}} \times E_{\Theta^{[3]}}$; each $Z_{\widetilde{\Theta}^{[1]}}$ consists of a single point. It is not too difficult to find a unimodular fine triangulation of $\Theta^{[3]}$ by hand. For this triangulation, it turns out that $\ell_1^*(\Theta^{[3]}) = 155$. This number satisfies $\ell^*(2\Theta^{[3]}) - \ell^*(\Theta^{[3]}) = N_{3,8} - N_{3,2} = 155 = \ell_1^*(\Theta^{[3]})$, a special case of (3.84). Because of this relation, $\ell_1^*(\Theta^{[3]})$ does not depend on the triangulation we choose.

For the mirror sectic, we can also compute the numbers $e_c^{p,q}$'s for $E_{\Theta^{[k]}}$ and $Z_{\widetilde{\Theta}^{[4-k]}}$ as well the primary stratum, and we can then use their multiplicativity and additivity to compute $e^{p,q}(Y)$, just as we did for the case of the sextic. All these details, however, are not recorded here.

JHEP01(2015)047

4.1.3 Evaluation of $h_V^{2,2}$, $h_H^{2,2}$ and $h_{RM}^{2,2}$

Let us now evaluate the dimension of the vertical, horizontal and the remaining components in $H^{2,2}$ given by (3.74), (3.93), (3.94), respectively; we do this both for the sextic $\hat{Z}_6$ and its mirror $\hat{Z}_{6,m}$.

Let us begin with the vertical component $H_V^{2,2}$ of the sextic $\hat{Z}_6$. Because all the faces of the polytope $\widetilde{P}_6$ do not have an interior point (except $\widetilde{P}_6$ itself), both $V_{\rm cor}(\hat{Z}_6)$ and $V^{\rm alg}(\hat{Z}_6)$ vanish. Therefore the vertical component comes purely from intersections of toric divisors,

$$h_V^{2,2}(\hat{Z}_6) = V_{\rm tor}(\hat{Z}_6) = \binom{6}{2} + 10 - 4\cdot 6 = 1\,, \tag{4.20}$$

where we have used (3.75). The vertical component $H_V^{2,2}(\hat{Z})$ is generated by $H^2|_{\hat{Z}_6}$, as we discussed already at the beginning of this section.

The same formula (3.74) can be used also to determine the dimension of the vertical (2,2)-forms on the mirror fourfold $\hat{Z}_{6,m}$, $h_V^{2,2}(\hat{Z}_{6,m})$. We first note that $V_{\rm cor}(\hat{Z}_{6,m})$ and $V^{\rm alg}(\hat{Z}_{6,m})$ vanish, as there are no interior points in $\widetilde{\Theta}^{[1]}$, $\widetilde{\Theta}^{[2]}$ and $2\widetilde{\Theta}^{[2]}$. In order to evaluate $V_{\rm tor}(\hat{Z}_{6,m})$, we need to count the number of 1-simplices in the polytope P_6. We find that

$$\ell_1((P_6)_{\le 3}) = \binom{6}{4}\cdot \ell_1(\Theta^{[3]}) + \binom{6}{3}\cdot \ell_1^*(\Theta^{[2]}) + \binom{6}{2}\cdot \ell_1(\Theta^{[1]}) = 3315, \tag{4.21}$$

using the 1-simplex counting presented in section 4.1.2. To determine the dimensions subtracted due to the toric rational equivalence, the second and third line of $V_{\rm tor}(\hat{Z}_{6,m})$, we also need $\sum_{\Theta^{[4]}\le P_6}\ell^*(\Theta^{[4]}) = \binom{6}{5}\cdot N_{4,1} = 30$ and $\sum_{\Theta^{[3]}\le P_6}\ell^*(\Theta^{[3]}) = \binom{6}{4}\cdot N_{3,2} = 150$. Hence

$$h_V^{2,2}(\hat{Z}_{6,m}) = V_{\rm tor}(\hat{Z}_{6,m}) = 3315 + 10 - 4(462 - 30 - 150 - 1) - 3\cdot 150 = 1751. \tag{4.22}$$

This result already indicates that $h_V^{2,2}(\hat{Z}_{6,m}) = 1751$ and $h_H^{2,2}(\hat{Z}_{6,m}) = h_V^{2,2}(\hat{Z}_6) = 1$ add up to yield all of $h^{2,2}(\hat{Z}_{6,m}) = 1752$. Thus, the remaining component should be absent in $\hat{Z}_{6,m}$ as well as in $\hat{Z}_6$. It is not difficult to see this directly. First, $RM_a(\hat{Z}_6) = RM_a^m(\hat{Z}_{6,m})$ vanishes because all the faces $\widetilde{\Theta}^{[3]}$ of $\widetilde{P}_6$ are minimal three-dimensional simplices and no 1-simplices are introduced upon triangulation; $\ell_1^{*\bullet}(\widetilde{\Theta}^{[3]}) = 0$. Secondly, $RM_a^m(\hat{Z}_6) = RM_a(\hat{Z}_{6,m})$ also vanishes because all of the one-dimensional faces $\widetilde{\Theta}^{[1]}$ of $\widetilde{P}_6$ do not have an interior point.

Similarly, one can evaluate the dimension of the horizontal component $h_H^{2,2}(\hat{Z}_6)$ and $h_H^{2,2}(\hat{Z}_{6,m})$ directly from the formulae in the previous section, although we already know their results. As in the discussion for the vertical component above, one can see that both $H^{\rm red}$ and $H_{\rm cor}$ vanish for both $\hat{Z}_6$ and $\hat{Z}_{6,m}$. Thus, the horizontal component only comes from the monomial deformation $H_{\rm mon}$; the results are

$$h_H^{2,2}(\hat{Z}_6) = H_{\rm mon}(\hat{Z}_6) = 3431 - 6\cdot 305 + 15\cdot 10 = 1751\,, \tag{4.23}$$

and

$$h_H^{2,2}(\hat{Z}_{6,m}) = H_{\rm mon}(\hat{Z}_6) = 1 - 0 + 0 = 1 \tag{4.24}$$

by using $\varphi_3(\widetilde{P}_6) = 1$.

JHEP01(2015)047

4.2 Computations in practice

For practical applications to fourfolds more complicated than the sextic, we clearly do not want to evaluate (3.74), (3.93), (3.94) by hand. What is even worse, it is a non-trivial task to find an appropriate triangulation of $\widetilde{\Delta}$. Certainly the value of $h_V^{2,2}$, $h_H^{2,2}$ and $h_{RM}^{2,2}$ do not depend on the choice of triangulation, as we have seen at the end of section 3.6, but at least we have to make sure that there is at least one triangulation that is fine, regular and unimodular (see section 3.1.1), or otherwise the formulae in the previous section cannot be applied.

In this section we hence explain how to evaluate (3.74), (3.93), (3.94) in practice using existing computer software. The computation of Hodge numbers is most efficiently carried out using the package PALP [48] (described in some more detail in [49]). In the present context, PALP is also useful to construct a reflexive polytope from a combined weight system.

In order to obtain triangulation we use the package `TOPCOM` [46]. It is able to perform fine regular triangulations, which are, however, not necessarily star. Furthermore, as we have explained in section 3.1.1, a fine triangulation does not always give rise to a smooth Calabi-Yau hypersurface, let alone a smooth ambient space.

Even though a fine star triangulation is naturally related to a maximally subdivided fan, we may also use a fine regular triangulation of $\widetilde{\Delta}$ which is not star for practical purposes. Let us hence assume we have found a regular, fine (non-star) triangulation of $\widetilde{\Delta}$. This clearly gives rise to triangulations of all faces of $\widetilde{\Delta}$ which are mutually consistent, i.e. the triangulations of any two neighbouring faces induce the same triangulation on their intersection. We may then construct a fan Σ' (or, if we like a star triangulation) over all simplices on $\partial\widetilde{\Delta}$ obtained this way. As discussed e.g. in [19] (see also [50]), regularity of the original triangulation implies existence of a strongly convex support function on the simplices on $\partial\widetilde{\Delta}$, which in turn can be lifted to a strongly convex support function on the cones of Σ'.

We hence feed the configuration of integral points on $\partial\widetilde{\Delta}$ into `TOPCOM` to generate a fine regular triangulation, given in terms of five-simplices. As explained above, this can be cast into the data of a fan Σ', or, equivalently, a star triangulation. Such manipulations can be conveniently carried out using the computer algebra system `sage` [47]. In particular, `sage` already contains many routines to construct and analyse lattice polytopes.

Having obtained a regular star triangulation, we only need to check unimodularity. Again, this can be easily done by checking that the lattice volumes of all five-dimensional cones are unity.

With a smooth ambient space at hand, we are ready to evaluate the formulae (3.74), (3.93), (3.94). This can again efficiently be done using `sage`. The computation of the whole procedure outlined above (without any optimization) can be done in a few hours (for polytopes $\widetilde{\Delta}$ with $\mathcal{O}(100)$ points such as the mirror sextic) to a few days (for polytopes with several 1000 points such as the mirrors of the cases discussed in section 4.4) using an off-the-shelf PC at the time of writing.

Note that a straightforward evaluation of eqs. (3.74), (3.93), (3.94) requires a triangulation of both $\widetilde{\Delta}$ and Δ, even though we expect the final result to be independent of any triangulation.

JHEP01(2015)047

4.3 Correction terms at work

The sextic and its mirror are clearly very degenerate examples for the evaluation of (3.74), (3.93), (3.94), as the polytope $\widetilde{P}_6$ for $\mathbb{P}^5$ does not have any interior points of any of its faces and furthermore does not require triangulation. In this section 4.3, we present some examples for which various correction terms in (3.74), (3.93), (3.94) give a non-zero contribution.

Our first example is given by the following pair of reflexive polytopes

$$\widetilde{P}_B = \begin{pmatrix} -2 & -2 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 2 & 2 \\ -2 & 0 & -2 & -2 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 2 & 2 & 0 & 2 \\ 0 & 0 & -2 & 0 & -2 & -2 & 0 & 0 & 0 & 0 & 2 & 2 & 0 & 2 & 0 & 0 \\ 0 & 0 & 0 & 0 & -2 & 0 & -2 & 0 & 0 & 2 & 0 & 2 & 0 & 0 & 0 & 0 \\ 1 & 1 & 1 & 1 & 1 & 1 & 1 & -1 & 1 & -1 & -1 & -1 & -1 & -1 & -1 & -1 \end{pmatrix}, \tag{4.25}$$

and

$$P_B = \begin{pmatrix} -1 & -1 & -1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 \\ 0 & 0 & 0 & -1 & -1 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 0 & 0 & 0 \\ -1 & 0 & 0 & 0 & 0 & -1 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 1 \\ 0 & -1 & 0 & -1 & 0 & 0 & -1 & 0 & 0 & 1 & 0 & 0 & 1 & 0 & 1 & 0 \\ -1 & -1 & -1 & -1 & -1 & -1 & -1 & -1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \end{pmatrix}. \tag{4.26}$$

As before, we have simply given the polytopes in terms of a matrix containing their vertices. We have confirmed, however, that there is a fine unimodular regular triangulation for both of the polytopes $\widetilde{P}_B$ and P_B, following the procedure described in section 4.2. The Calabi-Yau fourfold $\hat{Z}_B \subset \mathbb{P}^5_{\Sigma'_B}$ has the Hodge numbers

$$h^{p,q}(\hat{Z}_B) = \begin{vmatrix} 1 & & & & 1 \\ & 11 & 0 & 97 & \\ & 0 & 476 & 0 & \\ & 97 & 0 & 11 & \\ 1 & & & & 1 \end{vmatrix}. \tag{4.27}$$

The Hodge diamond of the mirror $\hat{Z}_{B,m} \subset \mathbb{P}^5_{\widetilde{\Sigma}'_B}$ is the left-right (or top-bottom) flip of the Hodge diamond above.

Evaluation of (3.74), (3.93), (3.94) gives that $h^{2,2}(\hat{Z}_B) = h^{2,2}(\hat{Z}_{B,m})$ should be decomposed as $h^{2,2}_V(\hat{Z}_B) = 440$, $h^{2,2}_H(\hat{Z}_B) = 32$ and $h^{2,2}_{RM}(\hat{Z}_B) = 4$. In particular

	$V_{\rm tor} + V^{\rm alg}_{\rm tor}$	$V_{\rm cor} + V^{\rm alg}_{\rm cor}$	$RM_a + V^{\rm alg}_{\rm rm}$	$RM^m_a + H^{\rm red}_{\rm rm}$	$H_{\rm cor} + H^{\rm re}_{\rm cor}$	$H_{\rm mon} + H^{\rm red}_{\rm mon}$
$\hat{Z}_B$	$442 - 2$	$0 - 0$	$0 - 0$	$4 - 0$	$0 - 0$	$32 - 0$
$\hat{Z}_{B,m}$	$32 - 0$	$0 - 0$	$4 - 0$	$0 - 0$	$0 - 0$	$442 - 2$

. (4.28)

JHEP01(2015)047

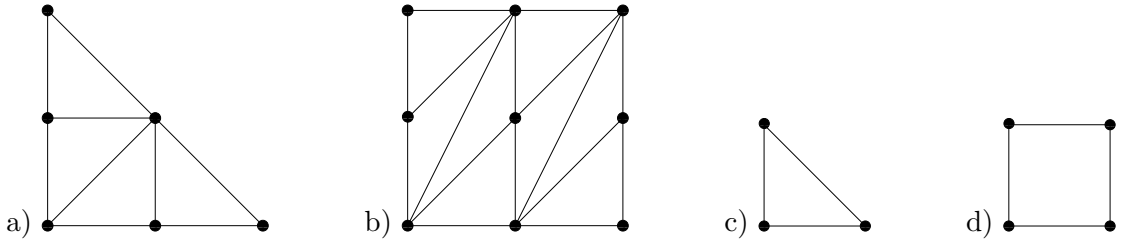

Figure 7. The two isomorphism classes of 2-dimensional faces of the polytope $\widetilde{P}_B$, $\widetilde{\Theta}^{[2]}_T$ and $\widetilde{\Theta}^{[2]}_S$ are shown in (a) and (b), whereas those of the polytope P_B, $\Theta^{[2]}_t$ and $\Theta^{[2]}_s$ are in (c) and (d), respectively. A specific fine unimodular triangulation of those faces is also shown in (a) and (b).

As can already be seen from the lists of vertices above, we find $\ell^*(\widetilde{\Theta}^{[1]}) = 1$ for all 1-dimensional faces of $\widetilde{P}_B$ and $\ell^*(\Theta^{[1]}) = 0$ for all 1-dimensional faces of P_B. This already explains why $[V_{\rm cor}(\hat{Z}_B) + RM_a(\hat{Z}_B)] = 0$, $[NV_1(\hat{Z}_{B,m}) + NV_3(\hat{Z}_{B,m})] = 0$. Furthermore, none of the 2-dimensional faces of P_B has any interior points (there are 80 triangles $\Theta^{[2]}_t$ and 18 squares $\Theta^{[2]}_s$ with 3, resp. 4 integral points; see figure 7 (c,d)), so that also $V^{\rm alg}(\hat{Z}_{B,m}) = 0$, $H^{\rm red}(\hat{Z}_B) = 0$ and $NV_3(\hat{Z}_B) = 0$ follows.

The correction term $V^{\rm alg}(\hat{Z}_B) = -2$ is understood as follows. There are 98 dual pairs of faces $(\widetilde{\Theta}^{[2]}, \Theta^{[2]})$ in the pair of polytopes $(\widetilde{P}_B, P_B)$; among them, 64 are of the type $(\widetilde{\Theta}^{[2]}_T, \Theta^{[2]}_t)$, 16 are of the type $(\widetilde{\Theta}^{[2]}_T, \Theta^{[2]}_s)$, 16 are of the type $(\widetilde{\Theta}^{[2]}_S, \Theta^{[2]}_t)$ and 2 are of the type $(\widetilde{\Theta}^{[2]}_S, \Theta^{[2]}_s)$, modulo lattice-isomorphism; see figure 7 (a–d) for the notation of $\widetilde{\Theta}^{[2]}_{T,S}$ and $\Theta^{[2]}_{t,s}$. The correction term $V^{\rm alg}(\hat{Z}_B) = -2$ originates from the 2 dual pairs $(\widetilde{\Theta}^{[2]}_S, \Theta^{[2]}_s)$. There is a divisor $\hat{Y}_i$ of $\hat{Z}_B$ for each pair, which is regarded as a surface fibration over a curve $\Sigma_{\Theta^{[2]}_s}$. The generic fibre is a surface, which is $\mathbb{P}^1 \times \mathbb{P}^1 \subset E_{\widetilde{\Theta}^{[2]}_S}$ in the case the triangulation of $\widetilde{\Theta}^{[2]}_S$ is the one in figure 7 (b). The base $\Sigma_{\Theta^{[2]}_s}$ is a curve of genus $g = \ell^*(\Theta^{[2]}_s) = 0$, because $\Theta^{[2]}_s$ corresponds to the complete linear system of $H_1 + H_2$ of $\mathbb{P}^1 \times \mathbb{P}^1$. he fibre may degenerate at $k_{\Theta^{[2]}_s} = 4$ points $\Sigma_{\Theta^{[2]}_s} \setminus Z_{\Theta^{[2]}_s}$. A naive toric calculation counts the fibre class $k_{\Theta^{[2]}_s} - 2$ times, and the correction term $\Delta V^{\rm alg}(\hat{Z}_B) = \bar{e}^{0,0}_c(\Theta^{[2]}_s) = -1$ removes the overcounting of the fibre class; $k_{\Theta^{[2]}_s} - 2 + \bar{e}^{0,0}_c = 1$ because of (3.69). Because all the four faces $\Theta^{[1]}$ of $\Theta^{[2]}_s$ do not have an interior point (see figure 7 (d)), this contributes to $V^{\rm alg}_{\rm tor}(\hat{Z}_B)$ and not to $V^{\rm alg}_{\rm cor+rm}$.

Although we do not have a particular geometric interpretation for the correction term $H^{\rm red}(\hat{Z}_{B,m})$, certainly the contribution $H^{\rm red}(\hat{Z}_{B,m}) = -2$ comes from the same two dual pairs of the faces isomorphic to $(\widetilde{\Theta}^{[2]}_S, \Theta^{[2]}_s)$.

The correction term $RM_a(\hat{Z}_{B,m}) = 4$ is understood as follows. The 64 dual pairs of faces $(\widetilde{\Theta}^{[1]}, \Theta^{[3]})$ are classified (modulo lattice isomorphisms) into four types. All the $\widetilde{\Theta}^{[1]}$'s are isomorphic, and $\Theta^{[3]}$'s have one of the four shapes, a tetrahedron, a pyramid with a rectangular base, a 3-dimensional prism, and a diamond, shown in figure 8. The correction term $RM_a(\hat{Z}_{B,m})$ comes from the pairs $(\widetilde{\Theta}^{[1]}, \Theta^{[3]}_{\rm dia})$. The one-simplex in $\Theta^{[3]}_{\rm dia}$ in figure 8 is surrounded by four triangles and four tetrahedra, realizing a geometry $\mathbb{T}^1 \times \mathbb{P}^1 \times \mathbb{P}^1$ in the toric ambient space $\mathbb{P}^5_{\widetilde{\Sigma}'_B} = \mathbb{P}^5_{\widetilde{P}_B}$ for $\hat{Z}_{B,m}$. The hypersurface equation selects $[1 + \ell^*(\widetilde{\Theta}^{[1]})] = \ell(\widetilde{\Theta}^{[1]}) - 1 = 2$ points out of $\mathbb{T}^1$. Thus, this one-simplex does not represent

JHEP01(2015)047

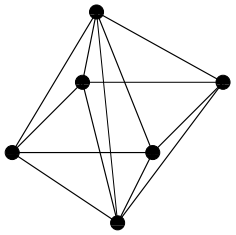

Figure 8. The 64 faces of 3-dimensions in P_B form four lattice-isomorphism classes. One of them looks like the one in this figure, and is denoted by $\Theta^{[3]}_{\text{dia}}$. Four out of 64 belong to this class. The face $\Theta^{[3]}_{\text{dia}}$ contains a single internal one-simplex (also shown in the figure) after triangulation. One example of such a face has $(-1, 0, -1, 0, -1)$, $(-1, 0, 0, -1, -1)$, $(-1, 0, 0, 0, -1)$, $(0, 0, 0, 0, 1)$, $(0, 0, 0, 1, 1)$, and $(0, 0, 1, 0, 1)$ as its vertices.

a single irreducible algebraic cycle, but consists of two irreducible ones, each of which is isomorphic to $\mathbb{P}^1 \times \mathbb{P}^1$. These two irreducible algebraic cycles combined are vertical and can be obtained as the intersection of divisors corresponding to the two boundary points of the 1-simplex in $\Theta^{[3]}_{\text{dia}} \leq P_B$. This piece is counted as part of $V_{\text{tor}}(\hat{Z}_{B,m})$. The other $\ell^*(\widetilde{\Theta}^{[1]}) = 1$ combination of the irreducible algebraic cycles, however, is not realized as a vertical cycle, and is counted as a part of $RM_a(\hat{Z}_{B,m})$. There are four such dual pairs of faces $(\widetilde{\Theta}^{[1]}, \Theta^{[3]}_{\text{dia}})$, and this is how $RM_a(\hat{Z}_{B,m}) = 4$ is obtained.

Finally, we obtain $RM^m_a(\hat{Z}_B) = 4$ in the following way. It comes from the same four dual pairs of type $(\widetilde{\Theta}^{[1]}, \Theta^{[3]}_{\text{dia}})$. As noted already, $\ell^*(\widetilde{\Theta}^{[1]}) = 1$ for all 1-dimensional faces of the polytope $\widetilde{P}_B$, and the 1-simplex in figure 8 contributes to $\ell^{*\bullet}_1(\Theta^{[3]}_{\text{dia}})$ *combinatorially*; each pair of dual faces $(\widetilde{\Theta}^{[1]}, \Theta^{[3]}_{\text{dia}})$ gives rise to a 1×1 contribution to $RM^m_a(\hat{Z}_B)$, and there are four such pairs. The *geometric* interpretation of this component, however, is not as directly related to the 1-simplex in $\Theta^{[3]}_{\text{dia}}$ as the interpretation of $RM_a(\hat{Z}_{B,m})$ is. Remember that $NV_3(\hat{Z}_B) = 0$, and note that $V_{\text{cor}}(\hat{Z}_{B,m}) = H_{\text{cor}}(\hat{Z}_B)$ vanishes in this example. The face $\Theta^{[3]}_{\text{dia}}$ does not have an interior point or 1-simplex ending on such an interior point. This means that $RM^m_a(\hat{Z}_B)$ originates purely from $NV_1(\hat{Z}_B)$ in this example. Let us now focus on one of the four pairs of $(\widetilde{\Theta}^{[1]}, \Theta^{[3]}_{\text{dia}})$, and let ν_i and $\hat{Y}_i$ be the interior point of $\widetilde{\Theta}^{[1]}$ and the corresponding divisor of $\hat{Z}_B$, respectively. This divisor $\hat{Y}_i$ contains a group of strata forming a $\mathbb{P}^1$ fibration over a surface $Z_{\Theta^{[3]}_{\text{dia}}}$. This surface has $\bar{e}^{1,1}_c(Z_{\Theta^{[3]}_{\text{dia}}}) = 1$, which is the origin of $RM^m_a(\hat{Z}_B) \neq 0$. The Hodge diamond of this divisor $\hat{Y}_i$ is reconstructed by collecting $e^{p,q}_c$ of all the relevant strata (see (3.27)), and we found that it is

$$h^{p,q}(\hat{Y}_i) = \begin{array}{|ccccc} & & & & 1 \\ & & & 11 & \\ & & 11 & & \\ & 1 & & & \\ \hline \end{array} \; ; \tag{4.29}$$

$h^{2,0}(\hat{Y}_i)$ vanishes because $\ell^*(\Theta^{[3]}_{\text{dia}}) = 0$. All of the components in $H^{1,1}_c(\hat{Y}_i)$ and $H^{2,2}_c(\hat{Y}_i)$ are therefore algebraic, but the exact sequence (3.65) shows that only a 10-dimensional subspace of the $h^{2,2}_c(\hat{Y}_i) = 11$-dimensional space of algebraic cycles is realized in the form

JHEP01(2015)047

of vertical cycles. The remaining $\bar{e}_c^{1,1} = 1$-dimensional contribution to $H_c^{2,2}(\hat{Y}_i)$ is regarded as part of the $RM_a^m(\hat{Z}_B)$ component, which is algebraic (and hence non-horizontal), but not vertical. In this example, we see that the $RM_a^m(\hat{Z}_B)$-component is also characterized by (3.95), not just the elements in $RM_a(\hat{Z})$ are.

In this example, the correction terms for $H^{1,1}(\hat{Z}_B)$ and $H^{1,1}(\hat{Z}_{B,m})$, i.e. the last term in (3.3), vanish and all divisor classes are generated by toric divisors for both fourfolds. This means we can easily compute the dimensions of $H_V^{2,2}(\hat{Z}_B)$ and $H_V^{2,2}(\hat{Z}_{B,m})$ by using the intersection ring of the ambient toric space restricted to $\hat{Z}_B$ and $\hat{Z}_{B,m}$. This computation reproduces the dimensions of the vertical components in (4.28), $h_V^{2,2}(\hat{Z}_B) = 440$ and $h_V^{2,2}(\hat{Z}_{B,m}) = 32$. Using mirror symmetry, we can then also recover the dimensions of the horizontal components. From $h^{2,2} = 476$ it follows again that the remaining component must be 4-dimensional.

A second example is defined by the dual pair of polyhedra

$$\widetilde{P}_S = \begin{pmatrix} -1 & 0 & 0 & 0 & 0 & 1 \\ -1 & 0 & 0 & 0 & 1 & 0 \\ -15 & -1 & 5 & 11 & 0 & 0 \\ -3 & 1 & 1 & 1 & 0 & 0 \\ -9 & -1 & 5 & 5 & 0 & 0 \end{pmatrix}, \; P_S = \begin{pmatrix} -1 & -1 & -1 & -1 & -1 & 5 \\ -1 & -1 & -1 & -1 & 5 & -1 \\ -1 & 0 & 0 & 1 & 0 & 0 \\ 0 & -1 & 4 & -1 & -1 & -1 \\ 2 & 0 & -1 & -1 & 0 & 0 \end{pmatrix}, \tag{4.30}$$

where we have displayed the vertices in the form of a matrix. It turns out that these two polyhedra are equivalent, so that they define the same Calabi-Yau fourfold, which is hence self-mirror. We have found fine regular and unimodular triangulations for both $\widetilde{P}_S$ and P_S, which are used for the computations below. The hodge numbers are

$$h^{p,q}(\hat{Z}_S) = \begin{array}{|ccccc|} \hline 1 & & & & 1 \\ & 30 & 101 & 30 & \\ & 101 & 82 & 101 & \\ & 30 & 101 & 30 & \\ 1 & & & & 1 \\ \hline \end{array} \; . \tag{4.31}$$

and we find

	$V_{\text{tor}} + V_{\text{tor}}^{\text{alg}}$	$V_{\text{cor}} + V_{\text{cor}}^{\text{alg}}$	$RM_a + V_{\text{rm}}^{\text{alg}}$	$RM_a^m + H_{\text{rm}}^{\text{red}}$	$H_{\text{cor}} + H_{\text{cor}}^{\text{re}}$	$H_{\text{mon}} + H_{\text{mon}}^{\text{red}}$
$\hat{Z}_S$	$41 - 0$	$0 - 0$	$150 - 150$	$150 - 150$	$0 - 0$	$41 - 0$

. (4.32)

As expected for a self-mirror fourfold with $h_{RM}^{2,2} = 0$, the result is $h_V^{2,2} = \frac{1}{2}h^{2,2}$.

Let us comment on the computation of $NV_3(\widetilde{P}_S)$, which was zero in the example before. There are three 1-dimensional faces with $\ell^*(\widetilde{\Theta}^{[1]}) = 5$. In $\widetilde{P}_S$ they have vertices at $\{(0,0,-1,1,-1),(0,0,5,1,5)\}$, $\{(0,0,-1,1,-1),(0,0,11,1,5)\}$ and $\{(0,0,5,1,5),(0,0,11,1,5)\}$. They are dual to 3-dimensional faces each of which contains 10 points interior to their 2-dimensional faces. As all other 1-dimensional faces have $\ell^* = 0$, we hence find $NV_3(\widetilde{P}_S) = 150$.

JHEP01(2015)047

Just like in the example P_B, the correction term for $H^{1,1}(\hat{Z}_S)$ vanishes and we can independently verify that $h^{2,2}_V(\hat{Z}_S) = h^{2,2}_V(\hat{Z}_{S,m}) = 41$ by using the intersection ring of the ambient space.

We now discuss an example for which $h^{2,2}_{RM} \neq 0$ and not all toric divisors are irreducible. The vertices of the polytopes defining this example and its mirror are

$$\widetilde{P}_3 = \begin{pmatrix} -1 & 0 & 0 & 0 & 0\,0\,0 & 0\,0\,0\,0\,0\,1 \\ -3 & -2 & -2 & -1 & -1\,0\,0 & 0\,2\,2\,4\,4\,0 \\ -5 & -3 & -2 & -2 & -2\,0\,0 & 4\,1\,1\,3\,4\,0 \\ -8 & -5 & -4 & -3 & -2\,0\,2 & 2\,0\,1\,1\,2\,0 \\ -7 & -5 & -5 & -2 & -2\,1\,1 & -3\,1\,1\,1\,1\,0 \end{pmatrix} \tag{4.33}$$

and

$$P_3 = \begin{pmatrix} -1 & -1 & -1 & -1 & -1 & -1 & -1 & -1 & 0 & 1 & 1 & 8 & 10 \\ -1 & -1 & -1 & 0 & 1 & 1 & 3 & 4 & -1 & -1 & 4 & 0 & 1 \\ 1 & 1 & 2 & 0 & -2 & -1 & 0 & -1 & 1 & 2 & -1 & 0 & -1 \\ -1 & 0 & 0 & 0 & 2 & 0 & 0 & 0 & -1 & 0 & 0 & 0 & 0 \\ 1 & 0 & -1 & -1 & -1 & -1 & -1 & -1 & 1 & -1 & -1 & -1 & -1 \end{pmatrix}. \tag{4.34}$$

We have found a fine, regular and unimodular triangulation for both polytopes. The hodge numbers are

$$h^{p,q}(\hat{Z}_3) = \begin{array}{|ccccc|} \hline 1 & & & & 1 \\ & 76 & 11 & 67 & \\ & 11 & 594 & 11 & \\ & 67 & 11 & 76 & \\ 1 & & & & 1 \\ \hline \end{array}\,. \tag{4.35}$$

Evaluation of (3.74), (3.93) and (3.94) gives

	$V_{\rm tor} + V^{\rm alg}_{\rm tor}$	$V_{\rm cor} + V^{\rm alg}_{\rm cor}$	$RM_a + V^{\rm alg}_{\rm rm}$	$RM^m_a + H^{\rm red}_{\rm rm}$	$H_{\rm cor} + H^{\rm re}_{\rm cor}$	$H_{\rm mon} + H^{\rm red}_{\rm mon}$
$\hat{Z}_3$	$212 - 6$	$0 - 0$	$177 - 74$	$118 - 61$	$29 - 0$	$199 - 0$
$\hat{Z}_{3,m}$	$199 - 0$	$29 - 0$	$118 - 61$	$177 - 74$	$0 - 0$	$212 - 6$

, (4.36)

so that

$$h^{2,2}_V(\hat{Z}_3) = 206 \qquad h^{2,2}_{RM}(\hat{Z}_3) = 160 \qquad h^{2,2}_H(\hat{Z}_3) = 228 \tag{4.37}$$

In this example, the correction term to $h^{1,1}(\hat{Z}_{3,m})$ is equal to 10 and some of the toric divisors are reducible, giving rise to a non-zero contribution to $V_{\rm cor}(\hat{Z}_{3,m})$. One can check that the intersection ring of the ambient toric space restricted to $\hat{Z}_{3,m}$ gives rise to 199 four-cycles in this case, as expected from $V_{\rm tor}(\hat{Z}_{3,m}) + V^{\rm alg}_{\rm tor}(\hat{Z}_{3,m}) = 199$. For $V_{\rm cor}(\hat{Z}_3)$, the correction term to $h^{1,1}$ vanishes and all 206 vertical four-cycles are obtained by the restriction of intersections of toric divisors.

JHEP01(2015)047

4.4 Elliptic fourfolds

In this section we come to our objects of interest, which are elliptic fourfolds. With the machinery to treat toric hypersurfaces in place, let us discuss elliptic fibrations over toric base manifolds. A smooth elliptic fourfold over a toric base B_3 not supporting any gauge group can be obtained by taking a generic Calabi-Yau hypersurface in an appropriate fibration of $\mathbb{P}^2_{123}$ over B_3. The elliptic fibration morphism π then descends from the toric morphism projecting down to B_3. Torically, we may realize such a situation by setting up a polytope $\widetilde{\Delta}^{\pi}_{B_3}$ with vertices

$$\begin{pmatrix} -1 \\ 0 \\ 0 \end{pmatrix}, \begin{pmatrix} 0 \\ -1 \\ 0 \end{pmatrix}, \begin{pmatrix} 3 \\ 2 \\ 0 \end{pmatrix}, \begin{pmatrix} 3 \\ 2 \\ \vec{v}_1 \end{pmatrix}, \cdots, \begin{pmatrix} 3 \\ 2 \\ \vec{v}_n \end{pmatrix}. \tag{4.38}$$

Here, the $\vec{v}_i$ are the generators of the 1-dimensional cones in the fan of the toric variety B_3. The above assignment ensures that X_1 (the coordinate associated with $(-1,0,0,0,0)$) is a section of $-3K_{B_3}$ and X_2 (the coordinate associated with $(0,-1,0,0,0)$) is a section of $-2K_{B_3}$.

For appropriate base manifolds B_3, a generic hypersurface $\hat{Z}^{\pi}_{B_3}$ in the toric variety defined by a fan over faces of the polytope $\widetilde{\Delta}^{\pi}_{B_3}$ is a smooth elliptic Calabi-Yau manifold with $h^{1,1}(\hat{Z}^{\pi}_{B_3}) = h^{1,1}(B_3)+1$. A compactification of F-theory on such a manifold will not give rise to any gauge symmetry in the low energy effective action.

The (combinatorially) simplest example is $B_3 = \mathbb{P}^3$, where we choose

$$\vec{v}_1 = \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix}, \vec{v}_2 = \begin{pmatrix} 0 \\ 1 \\ 0 \end{pmatrix}, \vec{v}_3 = \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}, \vec{v}_4 = \begin{pmatrix} -1 \\ -1 \\ -1 \end{pmatrix}. \tag{4.39}$$

Another class of examples we will discuss in the following is given by taking a toric base defined by

$$\vec{v}_1 = \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix}, \vec{v}_2 = \begin{pmatrix} -1 \\ 0 \\ 0 \end{pmatrix}, \vec{v}_3 = \begin{pmatrix} n \\ 1 \\ 1 \end{pmatrix}, \vec{v}_4 = \begin{pmatrix} 0 \\ -1 \\ 0 \end{pmatrix}, \vec{v}_5 = \begin{pmatrix} 0 \\ 0 \\ -1 \end{pmatrix}. \tag{4.40}$$

Let us denote the resulting threefolds by $B_3^{(n)}$. We can also characterize them as $\mathbb{P}\left[\mathcal{O}_{\mathbb{P}^2} \oplus \mathcal{O}_{\mathbb{P}^2}(n)\right]$, i.e. they are themselves fibrations of $\mathbb{P}^1$ over $\mathbb{P}^2$. Hence the resulting fourfolds are K3 fibred and for F-theory compactifications there is a heterotic dual. One may think of $[z_1 : z_2]$ as coordinates on the $\mathbb{P}^1$ fibre (they also define two sections of the $\mathbb{P}^1$ fibration) and $[z_3 : z_4 : z_5]$ as coordinates on the $\mathbb{P}^2$ base.

Using the methods described earlier in this paper, we may now easily compute the Hodge numbers and the dimension of $H^{2,2}_V$, $H^{2,2}_H$ and $H^{2,2}_{RM}$ for these examples. The results are given in table 1.

JHEP01(2015)047

B_3	$\mathbb{P}^3$	$B_3^{(-3)}$	$B_3^{(-2)}$	$B_3^{(-1)}$	$B_3^{(0)}$	$B_3^{(1)}$	$B_3^{(2)}$	$B_3^{(3)}$

K	23320	26200	22596	20436	19716	20436	22596	26200

Table 1. Hodge numbers and $h^{2,2}_V$, $h^{2,2}_H$ and $h^{2,2}_{RM}$ for generic elliptic fibrations, based on the polytopes with vertices (4.38), over base spaces $\mathbb{P}^3$, and $B_3^{(n)}$.

For a fourfold given by toric data such as (4.38), we may engineer models with a prescribed gauge group G over a divisor S in the base by choosing the monomials appearing in the defining equation of the hypersurface $\hat{Z}^{\pi}_{B_3}$ appropriately. If S is given by a toric divisor of the ambient space, this is equivalent to deleting points from the dual polytope $\Delta^{\pi}_{B_3,G}$ in the M-lattice. If this process results in another reflexive polytope $\Delta^{\pi}_{B_3,G}$, we may construct the dual $\widetilde{\Delta}^{\pi}_{B_3,G}$, which contains more points than $\widetilde{\Delta}^{\pi}_{B_3}$. If the resulting hypersurface $\hat{Z}_G$ is smooth, these extra points can be interpreted as the exceptional divisors of a resolution.

We may also reverse this process and define our models with an appropriate $\widetilde{\Delta}^{\pi}_{B_3}$, which is what we will do in the following. This anticipates the resolution process (which is another way to find the new vertices to add) and only allows those monomials in Δ leading to the desired fibre structure. This approach is similar to the one used in [51] and the tops of [52–54]. Equivalently, the polytopes used may also be constructed from the combined weight systems of appropriately resolved fourfolds.

In the following we will present a few examples for gauge groups SU(5) and SO(10).

4.4.1 SU(5) along $\mathbb{P}^2$

For a fourfold given as a hypersurface in a toric ambient space via a reflexive polytope such as (4.38), we may engineer fibres of type I_5 in Kodaira's classification along a divisor $[z_k]$ in the base (leading to SU(5) gauge symmetry in a compactification of F-theory) by adding the vertices:[18]

$$\vec{v}_{e_1} = \begin{pmatrix} 2 \\ 1 \\ \vec{v}_k \end{pmatrix}, \vec{v}_{e_2} = \begin{pmatrix} 1 \\ 0 \\ \vec{v}_k \end{pmatrix}, \vec{v}_{e_3} = \begin{pmatrix} 0 \\ 0 \\ \vec{v}_k \end{pmatrix}, \vec{v}_{e_4} = \begin{pmatrix} 1 \\ 1 \\ \vec{v}_k \end{pmatrix} \tag{4.41}$$

[18]To be more precise, we take the convex hull of these points and the polytope (4.38). In the resulting polytope, $\vec{v}_{e_1}$ is not a vertex, but lies on an edge between $\vec{v}_k$ and $\vec{v}_{e_2}$.

K	13287	7557	8603	10403	12953	16253	20303	25104

Table 2. Hodge numbers, decomposition of $H^{2,2}$ and K for Calabi-Yau fourfolds with SU(5) gauge group based on the reflexive polytopes $\widetilde{\Delta}^{\pi}_{\mathbb{P}^3,\,\mathrm{SU}(5)}$ and $\widetilde{\Delta}^{\pi}_{B_3^{(n)},\,\mathrm{SU}(5)}$.

to the polytope (4.38). For the examples of B_3 discussed in the last section, this leads to reflexive polytopes $\widetilde{\Delta}^{\pi}_{\mathbb{P}^3,\,\mathrm{SU}(5)}$ and $\widetilde{\Delta}^{\pi}_{B_3^{(n)},\,\mathrm{SU}(5)}$ (for $n = -3\cdots 3$). For the bases $B_3^{(n)}$, we place S along the divisor $[z_1]$ (the divisor corresponding to $\vec{v}_1$ in (4.40)). This means that S is a $\mathbb{P}^2$ in the base of the elliptic fibration.

Evaluating (3.74), (3.93) and (3.94) gives the results in table 2.

Note that in each case, $h^{1,1}$ has increased by four, corresponding to the exceptional divisors. The value of $h^{2,2}_V(\hat{Z}^{\pi}_{B_3^{(0)},\,\mathrm{SU}(5)}) = 9$ has already been independently computed in [27]. In the last case, $h^{2,2}_V(\hat{Z}^{\pi}_{B_3^{(3)},\,\mathrm{SU}(5)}) = 8$ because the **10** matter curve is absent there.

4.4.2 SO(10) along $\mathbb{P}^2$

In a similar fashion as done in the last section we may construct the polytopes $\widetilde{\Delta}^{\pi}_{B_3,\,\mathrm{SO}(10)}$. As (generic) models with gauge group SO(10) can be obtained by a further degeneration of SU(5) models, the polytope $\widetilde{\Delta}^{\pi}_{B_3,\,\mathrm{SO}(10)}$ contains $\widetilde{\Delta}^{\pi}_{B_3,\,\mathrm{SU}(5)}$. The vertices which have to be added to $\widetilde{\Delta}^{\pi}_{B_3,\,\mathrm{SU}(5)}$ to achieve gauge group SO(10) along z_1 are:

$$\vec{v}_{e_5} = \begin{pmatrix} 2 \\ 1 \\ 2\vec{v}_k \end{pmatrix}, \; \vec{v}_{e_6} = \begin{pmatrix} 3 \\ 2 \\ 2\vec{v}_k \end{pmatrix}. \tag{4.42}$$

For these cases we find the hodge numbers given in table 3.

5 Fourfolds which are not hypersurfaces of toric varieties

In the last section, we have shown how $H^{2,2}(\hat{Z},\mathbb{Q})$ is decomposed into vertical cycles, horizontal cycles and the remaining part $H^{2,2}_{RM}(\hat{Z},\mathbb{Q})$ for the case of hypersurfaces in toric varieties. As we have seen, the remaining part can be non-zero when divisors of $\hat{Z}$ have algebraic cycles which are not obtained by intersection with other divisors, cf. (3.95).

Table 3. Hodge numbers, decomposition of $H^{2,2}$ and K for Calabi-Yau fourfolds with SU(5) gauge group based on the reflexive polytopes $\widetilde{\Delta}^{\pi}_{\mathbb{P}^3,\,\mathrm{SO}(10)}$ and $\widetilde{\Delta}^{\pi}_{B_3^{(n)},\,\mathrm{SO}(10)}$.

In this section we discuss another class of Calabi-Yau fourfolds which can have a non-vanishing remaining part and are motivated in the study of F-theory compactifications: elliptic fibrations with singular fibres of type I_5 along a divisor S.

Let B_3 be a smooth Fano threefold, and let Z_s be a fourfold given by imposing a Weierstrass equation in the ambient space $\mathbb{P}[\mathcal{O}_{B_3} \oplus \mathcal{O}_{B_3}(-2K_{B_2}) \oplus \mathcal{O}_{B_3}(-3K_{B_3})]$. We may choose the Weierstrass equation to be

$$X_1^2 = X_2^3 + a_5 X_1 X_2 X_3 + a_4 X_2^2 X_3^2 s + a_3 X_1 X_3^3 s^2 + a_2 X_2 X_3^4 s^3 + a_0 X_3^6 s^5, \tag{5.1}$$

where $X_{3,2,1}$ are the homogeneous coordinates of an ambient space containing the fibre $\mathbb{P}[\mathcal{O} \oplus \mathcal{O}(-2K_{B_3}) \oplus \mathcal{O}(-3K_{B_3})]$. A morphism $\bar{\pi} : Z_s \longrightarrow B_3$ defining an elliptic fibration naturally follows from this. Let $[S]$ be some divisor class of B_3 and s a global section of $\mathcal{O}_{B_3}(S)$, so that the zero locus of s is S. $a_{r=5,4,3,2,0}$'s are global sections of appropriate line bundles $\mathcal{O}_{B_3}(-(6-r)K_{B_3} - (5-r)S)$ making (5.1) a Calabi-Yau manifold. These conditions leave moduli for s and the $a_{r=5,4,3,2,0}$, and we assume that they are chosen generic (in the sense that they are not in a Noether-Lefschetz locus). Fourfolds Z_s obtained in this way have an A_4 singularity along the subvariety $s = X_2 = X_1 = 0$. A compact and non-singular fourfold $\hat{Z}$ can be obtained by carrying out the canonical resolution of the A_4 singularity in Z_s first, and then going through a small resolution. The elliptic fibration $\pi : \hat{Z} \longrightarrow B_3$ remains a flat morphism [30]. Some more details about this resolution procedure are reviewed in appendices A.1 and A.2 so that there is no ambiguity in the notation used in this article.

This class of geometries generalizes the examples discussed in section 4.4, where $\hat{Z}$ is realized as a hypersurface of a toric variety. As a canonical example, we can think of $B_3 = \mathbb{P}^3$, and S a quadratic or cubic (or possibly degree $d = 4$) hypersurface of B_3. It is known that $S = \mathbb{P}^1 \times \mathbb{P}^1$ in the $d = 2$ case, $S = dP_6$ when $d = 3$, and $S = \mathrm{K3}$ for $d = 4$. In these cases, $i^* : H^{1,1}(B_3; \mathbb{C}) \longrightarrow H^{1,1}(S; \mathbb{C})$ is not surjective, which is a welcome feature in F-theory compactifications [20, 21].

In this section we study the difference between the algebraic and vertical components in $H^{2,2}(\hat{Z}; \mathbb{Q})$ for this class of geometries. This is done by dividing $\hat{Z}$ into a collection of

JHEP01(2015)047

(transversally intersecting) divisors $Y = \cup_i \hat{Y}_i \subset \hat{Z}$ and its complement $Z := \hat{Z} \backslash Y$, just like we did in section 3 when studying the case where $\hat{Z}$ is a toric hypersurface. Here, we choose a collection of divisors $Y = \cup_i \hat{Y}_i$ exploiting the fibration structure: the first five $\hat{Y}_i$, $i = 0, 1, 2, 3, 4$, are reserved for the five irreducible components of the family of I_5 Kodaira fibres over the divisor S in B_3. Apart from those, the collection $\cup_i \hat{Y}_i$ consists of the zero section σ of the elliptic fibration $\pi : \hat{Z} \longrightarrow B_3$ and the divisors $\pi^*(D_i)$'s, where $\{D_i\}$ is some basis of $\mathrm{Pic}(B_3)$.

We use the long exact sequence (3.11) with the separation $\hat{Z} = Y \amalg Z$ described above. The $H_c^4(Y)$-based algebraic cycles are studied by looking at

$$\mathrm{Ker}\left[[H_c^4(Y)]^{2,2} \longrightarrow [H_c^5(Z)]^{2,2}\right]. \tag{5.2}$$

There are two things to be worked out: the first is to determine the (dimension of the) algebraic components in $[H_c^4(Y)]^{2,2}$ for cases where $\hat{Z}$ is not necessarily a hypersurface of a toric variety, and the second is to determine $h^{2,2}[H_c^5(Z)] = h^{2,2}[H^3(Z)]$. It is known that $h^{2,2}[H_c^5(\hat{Z})] = 0$ when $\hat{Z}$ is a hypersurface of a toric variety, but this is not necessarily true for more general cases (note that $2 + 2 \geq 3$, and Z is smooth and non-compact).

Let us now work out $[H_c^4(Y)]^{2,2}$. It is determined by the Mayer-Vietoris spectral sequence, and by (3.16), in particular. This task consists of determining $H^4(\hat{Y}_i)$, $H^4(\hat{Y}_i \cap \hat{Y}_j)$ and the morphism between them.

5.1 The dimension of $h^{1,1}(\hat{Y}_i)$'s

We begin by computing the dimension of $h^2(\hat{Y}_i) = h^4(\hat{Y}_i)$ for the compact and generically smooth divisors $\hat{Y}_i \in \left\{\sigma, \pi^*(D_i), \hat{Y}_{0,1,2,3,4}\right\}$.

For $\hat{Y}_i = \sigma \simeq B_3$, $H_c^{2,2}(B_3) = H^{1,1}(B_3) = NS(B_3)$.

For $\hat{Y}_i = \pi^*(D_i)$ for one of the basis elements of $NS(B_3)$, $H^{1,1}(\pi^*(D))$ is generated by restrictions of the divisors σ, $\hat{Y}_{0,1,2,3,4}$ and divisors of B_3, where we assume that $D_i \cdot S$ is not empty in B_3 for now. To verify this, the Hodge diamond of the threefold $\pi^*(D) \subset \hat{Z}$ can be determined by decomposing $\hat{Z}$ into strata first, and then by collecting strata that belong to $\pi^*(D)$. It is convenient to start from the following stratification of the threefold $\pi^*(D)$: the surface $D \subset B_3$ is decomposed into $D \backslash (D \cap S)$, $D \cap (S \backslash (\Sigma_{(\mathbf{10})} \cup \Sigma_{(\mathbf{5})}))$ and $D \cap \Sigma_{(\mathbf{10})}$ and $D \cap \Sigma_{(\mathbf{5})}$, and the elliptically fibred threefold $\pi^*(D) \subset \hat{Z}$ is also decomposed accordingly to the stratification in the base. The Hodge number of the compact and smooth geometry $\pi^*(D)$ is obtained by summing up the Hodge-Deligne numbers of the strata. To $h^{1,1}(\pi^*(D)) = h^{2,2}(\pi^*(D))$, only the first two strata contribute.

$$\begin{aligned} h^{2,2}(\pi^*(D)) &= \left[e_c^{0,0}(T^2) e_c^{2,2}(D \backslash (D \cap S)) + e_c^{1,1}(T^2) e_c^{1,1}(D \backslash (D \cap S))\right] \\ &\quad + e_c^{1,1}(I_5) e_c^{1,1}(D \cap S) \\ &= 1 + [h^{1,1}_{\mathrm{alg}}(D \subset B_3) - 1] + 5 = 1 + h^{1,1}_{\mathrm{alg}}(D) + 4. \end{aligned} \tag{5.3}$$

The claim is now verified.[19] If $D_i \cdot S = 0$ in B_3, however, $H^{1,1}(\pi^*(D_i))$ is generated by $\pi^*(D_j|_{D_i})$ for D_j's in $NS(B_3)$ and $\sigma|_{\pi^*(D_i)}$.

[19] To be more precise, the term $e_c^{1,1}(T^2) e_c^{1,1}(D \backslash (D \cap S))$ should be decomposed into the region where the fibre is a smooth T^2 and type II fibre. However, $e_c^{1,1} = 1$ for the type II fibre, so that there is no difference after all.

JHEP01(2015)047

We assume that a basis $\{D_i\}$ of $NS(B_3)$ is chosen such that the number of D_i's with $D_i \cdot S \neq \phi$ is the same as the dimension $\tilde{\rho}_B$ of the image of

$$i^* : H^{1,1}(B_3) \longrightarrow H^{1,1}(S). \tag{5.4}$$

In order to determine the Hodge numbers of the five other divisors $\hat{Y}_{0,1,2,3,4}$ comprising the I_5 fibre over the divisor $S \subset B_3$, we introduce the following stratification of S:

$$S = S^\circ \amalg \Sigma^\circ_{(\mathbf{10})} \amalg \widetilde{\Sigma}^\circ_{(\mathbf{5})} \amalg P_{E6} \amalg P_{D6}\,. \tag{5.5}$$

Here, $\Sigma_{(\mathbf{10})}$ is the curve in S given by $a_5|_S = 0$, and $\Sigma_{(\mathbf{5})}$ the curve in S given by $(a_0 a_5^2 - a_2 a_5 a_3 + a_4 a_3^2)|_S = 0$. Those two curves intersect in S, and P_{E6} and P_{D6} denote the collection of such intersection points of two different kinds; P_{E6} are the points where $a_5 = a_4 = 0$, and P_{D6} where $a_5 = a_3 = 0$. $\Sigma^\circ_{(\mathbf{10})}$ is defined as $\Sigma_{(\mathbf{10})} \backslash (P_{E6} \cup P_{D6})$. The curve $\Sigma_{(\mathbf{5})}$ forms a double point singularity at each one of the points in P_{D6}; $\widetilde{\Sigma}^\circ_{(\mathbf{5})}$ is obtained by resolving the double point singularities (to obtain a curve $\widetilde{\Sigma}_{(\mathbf{5})}$), and then removing the lift of the points of P_{E6} and P_{D6}. Finally, $S^\circ := S \backslash (\Sigma_{(\mathbf{10})} \cup \Sigma_{(\mathbf{5})})$ (see [55, 56]).

The Hodge numbers of the five divisors can be calculated by using the stratification of the geometry of S as described above, and the additivity and multiplicativity of the Euler characteristics of the Hodge-Deligne numbers $e^{p,q}$. Appendix A.3 explains how to carry out the computation in practice, taking the Hodge numbers of $\hat{Y}_4$ as an example. The result is

$$e_c^{p,q}(\hat{Y}_4) = \begin{vmatrix} 0 & h^{2,0}(S) & 0 & 1 \\ h^{2,0}(S) & -2g_{10} & [h^{1,1}(S)+3] & 0 \\ 0 & [h^{1,1}(S)+3] & -2g_{10} & h^{2,0}(S) \\ 1 & 0 & h^{2,0}(S) & 0 \end{vmatrix} = (-)^{p+q} h^{3-p,3-q}(\hat{Y}_4)\,, \tag{5.6}$$

where the Hodge numbers are given in terms of $h^{2,0}(S)$ and $h^{1,1}(S)$ and the genera g_{10} and $\tilde{g}_5$ of the (resolved) matter curves; we assume that $h^{1,0}(S) = 0$ here. The appendix A contains more information on the generators of $H^{1,1}(\hat{Y}_4)$.

Similar computations can be carried out for the four other divisors in the I_5 fibre. The results are:

$$e_c^{p,q}(\hat{Y}_0) = e_c^{p,q}(\hat{Y}_1) = \begin{vmatrix} 0 & h^{2,0}(S) & 0 & 1 \\ h^{2,0}(S) & 0 & [h^{1,1}(S)+1] & 0 \\ 0 & [h^{1,1}(S)+1] & 0 & h^{2,0}(S) \\ 1 & 0 & h^{2,0}(S) & 0 \end{vmatrix}, \tag{5.7}$$

$$e_c^{p,q}(\hat{Y}_2) = \begin{vmatrix} 0 & h^{2,0}(S) & 0 & 1 \\ h^{2,0}(S) & -g_{10} & [h^{1,1}(S)+2] & 0 \\ 0 & [h^{1,1}(S)+2] & -g_{10} & h^{2,0}(S) \\ 1 & 0 & h^{2,0}(S) & 0 \end{vmatrix}, \tag{5.8}$$

JHEP01(2015)047

$$e_c^{p,q}(\hat{Y}_3) = \begin{vmatrix} 0 & h^{2,0}(S) & 0 & 1 \\ h^{2,0}(S) & -\tilde{g}_5 & [h^{1,1}(S)+2] & 0 \\ 0 & [h^{1,1}(S)+2] & -\tilde{g}_5 & h^{2,0}(S) \\ 1 & 0 & h^{2,0}(S) & 0 \end{vmatrix} . \tag{5.9}$$

5.2 Determination of $H^4(Y)$

Next, $H^4(Y)$ is determined as the kernel of (3.16). Since we have chosen all of the $\hat{Y}_i$'s to be irreducible, $h^4(\hat{Y}_i \cdot \hat{Y}_j) = 1$ for any pair of those divisors $(i \neq j)$ with a non-empty intersection $\hat{Y}_i \cdot \hat{Y}_j$. We switch to the dual (homology group) language in this subsection and the next. $H_4(Y)$ is the cokernel of the morphism

$$d^1 : \quad \left[\oplus_{i<j} H_4(\hat{Y}_i \cdot \hat{Y}_j)\right] = E_{1,4}^1 \longrightarrow E_{0,4}^1 = \left[\oplus_i H_4(\hat{Y}_i)\right], \tag{5.10}$$

and the contribution to $H_4(\hat{Z})$ from $H_4(Y)$ is characterized as the cokernel of the boundary map

$$\delta : \left[H_5^{\mathrm{BM}}(Z) = H_5(\hat{Z}, Y)\right] \longrightarrow H_4(Y). \tag{5.11}$$

We have already learned that

$$\begin{aligned} \dim[H_4(\sigma \simeq B_3)] &= \rho_B, \\ \dim[H_4(\pi^*(D_i)] &= h^{1,1}(D_i) + 1, && (\text{if } D_i \cdot S = \phi) \\ \dim[H_4(\pi^*(D_i)] &= h^{1,1}(D_i) + 1 + 4, && (\text{if } D_i \cdot S \neq \phi) \\ \dim[H_4(\hat{Y}_0)] &= \rho_S + 1, \\ \dim[H_4(\hat{Y}_1)] &= \rho_S + 1, \\ \dim[H_4(\hat{Y}_2)] &= \rho_S + 2, \\ \dim[H_4(\hat{Y}_3)] &= \rho_S + 2, \\ \dim[H_4(\hat{Y}_4)] &= \rho_S + 3, \end{aligned} \tag{5.12}$$

where $\rho_S := h^{1,1}(S)$ and $\rho_B = h^{1,1}(B_3)$. On the other hand,

$$\dim\left[\oplus_{i<j} H_4(\hat{Y}_i \cap \hat{Y}_j)\right] = \rho_B + \frac{\rho_B(\rho_B - 1)}{2} + 5\tilde{\rho}_B + 8\,, \tag{5.13}$$

and $\oplus_{i<j} H_4(\hat{Y}_i \cap \hat{Y}_j)$ is generated by four-cycles of the form

i) $\sigma \cdot \pi^*(D_i)$

ii) $\pi^*(D_i \cdot D_j)$ with $i \neq j \leq \rho_B$

iii) $\pi^*(D_i) \cdot \hat{Y}_{0,1,2,3,4}$ for $D_i \cdot S \neq \phi$

iv) intersections among $\hat{Y}_{0,1,2,3,4}$, neglecting self-intersections

There are ρ_B four-cycles in the group i) above. In $[\oplus_i H_4(\hat{Y}_i)]$, a given cycle of the form $(\hat{Y}_i \cdot \hat{Y}_j) = \sigma \cdot D_i$ appears once in $H_4(\sigma)$ and once in $H_4(\pi^*(D_i))$. Thus, there are ρ_B independent four-cycles $[\sigma \cdot D_i]$ in $H_4(Y)$ remaining in the Cokernel of the morphism (5.10).

JHEP01(2015)047

The second group ii) of four-cycles above are mapped into $\oplus_i H_4(\pi^*(D_i))$, and also leave a cokernel of dimension ρ_B. These cycles are represented by $\pi^*(\text{curves} \subset B_3)$.

A given four-cycle of the form $\pi^*(D_i) \cdot \hat{Y}_{1,2,3,4}$ (with $D_i \cdot S \neq \phi$) among the group iii) of four-cycles appears once in $H_4(\hat{Y}_{1,2,3,4})$ and once in $H_4(\pi^*(D_i))$. Thus, all of the $4\rho_S$ generators of $H_4(\hat{Y}_{1,2,3,4})$ are in the cokernel. The remaining four-cycles in the third group are of the form $\pi^*(D_i) \cdot \hat{Y}_S$. As only a $\tilde{\rho}_B$-dimensional subspace of $H^{1,1}(S)$ descends from $H^{1,1}(B_3)$, the images of these cycles in $H_4(\pi^*(D_i))$ are mapped to a $\tilde{\rho}_B$-dimensional subspace of $H_4(\hat{Y}_S)$, so that their contribution to the cokernel is $\rho_S - \tilde{\rho}_B$-dimensional.

So far, we have identified $2\rho_B + 4\rho_S + \rho_S - \tilde{\rho}_B$ independent generators of the cokernel of (5.10) in $H_4(Y)$. Besides the summands already covered in the discussion above, there are $(1 + 1 + 2 + 2 + 3) = 9$-dimensions remaining in $\oplus_i H_4(\hat{Y}_i)$, and eight dimensions remaining in $\oplus_{i<j} H_4(\hat{Y}_i \cdot \hat{Y}_j)$. We choose $\hat{Y}_2 \cdot \hat{Y}_4$ as the remaining representative of thecokernel and may conclude that

$$\dim[H_4(Y)] = 2\rho_B + 5\rho_S - \tilde{\rho}_B + 1. \tag{5.14}$$

5.3 The vertical components in $H_4(Y)$

The $(2\rho_B+1)$-dimensional subspace of $H_4(Y)$ which may be represented by $\sigma \cdot D_i$ and $D_i \cdot D_j$ is clearly composed of vertical four-cycles. However, not all of $H_4(Y)$ arises in this way.

The remaining $4\rho_S + (\rho_S - \tilde{\rho}_B)$-dimensional subspace of $H_4(Y)$ is generated by four-cycles of the form $\hat{Y}_{1,2,3,4} \cdot \pi^*(\omega)$ or $\hat{Y}_S \cdot \pi^*(\omega)$ for some $\omega \in H^{1,1}(S)$ (Poincaré duality is implicit everywhere). If ω is in the image of (5.4), then such a four-cycle is vertical. Thus, at least a subspace of dimension $4\tilde{\rho}_B$ is also vertical.

Intersections of the form $\hat{Y}_i \cdot \hat{Y}_j$ for $i, j \in \{0, 1, 2, 3, 4\}$ and $i \neq j$ are all vertical four-cycles as well. They are already contained in the $(2\rho_B + 1)$-dimensional subspace of $H_4(Y)$ referred to at the beginning of this subsection, however.

The last remaining group of vertical four-cycles are of the form $\hat{Y}_i \cdot \hat{Y}_i$ for $i = 0, 1, 2, 3, 4$. Such self-intersections can be computed by using such relations as

$$\hat{Y}_1 \cdot \hat{Y}_1 \sim \hat{Y}_1 \cdot \left[\nu^*_{\text{tot}}(D_S) - \hat{Y}_0 - \hat{Y}_2 - \hat{Y}_3 - \hat{Y}_4\right]. \tag{5.15}$$

Noting that both $c_1(N_{S|B_3})$ and $c_1(B_3)|_S$ are in the image of (5.4), and using the relations (A.46)–(A.47), one finds that these vertical four-cycles are not independent from those that we have discussed already. Therefore, we conclude that the vertical four-cycles form a subspace of dimension

$$2\rho_B + 4\tilde{\rho}_B + 1 \tag{5.16}$$

in $H_4(Y)$.

The remaining $5(\rho_S - \tilde{\rho}_B)$-dimensional subspace of $H_4(Y)$ cannot be represented by vertical four-cycles. This subspace has a clear geometric interpretation: for any cycle in S which does not descend from B_3, we can form five vertical four-cycles by taking the fibre components of the I_5 fibre over S.

JHEP01(2015)047

5.4 The remaining component

A four-cycle in $H_4(Y)$ represents a topological four-cycle in $\hat{Z}$ only if it is in the cokernel of the boundary map,

$$\text{Coker}\left[H_5(\hat{Z},Y) \longrightarrow H_4(Y)\right] \subset H_4(\hat{Z}). \tag{5.17}$$

For the general class of geometries $\hat{Z}$ described at the beginning of this section, we do not have a clear method of computation for $H_5(\hat{Z},Y)$. Although it is difficult to find *all* the generators of $H_5(\hat{Z},Y)$ and their images in $H_4(Y)$, it is easier to identify *some* generators of $H_5(\hat{Z},Y)$ and study their images in $H_4(Y)$. This way, we can at least establish an upper bound on the cokernel.

For every two-cycle Σ in $H_2(S)$ whose Poincaré dual is in the cokernel of (5.4), there exists a three-chain γ in B_3 with $\Sigma = \partial\gamma$. This three-chain γ and the boundary morphism $H_3(B_3,S) \longrightarrow H_2(S)$ are lifted under the elliptic fibration. Clearly, $\pi^{-1}(\gamma)$ is in $H_5(\hat{Z},Y)$ and its boundary in $H_5(\hat{Z},Y) \longrightarrow H_4(Y)$ is represented by $\pi^{-1}_{\hat{Y}_0}(\Sigma)+\pi^{-1}_{\hat{Y}_1}(\Sigma)+\cdots+\pi^{-1}_{\hat{Y}_4}(\Sigma)$; there are $(\rho_S-\tilde{\rho}_B)$ independent choices of Σ and consequently $(\rho_S-\tilde{\rho}_B)$ independent choices of $\pi^{-1}(\gamma)$. This means that only $4(\rho_S-\tilde{\rho}_B)$ out of the $5(\rho_S-\tilde{\rho}_B)$ non-vertical cycles in $H_4(Y)$ can become non-trivial four-cycles in $H_4(\hat{Z})$. If there are more cycles in $H_5(\hat{Z},Y)$ than the ones considered, this number may decrease.

As the five-chains $\pi^{-1}(\gamma)$ constructed above map only to non-vertical cycles in $H_4(Y)$ under the boundary map (5.17), we find that there is at most a $(2\rho_B+4\tilde{\rho}_B+1)$-dimensional subspace of $H_4(\hat{Z})$ that is represented by vertical four-cycles. If there are more five-chains in $H_5(\hat{Z},Y)$ than those we discussed above, this subspace may be smaller. Since all the independent divisors are included in the collection $\cup_i \hat{Y}_i$, all the vertical four-cycles have already been listed up.

The case $(\rho_S-\tilde{\rho}_B) > 0$ is not without phenomenological motivation [20, 21]. The non-vertical cycles spanning at most $4(\rho_S-\tilde{\rho}_B)$-dimensions in $H_4(\hat{Z})$, are precisely the Poincaré duals of four-forms that can break SU(5) unification symmetry down to the gauge group of the Standard Model, while keeping the vector field of $\text{U}(1)_Y$ massless. In this scenario, those four-cycles of $H_4(Y)$ need to represent topologically non-trivial four-cycles in $H_4(\hat{Z})$. If $h^{2,0}(S) = 0$, those four-cycles are automatically algebraic, so they are not horizontal either. The four-forms (four-cycles) of this type in the class of geometries studied in this section are another class of examples of the remaining component $H^{2,2}_{RM}(\hat{Z})$, and they are also characterized by the property (3.95). See [57] for an explicit construction of such cycles.

Certainly, all of the components of $H^{2,2}_V(\hat{Z})$ are contained in (5.17), and some cycles from $H^{2,2}_{RM}(\hat{Z})$ also are, but we cannot say we have exhausted all the components of $H^{2,2}_{RM}(\hat{Z})$. Therefore we should use mirror symmetry, $h^{2,2}_H(\hat{Z}) = h^{2,2}_V(\hat{Z}_m)$, in order to determine $h^{2,2}_H(\hat{Z})$. That will be doable once we can construct a smooth model $\hat{Z}$ as a complete intersection Calabi-Yau of a toric ambient space [58, 59]. Such an analysis will be a generalization of what we have done in section 3. A crucial step in constructing such a smooth model is to carry out the resolution of the singularities in the Weierstrass model Z_s in toric language. This process was to add the points (4.41) in section 4.4.1. The essence of this procedure lies in the fact that the divisor S, the component of the discriminant locus for an

JHEP01(2015)047

I_5 fibre, is a toric divisor of B_3 (represented by a vertex in the polytope). This procedure works not just in the case when B_3 itself is toric (as in section 4.4.1), but also in cases where B_3 is regarded as a complete intersection in a toric ambient space $\mathbb{P}^k_{\Sigma'_*}$, as long as this property — S is regarded as a toric divisor of $P^k_{\Sigma'_*}$ restricted on B_3 — is maintained, as discussed in [51].[20] It is an extra step to verify that a further small resolution exists, which is equivalent to finding an appropriate triangulation of the polytope; a smooth model $\hat{Z}$ needs to come out as a complete intersection Calabi-Yau, while satisfying the flat-fibration condition [30]. It is beyond the scope of this article, however, to study all of these issues.

The examples discussed in section 4.4 indeed satisfy (5.16). In section 4.4, we furthermore found that $H^{2,2}_{RM} = 0$ for all examples. This of course fits with the facts that S was a toric divisor of the (toric) bases B_3 of the elliptic fibrations in all cases, so that all of $H^{1,1}(S)$ is obtained by restricting divisors of the base; at least there is no component in $H^{2,2}_{RM}$ that is characterized by (5.17) because of $\rho_S = \tilde{\rho}_B$.

6 Distribution of rank of unification group and number of generations

There is mounting evidence that the decomposition of $H^4(\hat{Z};\mathbb{R})$ of a Calabi-Yau fourfold $\hat{Z}$ in a family $\pi : \mathcal{Z} \longrightarrow \mathcal{M}_*$ has a non-trivial $H^{2,2}_{RM}(\hat{Z};\mathbb{R})$ component. In addition to the families of $\hat{Z} = \mathrm{K3} \times \mathrm{K3}$ in [16] (see also (1.5)), we have seen in sections 3–5 that the four-forms in $H^{2,2}_{RM}(\hat{Z};\mathbb{R})$ are often Poincaré dual to topologically non-trivial cycles on divisors. Flux in such a four-cycle violates the condition (2.3), and hence we are led to take $H_{\mathrm{scan}} \otimes \mathbb{R}$ to be the primary horizontal subspace $H^4_H(\hat{Z};\mathbb{R})$ of a family $\mathcal{Z} \longrightarrow \mathcal{M}_*$ specified by $(B_3, [S], R)$, for an ensemble with the same unbroken symmetry in the effective theories (as stated already in section 2).

The vacuum index density distribution $d\mu_I$ of such a subensemble of F-theory flux vacua becomes a product of a prefactor and a distribution ρ_I (top-dimensional differential form) on $\mathcal{M}_*$, as in (2.8), (2.9). Since the integral of ρ_I over the fundamental domain of $\mathcal{M}_*$ often returns a number of order unity (see [14]; so called "D-limit" regions may have to be removed from $\mathcal{M}_*$), the prefactor therefore gives an estimate of the number of flux vacua with a given set of gauge group, matter representations, multiplicities and choice of $(B_3, [S])$. The distribution of the value of coupling constants of such a class of low-energy effective theories is given by the distribution ρ_I on $\mathcal{M}_*$ without being integrated. In this article and ref. [22], we only discuss the physics consequences coming from the prefactor. We

[20] In case B_3 is a complete intersection of a toric ambient space $\mathbb{P}^k_{\Sigma'_*}$ and S is given by $s|_{B_3} = 0$ of some section $s \in \Gamma(\mathbb{P}^k_{\Sigma'_*}; \mathcal{O}(D_S))$ on the toric ambient space, (D_S is a Cartier divisor of the fine unimodular Σ'_*) it is possible to embed the original toric ambient space $\mathbb{P}^k_{\Sigma'_*}$ into another toric variety, the total space of $\mathcal{O}(D_S)$, by s, and so are B_3 and S. B_3 is still a complete intersection of the new toric ambient space, and now S is also regarded as a toric divisor, satisfying the condition in the main text. This case, however, lacks generality, in that the divisor class of S needs to be in the image of $i^* : \mathrm{Pic}(\mathbb{P}^k_{\Sigma'_*}) \longrightarrow \mathrm{Pic}(B_3)$. Such a situation can be improved by choosing a different embedding in many cases. An alternative approach exists in the case the divisor S of B_3 is very ample. One can use the projective embedding of B_3 using the complete linear system of S; the divisor S is regarded as the hyperplane divisor of the new ambient space $\mathbb{P}^{\dim|S|-1}$ restricted on the image of B_3, one of the conditions assumed in the main text. We do not know, however, what kind of conditions have to be imposed on B_3 so that the image of B_3 in $\mathbb{P}^{\dim|S|-1}$ is regarded as a complete intersection.

JHEP01(2015)047

learn how the number of vacua depends on the choice of the algebraic information (7-brane gauge group = unification group R) and topological information (number of generations $N_{\rm gen}$) of the low-energy effective theories, starting with concrete examples and extracting the essence later on.

Let us begin with the choice $R = \mathrm{SU}(5)$ for the unification group and use the $(B_3, [S])$ we studied explicitly already in section 4.4.1 (except the one with $B_3 = \mathbb{P}^3$). At the beginning, we pay attention to the sub-ensembles for individual $N_{\rm gen}$, the net chirality in the $\mathbf{10}+\bar{\mathbf{5}}$ vs $\overline{\mathbf{10}}+\mathbf{5}$ representations of SU(5). This is done by taking $H_{\rm scan}\otimes\mathbb{R}$ to be that of the real primary horizontal subspace of the families in section 4.4.1, and $G^{(4)}_{\rm fix}$ to be the flux generating chirality. As this class of F-theory compactifications has a dual description in Heterotic string theory, it is well-known how chirality is generated. For the Heterotic string compactified on an elliptically fibred Calabi-Yau threefold with the base $B_2 = S = \mathbb{P}^2$, $\pi_{\rm Het} : Z_{\rm Het} \longrightarrow B_2 = S$. Reference [60] introduced the origin of chirality in the form of

$$\gamma_{FMW} = \lambda_{FMW}\left[5j_*(\Sigma_{(\mathbf{10})}) - (\pi_{\rm Het}\cdot i_C)^*(\Sigma_{(\mathbf{10})})\right], \qquad \lambda_{FMW} \in \frac{1}{2}+\mathbb{Z}, \tag{6.1}$$

where γ is a divisor with (possibly half) integral coefficient on a spectral surface $C \subset Z_{\rm Het}$, $i_C : C \hookrightarrow Z_{\rm Het}$ and $j : \Sigma_{(\mathbf{10})} \hookrightarrow C$ are the embedding maps. It is known from [61, 62] that

$$N_{\rm gen} = -(18-n)(3-n)\lambda_{FMW}. \tag{6.2}$$

The F-theory dual description of γ_{FMW} has also been known in the literature [25]; necessary details are reviewed briefly in the appendix C; see (C.2) for the explicit form of the flux. The maximum contribution to the D3-brane charges from $G^{(4)}_{\rm scan}$, L_*, is given by (C.1), where $G^{(4)}_{\rm fix}$ is assumed to be orthogonal to the scanning space $H_{\rm scan}$.

The flux scanning space $H_{\rm scan}\otimes\mathbb{R}$ is chosen to be the real primary horizontal subspace $H^4_H(\hat{Z};\mathbb{R})$, for the reason discussed in section 2. The dimension of this subspace, K, and the value of L_* above, are computed in section 4.4.1 and appendix C, respectively. These numbers can be fed into the prefactor $(2\pi L_*)^{K/2}/[(K/2)!]$ in (2.8).

We should note by looking at the values of L_* and K summarized in table 6, however, that the condition $K \ll L_*$ is not satisfied. It is thus expected that the formula (2.8) is not going to be very precise. In fact, it is not surprising that $L_* \ll K$ holds in the examples of our interest, rather than $L_* \gg K$. As we have considered base spaces with only small $h^{1,1}$, the resulting fourfolds $\hat{Z}$ also only have a rather small number of divisors whereas $h^{3,1}(\hat{Z})$ is rather large. More generally, one could try to argue that taking B_3 to be Fano leads to $h^{3,1}(\hat{Z}) \gg h^{1,1}(\hat{Z})$. In any case, $h^{2,2}_H \gg h^{2,2}_V$ in table 2 should be regarded as a natural consequence of $h^{3,1} \gg h^{1,1}$. Although we do not have a general feeling about when $h^{2,2}_{RM}$ becomes large or small relatively to $h^{2,2}_H$ or $h^{2,2}_V$ for general Calabi-Yau fourfolds, at least the remaining component is much smaller than the horizontal component in dimension, $h^{2,2}_{RM} \ll h^{2,2}_H$, in table 2. It seems reasonable to even make a guess from this experience and the result (1.5) that $h^{2,2}_{RM} \ll \max[h^{2,2}_H, h^{2,2}_V]$ whenever $h^{3,1} \gg h^{1,1}$ or $h^{3,1} \ll h^{1,1}$.

In cases where

$$h^{3,1} \gg h^{1,1}, \qquad h^{2,2}_H \gg h^{2,2}_V, \qquad h^{2,2}_H \gg h^{2,2}_{RM}, \quad \text{and} \quad h^{2,1} \approx \mathcal{O}(1), \tag{6.3}$$

JHEP01(2015)047

we find a relation

$$\chi(\hat{Z}) \approx K, \qquad L_*|_{G_{\rm fix}^{(4)}=0} \sim \frac{\chi(\hat{Z})}{24} \sim \frac{K}{24}, \tag{6.4}$$

which implies $L_* \ll K$. In such cases, one can even use (3.62) to derive a relation

$$K \approx 6h^{3,1} + \text{const.}, \tag{6.5}$$

where the constant term comes from "44" in (3.62); the relation (3.62) implies that $h_H^{2,2}$ does not increase quadratically in $h^{3,1}$, but only linearly.

Let us now try to find a better estimate for the number of vacua when $L_* \ll K$ holds. The reason (2.8) predicts essentially no vacua in this case is that it approximates the number of lattice points at a specific distance L_* from the origin in a K dimensional lattice by the surface area of a sphere. We hence count the number of lattice points at 'generic' positions on such a sphere. If we increase the dimension K while holding L_* fixed it is hence no surprise that no such points remain. This does not mean, however, that there are no more solutions; this is easily seen by restricting the flux quanta to an n-dimensional subspace. Applying (2.8), we then count the points at generic positions of an n-dimensional sphere.

Following this logic, we may approximate the number of flux vacua in the case $L_* \ll K$ by[21]

$$\sum_{n=1}^{L_*} \binom{K}{n} \frac{(2\pi L_*)^{n/2}}{(n/2)!}\,. \tag{6.6}$$

The reason we only sum contributions up to $n = L_*$ is that we expect no more solutions with $n > L_*$ non-zero flux quanta switched on. We may further approximate the above sum by only taking the dominant contribution, corresponding to the last term with $n = L_*$. This gives the estimate

$$\binom{K}{L_*} \frac{(2\pi L_*)^{L_*/2}}{(L_*/2)!} \approx e^{L_* \ln(\sqrt{2\pi}K/L_*)} \tag{6.7}$$

for the number of flux vacua in the case $L_* \ll K$.

L_* is always an upper convex quadratic function of $N_{\rm gen}$,

$$L_* = L_*|_{G_{\rm fix}^{(4)}=0} - cN_{\rm gen}^2 \tag{6.8}$$

for some $c > 0$ as in (C.6), and we can expand the exponent in terms of $N_{\rm gen}$ for relatively small number of generations. Retaining only the next-to-leading term and using (6.4) we obtain

$$\exp[L_*|_{G_{\rm fix}^{(4)}=0} \ln(K/L_*|_{G_{\rm fix}^{(4)}=0}) - cN_{\rm gen}^2(1 + \ln(K/L_*|_{G_{\rm fix}^{(4)}=0}))] \tag{6.9}$$

$$\simeq\ e^{K/6} \exp\left[-5cN_{\rm gen}^2\right]. \tag{6.10}$$

for the distribution of vacua as a function of $N_{\rm gen}$.

It is interesting to note that the distribution function (6.10) has a factorized form. The first factor $e^{K/6}$ depends on the algebraic information such as R as well as $(B_3, [S])$,

[21] A similar approach to tackle cases with $L_* \ll K$ is proposed in [14].

JHEP01(2015)047

but it does not depend on $N_{\rm gen}$. The second factor contains the $N_{\rm gen}$-dependence. The distribution function on the value of coupling constants of the low-energy effective theories, ρ_I, can be multiplied to (6.10), as it was in (2.8), if one wishes. One should not expect that the formula (2.9) remains to be a very good approximation at the quantitative level because the condition $K \ll L_*$ does not hold, but still it is not terribly bad to expect that ρ_I still retains qualitative aspects of the distribution of the coupling constants after smearing over local regions in the moduli space $\mathcal{M}_*$.

The distribution of the number of generations in the low-energy effective theories is given by the second factor, which is the Gaussian distribution with the variance $1/(10c)$, for relatively small $N_{\rm gen}$. This should be regarded as a very robust prediction of landscapes based on F-theory flux compactification, as long as the condition (6.3) is satisfied in the relevant family of fourfolds $\pi : \mathcal{Z} \longrightarrow \mathcal{M}_*^R$. As for the coefficient c in (6.8), we can read it out from (C.6),

$$c = \frac{5}{(18-n)(3-n)}, \tag{6.11}$$

for the examples we studied in section 4.4.1. Also for many other choices of $(B_3, [S])$, the coefficient c is determined by the intersection ring associated with only a few divisors in $\hat{Z}$, and is expected to be more or less of order unity, as in (6.11). Of course the Gaussian distribution is not a good approximation for $N_{\rm gen}^2$ large enough to be comparable to the absolute limit $\chi(\hat{Z})/24$; the distribution absolutely vanishes, since it is impossible to satisfy the D3-tadpole condition without supersymmetry breaking. Since the value of $\chi(\hat{Z})/24$ often comes at the order of hundreds to thousands [9, 12, 63], however, the distribution of $N_{\rm gen}$ is approximately Gaussian at least for the range $N_{\rm gen} \lesssim 10$. The distribution for this range (covering $N_{\rm gen} = 3$) will be sufficient information for our practical interest. The variance $\langle N_{\rm gen}^2 \rangle$ is of order $1/(10c) \sim 10^{-1}$.

Let us now focus on the first factor of the distribution function (6.10), $e^{K/6}$, from which we learn the statistical cost of unified symmetry (7-brane gauge group) R with higher rank. For the purpose of taking ratios of the number of vacua with different unified symmetries R_1 and R_2, the ratio $e^{(K_1-K_2)/6}$ may be studied instead by $e^{h_1^{3,1}-h_2^{3,1}}$, when the condition (6.3) is satisfied. This makes things much easier, since it is much easier to compute/estimate $h^{3,1}$ than $h_H^{2,2}$. Appendix B exploits this $\Delta K \approx 6\Delta h^{3,1}$ relation and develops the discussion further. In the rest of this section, however, we stick to the dimension K of the primary horizontal space. It is also worth mentioning that $e^{K/6}$ is regarded as a refinement of the popular "10^{500}", a crude estimate of the number of flux vacua of Type IIB Calabi-Yau orientifold compactifications.

It has been widely accepted at the intuitive level that more general flux leads to geometry stabilized at more general values of the complex structure, and hence with less unbroken symmetry (fewer independent divisors). This intuition has been made quantitative by the factor $e^{K/6}$; ref. [16] used a family of Calabi-Yau fourfolds that are topologically $\hat{Z} = \mathrm{K3} \times \mathrm{K3}$, and the computation of K for other families in this article adds more examples. The results in the family $\hat{Z} = \mathrm{K3} \times \mathrm{K3}$ and in the cases in section 4.4 remain similar, though there is difference in detail. In the family of $\hat{Z} = \mathrm{K3} \times \mathrm{K3}$, K is linear in the rank of 7-brane gauge group, and $K = 21 \times (20 - \mathrm{rank}_7)$ (where vanishing cosmological constant is not required;

$\Delta K_{4\text{-}5}$	87	165	123	87	57	33	15	4	21

Table 4. The value of $K_{R=\phi}$, $K_{R=A4}$ and $K_{R=D5}$ in the first three rows are extracted from tables 1, 2 and 3, respectively. In the case $B_3 = \mathbb{P}^1 \times$ K3, the value of $\Delta K_{0\text{-}4} = K_{R=\phi} - K_{R=A4}$ and $\Delta K_{4\text{-}5} = K_{R=A4} - K_{R=D5}$ is determined by using $21 \times \Delta\text{rank}_7$.

see [16] for more). The value of K becomes smaller for a subensemble with higher-rank unification group R. This remains true in the cases we studied in section 4.4 (see table 4).

At the quantitative level, the difference in the dimension of the flux scanning space K for SU(5) unification and SO(10) unification, $K_{R=A4} - K_{R=D5}$, remains more or less around order $\mathcal{O}(10)$ for all the geometries listed in table 4, and the ratio of the number of vacua with a stack of SU(5) 7-branes to that with a stack of SO(10) 7-branes remains of order $e^{\mathcal{O}(10)}$. The fraction of vacua with a stack of SU(5) 7-branes in $[S]$ in all the flux vacua on B_3 is given by $e^{-\Delta K_{0\text{-}4}/2}$; the value of $\Delta K_{0\text{-}4} = K_{R=\phi} - K_{R=A4}$ can be 1000–10000 for $B_3 = \mathbb{P}^3$ and $B_3^{(n)}$ studied in section 4.4, as opposed to the value $\Delta K_{0\text{-}4} \sim 100$ in the family $\hat{Z} =$ K3 $\times$ K3. As we have discussed, we may estimate $\Delta K_{R_1 R_2}$ by (six times) the number of complex structure moduli which are fixed when enhancing R_1 to R_2. The result for $\hat{Z} =$ K3 $\times$ K3 is certainly very special. For more general fourfolds, where the number of moduli is much larger, it seems plausible that the number of complex structure moduli we need to fix to achieve a gauge group of rank 4 or 5 is typically $\mathcal{O}(100)$ to $\mathcal{O}(1000)$, irrespective of the specific $(B_3, [S])$ used. Besides our concrete results (summarized in table 4), such numbers are typical for the dimensions of the middle cohomology of Calabi-Yau fourfolds.

Note that we have assumed a fixed choice of $[S]$ so far. This way of thinking is perfectly reasonable when comparing the statistical cost of enhancing a group of low rank, which we assume is given on $[S]$, to a group of higher rank. When we want to tackle the physically more interesting question of comparing the abundance of models with no gauge group to a model with gauge group R for *some* $[S]$, we need to be able to sum over various choices of $[S]$. While we do not expect this to make a relevant contribution in cases where $h^{1,1}(B_3)$ is small, an exhaustive discussion is beyond the scope of the present work.

7 Outlook

Let us leave a few remarks on open problems at the end of the main text. We start off with an obvious open problem of mathematical flavour. The study we carried out in section 3 for toric-hypersurface Calabi-Yau fourfolds has a clear generalization to Calabi-Yau fourfolds obtained as complete intersection in toric ambient spaces [58, 59]. This makes it possible to determine the dimension of the primary horizontal subspace $H^4_H(\hat{Z}; \mathbb{R})$ and

JHEP01(2015)047

also to elucidate the geometric origin of the cycles in the remaining component $H^{2,2}_{RM}(\hat{Z})$ for more general cases. We stopped at the level of finding evidence that $H^{2,2}_{RM}(\hat{Z})$ is non-empty in geometries that are motivated for phenomenological applications, and provided their geometric characterization (3.95) for the cycles we identified; not all of the cycles in the remaining component may have been found, however. More detail will be learned about this geometry by this generalization, as we already stated at the end of section 5.

One can come up with various physics applications of the idea developed in [14–16, 64] and this article. For example, it is an interesting question whether SU(5) unification due to the presence of a stack of SU(5) 7-brane is more "natural" than accidental gauge coupling unification in supersymmetric Standard Models with stacks of U(3), U(2) and U(1) D7-branes wrapped on different topological cycles, with one U(1) remaining anomaly free. At least by comparing the number of flux vacua in those two categories, we will have a partial information that is needed in answer to this "naturalness" question. Although a very crude baby-version study was carried out in [16], this question deserves much more serious study.

This article did not try to include the symmetry breaking $\mathrm{SU}(5)_{\mathrm{GUT}} \longrightarrow \mathrm{SU}(3)_C \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$. If one is to use the geometry with non-surjective $H^{1,1}(B_3) \longrightarrow H^{1,1}(S)$ as motivated in [20, 21], the flux $G^{(4)}_{\mathrm{fix}}$ needs to have non-zero component both in $H^{2,2}_{V}(\hat{Z})$ for $N_{\mathrm{gen}} \neq 0$, and in $H^{2,2}_{RM}(\hat{Z})$ for the $\mathrm{SU}(5)_{\mathrm{GUT}}$ symmetry breaking. One then needs to think more carefully about the integral structure (flux quantization) of the space $H^{2,2}_{V}(\hat{Z}) \oplus H^{2,2}_{RM}(\hat{Z}) \oplus H^{2,2}_{H}(\hat{Z})$; a study of the integral structure in the H_{mon} component is found in [17, 18]. Note also that if we set $G^{(4)}_{\mathrm{fix}}$ so that $G^{(4)}_{\mathrm{scan}} = 0$ is contained in H_{scan}, then $G^{(4)}_{\mathrm{fix}}$ may not always be orthogonal to the elements of H_{scan}.

The statistical cost of requiring an extra global U(1) symmetry can also be studied by computing the dimension $K = \dim_{\mathbb{R}}[H_{\mathrm{scan}} \otimes \mathbb{R}]$. One needs to be careful in how we take the scanning space of the flux H_{scan}. The U(1) vector field does not have to remain in the massless spectrum (indeed, we do not want it to be), but its symmetry should not be broken spontaneously (possibly apart from non-perturbative symmetry breaking exponentially suppressed to the level harmless in phenomenology). Eventually this statistical cost needs to be compared against the cost of alternatives. In the application to the dimension-4 proton decay problem, an alternative will be a discrete symmetry, while in the application to the "approximately rank-1" problem of Yukawa matrices (cf. [65, 66]), the alternative is to tune a moduli parameter. See also [18].

Obviously one can also exploit the distribution ρ_I in (2.9) to study distribution of the values of the coupling constants in a low-energy effective theory. Certainly the formula[22] (2.9) is not expected to be very precise, because we expect $L_* \ll K$ in many cases. Experience in explicit numerical studies suggests (see [15] and also figure 5 of [16]) that qualitative aspects of the actual distribution are still captured by the distribution function ρ_I even in cases where $L_* \ll K$.

[22] See [18] and references therein for the period integral computation to be used in formula (2.9). In the presence of corrections to the Kähler potential $-\ln[\int_{\hat{Z}} \Omega \wedge \overline{\Omega}]$, ρ_I may not be given simply by the formula (2.9) with the Weil-Peterson metric of $\mathcal{M}_*$. The authors thank Y. Nakayama and Y. Sumitomo for raising this issue.

JHEP01(2015)047

It should also be noted that the scanning component of the flux, $G^{(4)}_{\rm scan}$, may play another role in addition to determining the coupling constants of the low-energy effective theories. All the fluxes in the form of $G^{(4)}_{\rm fix} + G^{(4)}_{\rm scan}$ with $G^{(4)}_{\rm scan} \in H^4_H(\hat{Z};\mathbb{R})$ give rise to effective theories with the same $N_{\rm gen}$, but the number of extra vector-like pairs of matter in the $\mathrm{SU}(5)_{\rm GUT}$ $\bar{\mathbf{5}}+\mathbf{5}$ representations may vary among such an ensemble of vacua. It has been known widely since the work of [67] that there tend to be many vector-like pairs that do not seem to be present in supersymmetric Standard Models that work phenomenologically well. It took an enormous effort to find a topological choice that leads to small number of vector like pairs. Such studies as [65, 67], however, are equivalent to only use the flux $G^{(4)}_{\rm fix}$ in the form of (C.2), or γ_{FMW} in (6.1), and set $G^{(4)}_{\rm scan} = 0$. With the freedom for $G^{(4)}_{\rm scan}$, however, there may be a new insight on the issue of the number of vector like pairs.

As already mentioned in section 3.6.1, specifying fluxes in F-theory (or, more generally M-theory) backgrounds via a four-form G_4 in (co)homology is not sufficient information to properly characterize all degrees of freedom [68, 69]. In particular, we need to specify the three form C_3. It is an open problem how to include this data in the vacuum counting problem, i.e. the setup of [14, 15].

A Geometry of elliptic-fibred Calabi-Yau fourfold for general F-theory SU(5) models

A.1 Construction

The geometry considered in section 5, smooth elliptically fibred Calabi-Yau fourfolds for general F-theory SU(5) models, has been studied in [25, 30, 70], see also [51, 71]. We briefly review the construction of the geometry here, so that no ambiguity remains in the notation used.

The construction begins with an ambient space

$$A_0 := \mathbb{P}\left[\mathcal{O}_{B_3} \oplus \mathcal{O}_{B_3}(-2K_{B_3}) \oplus \mathcal{O}_{B_3}(-3K_{B_3})\right], \tag{A.1}$$

where B_3 is a complex 3-dimensional (Fano) variety. A fourfold Z_s is defined as a hypersurface of A_0 by the equation (5.1). The projection $\pi_{A_0} : A_0 \longrightarrow B_3$ defines an elliptic fibration morphism $\pi_{Z_s} : Z_s \longrightarrow B_3$.

Let X_3, X_2 and X_3 be the homogeneous coordinates corresponding to the $W\mathbb{P}^2_{1:2:3}$ fibre of the ambient space $\pi_{A_0} : A_0 \longrightarrow B_3$, and σ be the zero section defined by $X_3 = 0$. D_{X_1}, D_{X_2} and D_{X_3} denotes the zero locus of X_1, X_2 and X_3 in A_0, respectively. It follows that

$$D_{X_1} \sim 3\left(\sigma + c_1(B_3)\right), \qquad D_{X_2} \sim 2\left(\sigma + c_1(B_3)\right). \tag{A.2}$$

JHEP01(2015)047

Consider a line bundle on B_3, and let s be a global holomorphic section of this line bundle. The divisor defined by the zero locus of s is denoted by S, i.e. $s \in \Gamma(B_3; \mathcal{O}_{B_3}(S))$. The section s is used in the hypersurface equation of Z_s in (5.1), which implements the condition for an I_5 Kodaira fibre over S [72]. The divisor $\pi_{A_0}^*(S)$ in A_0 is denoted by D_S.

First blow-up. The fourfold Z_s has A_4 singularity along a subvariety of A_0 given by

$$Y_1 := D_S \cdot D_{X_1} \cdot D_{X_2}. \tag{A.3}$$

Thus, we blow up at this locus and let $A_1 := \mathrm{Bl}_{Y_1} A_0$. The blow-up morphism is denoted by $\nu_1 : A_1 \longrightarrow A_0$, and the exceptional divisor by $\mathcal{E}_1$. The center of the blowup Y_1 is contained in Z_s, and Z_s is of multiplicity $k = 2$ along Y_1. Thus,

$$\nu_1^*(Z_s) = Z_s^{(1)} + 2\mathcal{E}_1, \tag{A.4}$$

where $Z_s^{(1)}$ is the proper transform of Z_s. The proper transforms of D_S, D_{X_1} and D_{X_2} are denoted by $D_S^{(1)}$, $D_{X_1}^{(1)}$ and $D_{X_2}^{(1)}$, respectively.

Second blow-up. The fourfold $Z_s^{(1)}$ still has a singularity of type A_2 along the subvariety

$$Y_2 := \mathcal{E}_1 \cdot D_{X_1}^{(1)} \cdot D_{X_2}^{(1)} \tag{A.5}$$

in A_1. Thus, let $A_2 := \mathrm{Bl}_{Y_2} A_1$. The blow-up morphism is denoted by $\nu_2 : A_2 \longrightarrow A_1$, and the exceptional divisor $\mathcal{E}_2$. The hypersurface $Z_s^{(1)}$ of A_1 contains Y_2 with the multiplicity 2, and hence

$$\nu_2^*(Z_s^{(1)}) = Z_s^{(2)} + 2\mathcal{E}_2, \tag{A.6}$$

where $Z_s^{(2)}$ is the proper transform of $Z_s^{(1)}$ under this blow-up morphism. The proper transforms of $\mathcal{E}_1$, $D_{X_1}^{(1)}$ and $D_{X_2}^{(1)}$ are denoted by $\mathcal{E}_1^{(2)}$, $D_{X_1}^{(2)}$ and $D_{X_2}^{(2)}$, respectively. $\nu_2^*(D_S^{(1)})$ is denoted by $D_S^{(2)}$.

Small resolution. The fourfold $Z_s^{(2)}$ still has singularities at loci with codimension higher than two. These singularities can be resolved while the proper transform of $Z_s^{(2)}$ remains a flat family of curves over B_3 [30]. We provide a description of two such small resolutions in the following. The two small resolutions correspond, when B_3 and $[S]$ are the ones studied in section 4.4.1, to having $\langle \vec{v}_{e_1}, \vec{v}_{e_3} \rangle$ in the SR ideal, or having $\langle \vec{v}_{e_2}, \vec{v}_{e_4} \rangle$ in the SR ideal. We only describe the first resolution in detail and then add a brief comment concerning the second type.

Small resolution [a]. Let $Y_3^{[a]} := \mathcal{E}_1^{(2)} \cdot D_{X_1}^{(2)}$, and $A_3^{[a]} := \mathrm{Bl}_{Y_3^{[a]}} A_2$. The blow-up morphism is $\nu_3^{[a]} : A_3^{[a]} \longrightarrow A_2$, and the exceptional divisor is $\mathcal{E}_3^{[a]}$. The hypersurface $Z_s^{(2)}$ of A_2 contains $Y_3^{[3]}$ with multiplicity 1, and hence

$$(\nu_3^{[a]})^*(Z_s^{(2)}) = Z_s^{(3)[a]} + \mathcal{E}_3^{[a]}, \tag{A.7}$$

where $Z_s^{(3)[a]}$ is the proper transform of $Z_s^{(2)}$ under the morphism $\nu_3^{[a]}$. Proper transforms of other divisors in A_2 are denoted by

$$(\nu_3^{[a]})^*(\mathcal{E}_1^{(2)}) = \mathcal{E}_1^{(3)[a]} + \mathcal{E}_3^{[a]}, \quad (\nu_3^{[a]})^*(D_{X_1}^{(2)}) = D_{X_1}^{(3)[a]} + \mathcal{E}_3^{[a]} \tag{A.8}$$

JHEP01(2015)047

for divisors involved in the blow-up, and $D_{X_2}^{(3)[a]} := (\nu_3^{[a]})^*(D_{X_2}^{(2)})$, $D_S^{(3)[a]} := (\nu_3^{[a]})^*(D_S^{(2)})$ and $\mathcal{E}_2^{(3)[a]} := (\nu_3^{[a]})^*(\mathcal{E}_2)$ for the others.

The fourfold $Z_s^{(3)[a]}$ only becomes non-singular after one more step of blow-up in the ambient space. Let us take $Y_4^{[a]} := \mathcal{E}_2^{(3)[a]} \cdot D_{X_1}^{(3)[a]}$ as the centre of the blow-up; $A_4^{[a]} := \mathrm{Bl}_{Y_4^{[a]}} A_3^{[a]}$. The blow-up morphism is denoted by $\nu_4^{[a]} : A_4^{[a]} \longrightarrow A_3^{[a]}$, and the exceptional divisor by $\mathcal{E}_4^{[a]}$. The hypersurface $Z_s^{(3)[a]}$ of $A_3^{[a]}$ contains $Y_4^{[a]}$ with the multiplicity 1, and hence

$$(\nu_4^{[a]})^*(Z_s^{(3)[a]}) = \hat{Z}^{[a]} + \mathcal{E}_4^{[a]}. \tag{A.9}$$

The proper transforms of other divisors of A_3 are

$$(\nu_4^{[a]})^*(\mathcal{E}_2^{(3)[a]}) = \mathcal{E}_2^{(4)[a]} + \mathcal{E}_4^{(4)[a]}, \qquad (\nu_4^{[a]})^*(D_{X_1}^{(3)[a]}) = \hat{D}_{X_1}^{[a]} + \mathcal{E}_4^{(4)[a]}, \tag{A.10}$$

and

$$(\nu_4^{[a]})^*(D_{X_2}^{(3)[a]}) = \hat{D}_{X_2}^{[a]}, \qquad (\nu_4^{[a]})^*(D_S^{(3)[a]}) = \hat{D}_S^{[a]}, \tag{A.11}$$

$$(\nu_4^{[a]})^*(\mathcal{E}_1^{(3)[a]}) = \mathcal{E}_1^{(4)[a]}, \qquad (\nu_4^{[a]})^*(\mathcal{E}_3^{[a]}) = \mathcal{E}_3^{(4)[a]}. \tag{A.12}$$

In order to simplify the notation, we now relabel the exceptional divisors according to their intersections. Over a generic point on S, the four exceptional divisors $\mathcal{E}_{1,2,3,4}^{(4)[a]}$ together with $D_S^{(4)[a]}$ meet according to the extended Dynkin diagram of A_4 (see the first picture in figure 10). Namely,

$$D_S^{(4)[a]} \equiv \hat{E}_0 \tag{A.13}$$

$$\mathcal{E}_1^{(4)[a]} \equiv \hat{E}_1 \qquad \mathcal{E}_2^{(4)[a]} \equiv \hat{E}_2 \tag{A.14}$$

$$\mathcal{E}_3^{(4)[a]} \equiv \hat{E}_4 \qquad \mathcal{E}_4^{(4)[a]} \equiv \hat{E}_3\,. \tag{A.15}$$

As a consequence of four successive morphisms, $(\nu_{\mathrm{tot}}^{[a]} := \nu_1 \cdot \nu_2 \cdot \nu_3^{[a]} \cdot \nu_4^{[a]}) : A_4 \longrightarrow A_0$,

$$\nu_{\mathrm{tot}}^*(Z_s) = \hat{Z}^{[a]} + 2\hat{E}_1 + 4\hat{E}_2 + 5\hat{E}_3 + 3\hat{E}_4. \tag{A.16}$$

One also finds that

$$\nu_{\mathrm{tot}}^*(D_S) = \hat{D}_S + \hat{E}_1 + \hat{E}_2 + \hat{E}_3 + \hat{E}_4, \tag{A.17}$$

$$\nu_{\mathrm{tot}}^*(D_{X_2}) = \hat{D}_{X_2}^{[a]} + \hat{E}_1 + 2\hat{E}_2 + 2\hat{E}_3 + \hat{E}_4, \tag{A.18}$$

$$\nu_{\mathrm{tot}}^*(D_{X_1}) = \hat{D}_{X_1}^{[a]} + \hat{E}_1 + 2\hat{E}_2 + 3\hat{E}_3 + 2\hat{E}_4. \tag{A.19}$$

A simple way to represent intersections among divisors of the ambient space is by a diagram such as figure 9. It organizes the information in the same way as a fan over faces of a polytope does in the context of toric geometry. In fact, figure 9 is a two-dimensional projection of a A_4 'top' with a triangulation corresponding to the resolution $[a]$.

The divisors $\hat{D}_{X_1}$, $\hat{D}_{X_2}$, $\hat{E}_{1,2,3,4}$ and $\hat{E}_0$ of $A_4^{[a]}$ define divisors of $\hat{Z}^{[a]}$. They are denoted by $\hat{Y}_{X_1}$, $\hat{Y}_{X_2}$, $\hat{Y}_{1,2,3,4}$ and $\hat{Y}_0$, respectively.

JHEP01(2015)047

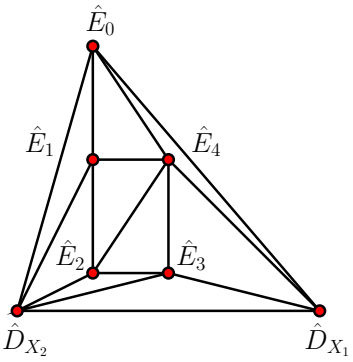

Figure 9. A schematic diagram showing how (some of) the divisors of the ambient space $A_4^{[a]}$ intersect; if a set of points in this diagram does not share a simplex, the corresponding divisors has empty intersection. This diagram shows the history of successive blow-ups starting from the original ambient space A_0. This diagram for $A_4^{[b]}$ is such that the 1-simplex joining $\hat{E}_2$ and $\hat{E}_4$ is replaced by another joining $\hat{E}_1$ and $\hat{E}_3$. In the examples we used in section 4.4.1, this diagram appears in the form of 2-dimensional faces of the polytope $\widetilde{\Delta}$.

Small resolution [b]. In an alternative small resolution, one can take $Y_3^{[b]} := \mathcal{E}_2 \cdot D_{X_1}^{(2)}$ in A_2, so that $A_3^{[b]} := \mathrm{Bl}_{Y_3^{[b]}} A_2$. In the next step, the subvariety $Y_4^{[b]} := \mathcal{E}_1^{(3)[b]} \cdot D_{X_1}^{(3)[b]}$ of $A_3^{[b]}$ is chosen as the centre of the blow-up; it will be clear what the divisors $\mathcal{E}_1^{(3)[b]}$ and $D_{X_1}^{(3)[b]}$ stand for. The resulting non-singular fourfold is denoted by $\hat{Z}^{[b]}$.

Note that in the small resolution [b] $\mathcal{E}_4^{[b]}$ corresponds to the fourth fibre component and $\mathcal{E}_3^{(4)[b]}$ to the third, instead of the other way around. By computing which intersections between the exceptional divisors vanish, one finds that this resolution furthermore corresponds to a triangulation where the line connection between $\hat{E}_2$ and $\hat{E}_4$ has been replaced by a line from $\hat{E}_1$ to $\hat{E}_3$

It is obvious from this property of the intersection ring that $\hat{Z}^{[a]}$ and $\hat{Z}^{[b]}$ are not the same geometries. In fact, we can turn $\hat{Z}^{[a]}$ into $\hat{Z}^{[b]}$ by a flop transition, which can already be anticipated from the fact that they only differ by a small resolution. The rich net of phases connected by flop transitions in F-theory compactifications with non-abelian gauge groups and the connection to group- and gauge theory has been explored in [30–35].

Any physics consequences in an SU(5) symmetric vacuum should remain the same whether the resolution [a] or [b] is used in formulating the flux background, as we have remarked in section 2. It is quite likely (see section 2) that $h_V^{2,2}$, $h_H^{2,2}$ and $h_{RM}^{2,2}$ will indeed turn out to be the same for both [a] and [b]. For this reason, we pay attention only to the small resolution [a] described above, and use in section 5 in the main text, as well as in the rest of this appendix. The superscript [a] will hence be dropped completely in the following.

A.2 Degeneration of singular fibres in higher codimension

An elliptic fibration $\pi_{\hat{Z}} : \hat{Z} \longrightarrow B_3$ is obtained by restricting $(\pi_{A_4} := \pi_{A_0} \cdot \nu_{\mathrm{tot}}) : A_4 \longrightarrow B_3$ on $\hat{Z} \subset A_4$. In this notation, the total fibre class over $S \subset B_3$ is $\pi_{\hat{Z}}^*(S) = \hat{Y}_0 + \hat{Y}_1 + \hat{Y}_2 + \hat{Y}_3 + \hat{Y}_4$. Over a generic point in S, the fibres of this projection become curves

JHEP01(2015)047

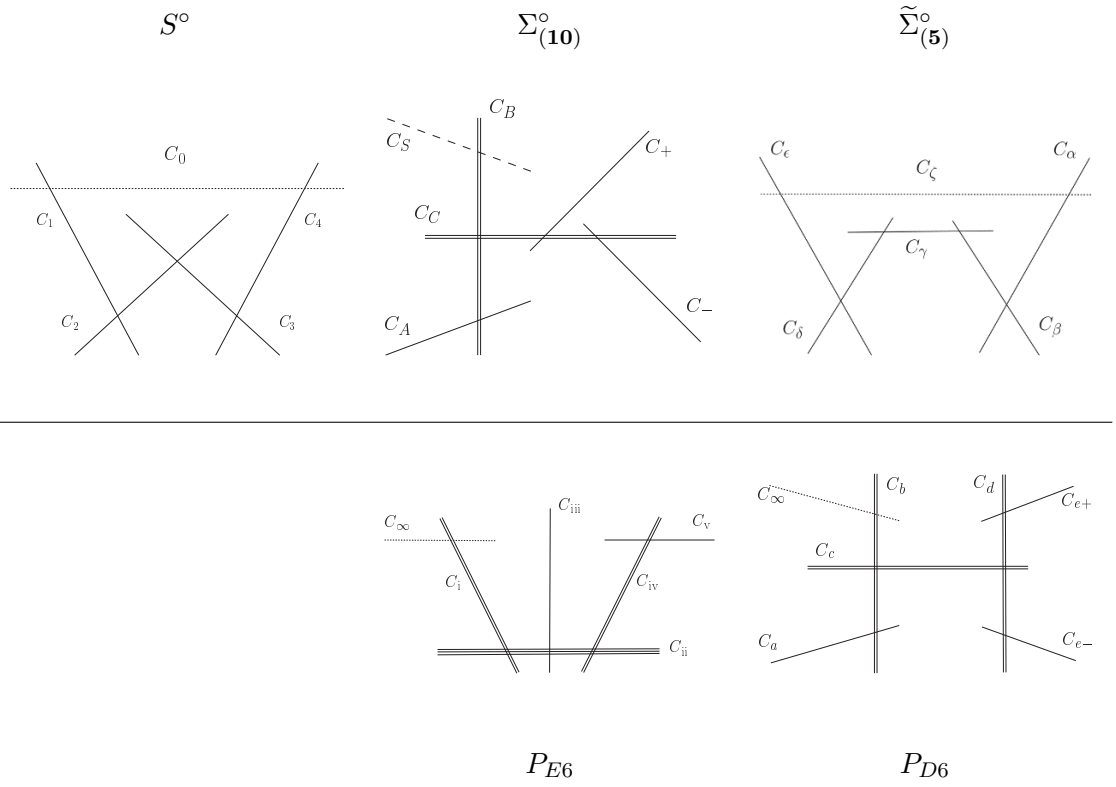

Figure 10. Schematic picture of how irreducible curves in singular fibre share points. This information is used in computing the Hodge diagrams of the divisors $\hat{Y}_{0,1,2,3,4}$ in section A.3.

$C_0+C_1+C_2+C_3+C_4$, which are all $\mathbb{P}^1$'s. A further restriction is given by only considering the divisors $\hat{Y}_i$, $\pi_{\hat{Y}_i}:\hat{Y}_i\longrightarrow S$.

Let us record known results on degeneration of singular fibre components, as we need them in the computation in the appendix A.3. The degeneration over the matter curve $\Sigma_{(\mathbf{10})}\subset S$ is:

$$\begin{aligned}
&\pi^*_{\hat{Y}_0}(\Sigma_{(\mathbf{10})})=S_\infty, \qquad &&\pi^*_{\hat{Y}_1}(\Sigma_{(\mathbf{10})})=S_B, \qquad &&\pi^*_{\hat{Y}_2}(\Sigma_{(\mathbf{10})})=S_C+S_+,\\
&\pi^*_{\hat{Y}_3}(\Sigma_{(\mathbf{10})})=S_-, \qquad &&\pi^*_{\hat{Y}_4}(\Sigma_{(\mathbf{10})})=S_A+S_B+S_C. &&
\end{aligned}\tag{A.20}$$

Within $\hat{Z}$, $\hat{Y}_1\cdot\hat{Y}_4=S_B$, and $\hat{Y}_2\cdot\hat{Y}_4=S_C$. At a generic point in $\Sigma_{(\mathbf{10})}$, the fibre becomes a collection of curves, $C_S+C_A+2C_B+2C_C+C_++C_-$, all $\mathbb{P}^1$'s.

The degeneration over the matter curve $\Sigma_{(\mathbf{5})}$ is:

$$\begin{aligned}
&\pi^*_{\hat{Y}_0}(\Sigma_{(\mathbf{5})})=S_\zeta, \qquad &&\pi^*_{\hat{Y}_1}(\Sigma_{(\mathbf{5})})=S_\epsilon, \qquad &&\pi^*_{\hat{Y}_2}(\Sigma_{(\mathbf{5})})=S_\delta,\\
&\pi^*_{\hat{Y}_3}(\Sigma_{(\mathbf{5})})=S_\gamma+S_\beta, \qquad &&\pi^*_{\hat{Y}_4}(\Sigma_{(\mathbf{5})})=S_\alpha, &&
\end{aligned}\tag{A.21}$$

Over a generic point in $\Sigma_{(\mathbf{5})}$ these surfaces become curves that are denoted by $C_{\alpha,\beta,\gamma,\delta,\epsilon}$ and C_ζ, respectively.

At any one of E_6 points,

$$C_0\longrightarrow C_\infty, \qquad C_1\longrightarrow C_{\rm i}, \qquad C_2\longrightarrow C_{\rm ii}+C_{\rm iii},$$

JHEP01(2015)047

$$C_3 \longrightarrow C_{\rm iv} + C_{\rm v}, \qquad C_4 \longrightarrow C_{\rm i} + 2C_{\rm ii} + C_{\rm iv}, \tag{A.22}$$

At any one of D_6 points,

$$\begin{aligned} &C_0 \longrightarrow C_\infty, && C_1 \longrightarrow C_b, && C_2 \longrightarrow C_c + C_d, \\ &C_3 \longrightarrow C_d + C_{e+} + C_{e-}, && C_4 \longrightarrow C_a + C_b + C_c \end{aligned} \tag{A.23}$$

A.3 Computation of Hodge numbers of the exceptional divisors $\hat{Y}_i = \hat{E}_i|_{\hat{Z}}$

Using the result reviewed in the appendix A.2 and the stratification described in section 5.1, we compute the Hodge numbers of the divisors $\hat{Y}_{0,1,2,3,4}$ in $\hat{Z}$. The computation of $\chi(\hat{Z})$ in [55] is similar in spirit.

Let us first work out the Hodge-Deligne numbers of the various strata of the surface $S \subset B_3$. Using the divisor $\eta := c_1(N_{S|B_3}) + 6c_1(S)$ on S the number of E_6 and D_6 points is given by

$$N_E := (5K_S + \eta) \cdot (4K_S + \eta), \qquad N_D := (5K_S + \eta) \cdot (3K_S + \eta). \tag{A.24}$$

Thus the only non-vanishing $e_c^{p,q}$ of P_{E6} and P_{D6} are

$$e_c^{0,0}(P_{E6}) = N_E, \qquad e_c^{0,0}(P_{D6}) = N_D\,. \tag{A.25}$$

The genus g_{10} of the matter curve $\Sigma_{(\mathbf{10})}$ is determined by

$$2g_{10} - 2 = (5K_S + \eta) \cdot (6K_S + \eta). \tag{A.26}$$

The complement of P_{E6} and P_{D6} in $\Sigma_{(\mathbf{10})}$, denoted by $\Sigma^\circ_{(\mathbf{10})}$, has the following Hodge-Deligne numbers:

$$e_c^{p,q}(\Sigma^\circ_{(\mathbf{10})}) = \begin{vmatrix} -g_{10} & 1 \\ (1 - N_E - N_D) & -g_{10} \end{vmatrix}. \tag{A.27}$$

The genus g_5 of the matter curve $\Sigma_{(\mathbf{5})}$ is formally given by

$$2g_5 - 2 = (10K_S + 3\eta) \cdot (11K_S + 3\eta)\,. \tag{A.28}$$

However, there is a double point singularity at each of the points in P_{D6}. The resolved curve $\widetilde{\Sigma}_{(\mathbf{5})}$ has the genus

$$\tilde{g}_5 = g_5 - N_D. \tag{A.29}$$

The curve $\widetilde{\Sigma}^\circ_{(\mathbf{5})}$ is obtained by removing the points P_{E6} and the lift of the points P_{D6} from $\widetilde{\Sigma}_{(\mathbf{5})}$. Thus we find that

$$e_c^{p,q}(\widetilde{\Sigma}^\circ_{(\mathbf{5})}) = \begin{vmatrix} -\tilde{g}_5 & 1 \\ (1 - N_E - 2N_D) & -\tilde{g}_5 \end{vmatrix}. \tag{A.30}$$

Finally, the Hodge-Deligne numbers of $S^\circ := S \backslash (\Sigma_{(\mathbf{10})} \cup \Sigma_{(\mathbf{5})})$ are obtained by using the additivity of $e_c^{p,q}$. Assuming that $h^{1,0}(S) = 0$, we find that

$$e_c^{p,q}(S^\circ) = (-)^{p+q} h^{p,q}(S) - e_c^{p,q}(\Sigma^\circ_{(\mathbf{10})}) - e_c^{p,q}(\widetilde{\Sigma}^\circ_{(\mathbf{5})}) - e_c^{p,q}(P_{E6}) - e_c^{p,q}(P_{D6})$$

JHEP01(2015)047

$$= \begin{vmatrix} h^{2,0}(S) & 0 & 1 \\ (g_{10}+\tilde{g}_5) & (h^{1,1}(S)-2) & 0 \\ (-1+N_E+2N_D) & (g_{10}+\tilde{g}_5) & h^{2,0}(S) \end{vmatrix} . \tag{A.31}$$

We are now ready to compute the Hodge numbers of the exceptional divisors $\hat{Y}_{0,1,2,3,4} = \hat{E}_{0,1,2,3,4}|_{\hat{Z}}$. Let us take $\hat{Y}_4$ as an example; the Hodge numbers of the other $\hat{Y}_i$ are determined analogously. The stratification of $\hat{Y}_4$ is:

$$\begin{aligned} \hat{Y}_4 = [C_4 \times S^\circ] \;\amalg\; \left[(C_A + C_B + C_C) \times \Sigma^\circ_{(\mathbf{10})}\right] \;\amalg\; \left[C_\alpha \times \widetilde{\Sigma}^\circ_{(\mathbf{5})}\right] \\ \amalg\; [(C_{\rm i} + C_{\rm ii} + C_{\rm iv}) \times P_{E6}] \;\amalg\; [(C_a + C_b + C_c) \times P_{D6}] \,. \end{aligned} \tag{A.32}$$

Using the multiplicativity and additivity of $e_c^{p,q}$, we find that

$$\begin{aligned} e_c^{2,2}(\hat{Y}_4) &= e_c^{1,1}(C_4)e_c^{1,1}(S^\circ) + e_c^{0,0}(C_4)e_c^{2,2}(S^\circ) \\ &\quad + e_c^{1,1}(C_A+C_B+C_C)e_c^{1,1}(\Sigma^\circ_{(\mathbf{10})}) + e_c^{1,1}(C_\alpha)e_c^{1,1}(\widetilde{\Sigma}^\circ_{(\mathbf{5})}) \\ &= (h^{1,1}(S)-2) + 1 + 3 + 1 = h^{1,1}(S) + 3, \end{aligned} \tag{A.33}$$

$$\begin{aligned} e_c^{2,1}(\hat{Y}_4) &= e_c^{1,1}(C_4)e_c^{1,0}(S^\circ) + e_c^{0,0}(C_4)e_c^{2,1}(S^\circ) \\ &\quad + e_c^{1,1}(C_A+C_B+C_C)e_c^{1,0}(\Sigma^\circ_{(\mathbf{10})}) + e_c^{1,1}(C_\alpha)e_c^{1,0}(\widetilde{\Sigma}^\circ_{(\mathbf{5})}) \\ &= (g_{10}+\tilde{g}_5) + 0 - 3g_{10} - \tilde{g}_5 = -2g_{10}. \end{aligned} \tag{A.34}$$

$h^{2,2}(\hat{Y}_4) = h^{1,1}(\hat{Y}_4)$ is given by $e_c^{2,2}(\hat{Y}_4)$, and $h^{2,1}(\hat{Y}_4)$ by $-e_c^{2,1}(\hat{Y}_4)$.

A.4 More on the geometry of the Cartan divisors $\hat{Y}_{1,2,3,4}$

$H^{1,1}(\hat{Y}_0)$ is generated by $\pi^*_{\hat{Y}_0}(H^{1,1}(S))$ and $\hat{Y}_1|_{\hat{Y}_0}$. Although σ defines a divisor on $\hat{Y}_0$ as well, it can be written in terms of the generators above. To see this, note that

$$\nu^*_{\rm tot}[-c_1(B_3)] = \sigma + \nu^*_{\rm tot}(D_{X_1} - 2D_{X_2}) = \sigma + \hat{D}_{X_1} - 2\hat{D}_{X_2} - \hat{E}_1 - 2\hat{E}_2 - \hat{E}_3. \tag{A.35}$$

From this, we obtain

$$0 = \left[\sigma - \hat{E}_1 + \nu^*_{\rm tot}(c_1(B_3))\right]|_{\hat{E}_0}, \tag{A.36}$$

because $\hat{E}_0 \cdot \hat{E}_2 = \hat{E}_0 \cdot \hat{E}_3 = 0$ in the ambient space A_4 (see figure 9). Using the relations $\hat{Z} \sim (3\hat{D}_{X_2} + \hat{E}_1 + 2\hat{E}_2 + \hat{E}_3) \sim (2\hat{D}_{X_1} + \hat{E}_3 + \hat{E}_4)$ and the intersection ring information of the ambient space A_4 in figure 9, it also follows that $(\hat{Y}_1 - \hat{Y}_4)|_{\hat{Y}_0} = (\hat{E}_1 - \hat{E}_4) \cdot \hat{E}_0 \cdot \hat{Z} \sim 0$.

$H^{1,1}(\hat{Y}_1)$ is generated by $\pi^*_{\hat{Y}_1}(H^{1,1}(S))$ and $\hat{Y}_2|_{\hat{Y}_1}$. A few more comments are in order here. First,

$$\left(\hat{Y}_0 - \hat{Y}_2\right)\Big|_{\hat{Y}_1} \sim (\nu^*_{\rm tot}(D_S) - \nu^*_{\rm tot}(D_{X_2}))|_{\hat{Y}_1} \sim \pi^*_{\hat{Y}_1}\left[c_1(N_{S|B_3}) - 2c_1(B_3)|_S\right]. \tag{A.37}$$

That is, both $\hat{Y}_0|_{\hat{Y}_1}$ and $\hat{Y}_2|_{\hat{Y}_1}$ are sections of the flat fibration $\pi_{\hat{Y}_1} : \hat{Y}_1 \longrightarrow S$, but they are different only modulo $\pi^*_{\hat{Y}_1}(H^{1,1}(S))$. In the derivation above, we have used

$$\hat{D}_{X_2}|_{\hat{Y}_1} = \hat{D}_{X_2} \cdot \hat{E}_1 \cdot \hat{Z} \sim \hat{D}_{X_2} \cdot \hat{E}_1 \cdot (2\hat{D}_{X_1} + \hat{E}_3 + \hat{E}_4) = 0\,, \tag{A.38}$$

JHEP01(2015)047

because none of $\hat{D}_{X_1}$, $\hat{E}_3$ and $\hat{E}_4$ share a face together with both $\hat{D}_{X_2}$ and $\hat{E}_1$. This is a generalization of the toric statement that the 1-simplex $\langle \hat{D}_{X_2}, \hat{E}_1 \rangle$ ($\langle \nu_2, \nu_9 \rangle$ in the notation of [27]) is inside a facet of the polytope and hence does not give rise to a non-trivial divisor in $\hat{Y}_1$. Finally, one can see that $\hat{Y}_1 \cdot \hat{Y}_4 = S_B$ is the total fibre component over the matter curve $\Sigma_{(\mathbf{10})}$ in $\pi_{\hat{Y}_1} : \hat{Y}_1 \longrightarrow S$, by observing that

$$\nu^*_{\rm tot}(D_{X_1} - D_{X_2})|_{\hat{Y}_1} = \left[\hat{D}_{X_1} - \hat{D}_{X_2} + \hat{E}_3 + \hat{E}_4\right]|_{\hat{Y}_1} = \hat{E}_4|_{\hat{Y}_1}, \tag{A.39}$$

$$\nu^*_{\rm tot}(\sigma + c_1(B_3))|_{\hat{Y}_1} = \nu^*_{\rm tot}(c_1(B_3)) = \pi^*_{\hat{Y}_1}(c_1(B_3)|_S)\,. \tag{A.40}$$

The matter curve $\Sigma_{(\mathbf{10})}$ is in the class $[5K_S + \eta] = c_1(N_{S|B_3}) + c_1(S) = c_1(B_3)|_S$.

$H^{1,1}(\hat{Y}_2)$ is generated by $\pi^*_{\hat{Y}_2}(H^{1,1}(S))$, $\hat{Y}_3|_{\hat{Y}_2}$ and $\hat{Y}_4|_{\hat{Y}_2}$. Both $\hat{Y}_1|_{\hat{Y}_2}$ and $\hat{Y}_3|_{\hat{Y}_2}$ are sections of the flat fibration $\pi_{\hat{Y}_2} : \hat{Y}_2 \longrightarrow S$, but they are different only by the pullback of $H^{1,1}(S)$:

$$\left(\hat{Y}_1 - \hat{Y}_3\right)\Big|_{\hat{Y}_2} = \nu^*_{\rm tot}\left(2D_S - D_{X_1}\right)|_{\hat{Y}_2} \sim \pi^*_{\hat{Y}_2}(2c_1(N_{S|B_3}) - 3c_1(B_3)|_S)\,. \tag{A.41}$$

The other generator $\hat{Y}_4|_{\hat{Y}_2} = S_C$ is one of the two singular fibre components in the flat family $\pi_{\hat{Y}_2} : \hat{Y}_2 \longrightarrow S$ along with the matter curve $\Sigma_{(\mathbf{10})}$. This four-cycle can be chosen as the matter surface for the hypermultiplets in the SU(5)-($\mathbf{10} + \overline{\mathbf{10}}$) representations.

$H^{1,1}(\hat{Y}_3)$ is generated by $\pi^*_{\hat{Y}_3}(H^{1,1}(S))$ and two other independent generators, which can be chosen as $\hat{Y}_4|_{\hat{Y}_3}$ and $\hat{Y}_2|_{\hat{Y}_3}$. $\hat{Y}_3$ is also regarded as a flat family of curves over S, $\pi_{\hat{Y}_3} : \hat{Y}_3 \longrightarrow S$, of which both $\hat{Y}_2|_{\hat{Y}_3}$ and $\hat{Y}_4|_{\hat{Y}_3}$ define a section. Divisors $\hat{D}_{X_1}|_{\hat{Y}_3}$ and $\hat{D}_{X_2}|_{\hat{Y}_3}$ are linearly equivalent to the generators above; using

$$\nu^*_{\rm tot}(D_{X_2} - 2D_S) = \hat{D}_{X_2} - 2\hat{D}_S - \hat{E}_1 - \hat{E}_4, \tag{A.42}$$

for example, one obtains a relation

$$\hat{Y}_4|_{\hat{Y}_3} \sim \hat{D}_{X_2}|_{\hat{Y}_3} + \pi^*_{\hat{Y}_3}(2K_S). \tag{A.43}$$

Also, by using $\nu^*_{\rm tot}(D_{X_1} - 3D_S)$ instead of $\nu^*_{\rm tot}(D_{X_2} - 2D_S)$, we find that

$$\hat{D}_{X_1}|_{\hat{Y}_3} \sim \hat{Y}_4|_{\hat{Y}_3} + \hat{Y}_2|_{\hat{Y}_3} - \pi^*_{hatY_3}(3K_S)\,. \tag{A.44}$$

The matter surface for the SU(5)-($\bar{\mathbf{5}} + \mathbf{5}$)-representations is given by a difference between the two divisors on $\hat{Y}_3$: $\mathrm{div}(a_3 X_{\hat{E}_4} + a_5 X_{\hat{D}_2})|_{\hat{Y}_3} - \hat{E}_2|_{\hat{Y}_3}$, where $X_{\hat{E}_4}$ and $X_{\hat{D}_{X_2}}$ are the homogeneous coordinates of $A_4^{[a]}$ corresponding to the divisors $\hat{E}_4$ and $\hat{D}_{X_2}$, respectively. The divisor $\{a_3 X_{\hat{E}_4} + a_5 X_{\hat{D}_{X_2}} = 0\}$ on $\hat{Y}_3$ consists of two irreducible components. One component is $\hat{E}_2|_{\hat{Y}_3}$, to be subtracted away, and the other one is an irreducible component of the singular fibre over the matter curve $\Sigma_{(\mathbf{5})}$, the matter surface S_γ. Thus, it is in the divisor class $[\hat{E}_4 + \nu^*_{\rm tot}(c_1(N_{S|B_3}) + 3c_1(B_3)|_S)] - \hat{E}_2$ on $\hat{Y}_3$. From this, we can conclude that the matter surface for the ($\bar{\mathbf{5}} + \mathbf{5}$) representations also belongs to the class of a vertical cycles.

$H^{1,1}(\hat{Y}_4)$ is generated by $\pi^*_{\hat{Y}_4}(H^{1,1}(S))$ and three more divisors $\hat{Y}_3|_{\hat{Y}_4}$, $\hat{Y}_1|_{\hat{Y}_4} = S_B$ and $\hat{Y}_2|_{\hat{Y}_4} = S_C$. The last two of these form two out of the three singular fibre components

JHEP01(2015)047

over the matter curve $\Sigma_{(\mathbf{10})}$. Although $\hat{Y}_0|_{\hat{Y}_4}$ also defines a section of the flat fibration $\pi_{\hat{Y}_4} : \hat{Y}_4 \longrightarrow S$, there is a relation

$$\begin{aligned}\left(\hat{Y}_3 - \hat{Y}_0\right)\Big|_{\hat{Y}_4} &= \nu_{\rm tot}^*(D_{X_2} - D_S)|_{\hat{Y}_4} - (\hat{E}_2 + \hat{D}_{X_2})|_{\hat{Y}_4} \\ &= -\hat{Y}_2|_{\hat{Y}_4} + \pi_{\hat{Y}_4}^*(2c_1(B_3)|_S - c_1(N_{S|B_3}))\,. \end{aligned} \tag{A.45}$$

Using all the relations above, one can derive the following rational equivalence relations:

$$\begin{aligned}
&\hat{Y}_0 \cdot \hat{Y}_1 \sim \pi^*(D_S)\cdot\sigma + c_1(B_3)\cdot\hat{Y}_0,\\
&\hat{Y}_1 \cdot \hat{Y}_2 \sim \pi^*(D_S)\cdot\sigma + c_1(B_3)\cdot(\hat{Y}_0 + 2\hat{Y}_1) - c_1(N_{S|B_3})\cdot\hat{Y}_1,\\
&\hat{Y}_2 \cdot \hat{Y}_3 \sim \pi^*(D_S)\cdot\sigma + c_1(B_3)\cdot(\hat{Y}_0 + 2\hat{Y}_1 + 3\hat{Y}_2) - c_1(N_{S|B_3})\cdot(\hat{Y}_1 + 2\hat{Y}_2),\\
&\hat{Y}_3 \cdot \hat{Y}_4 \sim \pi^*(D_S)\cdot\sigma - (\hat{Y}_2\cdot\hat{Y}_4) + c_1(B_3)\cdot(\hat{Y}_0 + 2\hat{Y}_4) - c_1(N_{S|B_3})\cdot\hat{Y}_4,\\
&\hat{Y}_4 \cdot \hat{Y}_0 \sim \pi^*(D_S)\cdot\sigma + c_1(B_3)\cdot\hat{Y}_0,
\end{aligned} \tag{A.46}$$

and

$$\hat{Y}_1 \cdot \hat{Y}_4 \sim c_1(B_3)\cdot\hat{Y}_1. \tag{A.47}$$

The matter surfaces for the **10** and $\bar{\mathbf{5}}$ representations are different under rational equivalence only by

$$\begin{aligned}[S_\gamma] - [-S_C] &\sim \left[\hat{Y}_3 \cdot \left\{\hat{Y}_4 + c_1(N) + 3c_1(B_3) - \hat{Y}_2\right\}\right] - \left[-\hat{Y}_2\cdot\hat{Y}_4\right] \\ &\sim c_1(B_3)\cdot(-2\hat{Y}_1 - 3\hat{Y}_2 + 3\hat{Y}_3 + 2\hat{Y}_4) + c_1(N_{S|B_3})\cdot(\hat{Y}_1 + 2\hat{Y}_2 + \hat{Y}_3 - \hat{Y}_4).\end{aligned} \tag{A.48}$$

If we turn on a flux which does not break SU(5) gauge invariance, this guarantees that the chirality in the **10** representation is the same as that in $\bar{\mathbf{5}}$ representation, as also observed in [25].

B Dependence of Hodge numbers on the rank of 7-brane symmetry

The number of flux vacua that have a stack of 7-branes with symmetry R scales as $e^{K/6}$, $K = \dim[H_H^4(X;\mathbb{R})]$, as we have seen in section 6. In this appendix, we use the approximate relation (6.5), which holds in the cases satisfying the condition (6.3), to study the statistics of the unification symmetry R. Instead of studying how the dimension of the primary horizontal subspace K depends on the symmetry R, we will estimate how $h^{3,1}$ changes for different choices of R.

Let us start from a family for $(B_3, [S], R_1)$, and suppose that the enhancement of the 7-brane symmetry R_1 to R_2 occurs when a section $f \in \Gamma(B_3; \mathcal{O}(D))$ of some line bundle $\mathcal{O}_{B_3}(D)$ vanishes along S; the section f is used in a defining equation of the Weierstrass model, and the geometry gets more singular for $f|_S = 0$. The line bundle $\mathcal{O}_{B_3}(D)$ here is determined by Tate's algorithm, as we will discuss more explicitly later on. Requiring f to vanish along S, the number of independent complex structure moduli is reduced roughly by

$$\Delta h^{3,1} = h^0(B_3; \mathcal{O}_{B_3}(D)) - h^0(B_3; \mathcal{O}_{B_3}(D - S)). \tag{B.1}$$

JHEP01(2015)047

One can then use the exact sequence

$$0 \longrightarrow \mathcal{O}_{B_3}(D-S) \longrightarrow \mathcal{O}_{B_3}(D) \longrightarrow i_* \left[\mathcal{O}_S(D|_S)\right] \longrightarrow 0 \tag{B.2}$$

to set an upper bound

$$\Delta h^{3,1} \leq h^0(S; \mathcal{O}_S(D|_S)). \tag{B.3}$$

This inequality is saturated when $h^1(B_3; \mathcal{O}_{B_3}(D-S))$ vanishes. From this, we can derive the crude estimate

$$e^{h^0(S;\mathcal{O}_S(D|_S))} \tag{B.4}$$

on the statistical cost of unification symmetry R_2 relatively to R_1.

Let us use the examples we studied in section 4.4 to see how this works in practice. We focus on the case $B_3^{(n)} = \mathbb{P}[\mathcal{O}_{\mathbb{P}^2} \oplus \mathcal{O}_{\mathbb{P}^2}(n)]$ and study the enhancement from $R_1 = A_4$ to $R_2 = D_5$ along $S = \mathbb{P}^2$. The condition for this $A_4 \to D_5$ enhancement is $(f = a_5)|_S = 0$; note also that $a_5 \in \Gamma(B_3; \mathcal{O}_{B_3}(-K_{B_3}))$ and hence $D|_S = S - K_S = (3-n)H_{\mathbb{P}^2}$. The estimated upper bound on $\Delta h^{3,1}$ therefore becomes

$$h^0\left(S; \mathcal{O}_S(D|_S)\right) = h^0\left(\mathbb{P}^2; \mathcal{O}_{\mathbb{P}^2}((3-n)H)\right) = \frac{(5-n)(4-n)}{2}. \tag{B.5}$$

The value of $\Delta K_{4\text{-}5}$ in table 4 is estimated reasonably well by $6 \times h^0(S; \mathcal{O}_S(D|_S)) = 3(5-n)(4-n)$ indeed.[23]

Let us now use this argument to study how the statistical cost varies for different enhancement of symmetries $R_1 \to R_2$. Suppose that the Weierstrass model Z_s is parametrized by the generalized Weierstrass equation (Tate's form),

$$y^2 + b_1 xy + b_3 y = x^3 + x^2 b_2 + x b_4 + b_6\,. \tag{B.6}$$

When b_i vanishes along S with the order of vanishing n_i, let $b_i = s^{n_i} b_{i|n_i}$. The dictionary between the order of vanishing n_i's and the 7-brane symmetry R is known [72], and the necessary information is recorded in table 5.

An immediate generalization of the $A_4 \to D_5$ enhancement is the enhancement $A_m \to D_{m+1}$, $m \in 2\mathbb{N}$. In these cases, $f = b_{1|0}$ and $D = -K_{B_3}$ for any $m \in 2\mathbb{N}$, not just for $m = 4$. Thus, the same value $h^0(S; \mathcal{O}_S(-K_{B_3}|_S)) = h^0(S; \mathcal{O}_S(S - K_S))$ provides an approximate upper bound on $\Delta h^{3,1}$ for any $m \in 2\mathbb{N}$.

One can also think of two separate chains of symmetry enhancement, $A_m \to A_{m+1} \to A_{m+2}$ and $D_{m+1} \to D_{m+2} \to D_{m+3}$. The statistical cost increases at the same pace in these two chains; as the rank increases by two from A_m to A_{m+2}, or from D_{m+1} to D_{m+3}, we need to set the sections $b_{3|m/2}|_S$, $b_{4|m/2+1}|_S$, $b_{6|m+1}|_S$ and $b_{6|m+2}|_S$ to zero in any one of those two chains (see table 5). This is consistent with the result above that the statistical

[23] It is a little misleading to use these examples to emphasize that this estimate is good. The $\mathbb{P}^1$-fibration structure over S in $B_3^{(n)}$ defines a normal coordinate of S that remains well-defined globally on $B_3^{(n)}$. We do not intend to claim that $6h^0(S; \mathcal{O}_S(D|_S))$ is a good estimate of ΔK rather than a good estimate of the upper bound on ΔK.

JHEP01(2015)047

		b_1	b_3	b_4	b_6

		b_1	b_2	b_3	b_4	b_6
A_4	I^s_5	0	1	2	3	5
D_5	I^{*s}_1	1	1	2	3	5
E_6	IV^{*s}	1	2	2	3	5
E_7	III^*	1	2	3	3	5
E_8	II^*	1	2	3	4	5

Table 5. Order of vanishing n_i of b_i's required for various types of singular fibre (7-brane gauge group); information relevant to the discussion in this section is extracted from a table in [72]. $m \in 2\mathbb{N}$ is assumed in this table. The order of vanishing for b_2 is 1 for any one in the I^s_k and I^{*s}_k series.

cost for the enhancement $A_m \to D_{m+1}$ remains much the same for any $m \in 2\mathbb{N}$. Noting that $b_{i|n_i} \in \Gamma(B_3; \mathcal{O}_{B_3}(-iK_{B_3} - n_i S))$, and hence

$$b_{3|m/2}|_S \in \Gamma(S; \mathcal{O}_S(-3K_{B_3}|_S - m/2 S)), \quad b_{6|m+1}|_S \in \Gamma(S; \mathcal{O}_S(-6K_{B_3}|_S - (m+1)S)),$$
$$b_{4|m/2+1}|_S \in \Gamma\Big(S; \mathcal{O}_S(-4K_{B_3}|_S - \frac{m+2}{2} S)\Big), \quad b_{6|m+2}|_S \in \Gamma(S; \mathcal{O}_S(-6K_{B_3}|_S - (m+2)S)), \tag{B.7}$$

one finds that the statistical cost for enhancement by rank-one, measured by $\Delta K/\Delta m \approx 6\Delta h^{3,1}/\Delta m$, becomes larger for higher rank m in the case $c_1(N_{S|B_3}) < 0$; if $c_1(N_{S|B_3}) > 0$, on the other hand, the cost for one-rank enhancement decreases for higher rank m, because $\Delta h^{3,1}$ is bounded from above by smaller value. One should be careful in interpreting this phenomenon for $c_1(N_{S|B_3}) > 0$; it looks as if higher rank gauge groups become just as "natural" as lower rank gauge groups at first sight, but it may also be that the choice of complex structure for such a high rank enhancement has already become impossible.

Let us finally look at the chain of symmetry enhancements $E_m \to E_{m+1}$; $A_4 \to D_5$ is also regarded as a part of this chain. In this chain, we need to set the section

$$\big[a_{9-m|0} \propto b_{m-3|m-4}\big]\big|_S \in \Gamma(S; \mathcal{O}_S(S - (m-3)K_S)) \tag{B.8}$$

to zero for the enhancement $E_m \to E_{m+1}$. Thus, the statistical cost for one-rank enhancement, $\Delta K/\Delta m$, becomes increasingly large in higher rank (larger m), if $K_S < 0$. [Note that there are chiral multiplets in the adjoint representation of E_m in the spectrum below the Kaluza-Klein scale, if $K_S > 0$ instead.][24] Interestingly, the behaviour of $\Delta K/\Delta m$ is controlled by the normal bundle $N_{S|B_3}$ in the (IIB-like) A_m type and D_m type chains of symmetry enhancement, and by the canonical bundle K_S in the E_m type chain available in F-theory.

[24] In the case of $\hat{Z} = \mathrm{K3} \times \mathrm{K3}$ [16], the dimension of the primary horizontal subspace, K, and $h^{3,1}$ are linear in the rank of the 7-brane gauge group rank_7, and $\Delta K/\Delta \mathrm{rank}_7$ remains constant, in particular. This simple result for $\mathrm{K3} \times \mathrm{K3}$ compactifications of F-theory should be understood as an artefact of trivial bundles K_S and $N_{S|B_3}$.

JHEP01(2015)047

C Flux controlling the net chirality

In order to consider an ensemble of fluxes leading to effective theories with a given number of generations (net chirality) $N_{\rm gen}$, $G^{(4)}_{\rm fix}$ needs to be chosen so that it generates the net chirality $N_{\rm gen}$. If we take the scanning space $H_{\rm scan}$ to be the real primary horizontal subspace $H^4_H(X;\mathbb{R})$, then all the flux vacua end up with effective theories with one and the same value of $N_{\rm gen}$ in such an ensemble. This appendix begins with writing down the four-form flux generating the net chirality, which is already a well-understood subject in the literature. We then move on to compute the D3-tadpole bound

$$\frac{\chi(\hat{Z})}{24} - \frac{1}{2}(G^{(4)}_{\rm fix})^2 = L_* \geq \frac{1}{2}(G^{(4)}_{\rm scan})^2. \tag{C.1}$$

We implicitly used that $G^{(4)}_{\rm fix} \wedge G^{(4)}_{\rm scan} = 0$, which follows because the chirality generating flux $G^{(4)}_{\rm fix}$ is chosen within the vertical component $H^{2,2}_V(\hat{Z};\mathbb{R})$ (because the matter surface belongs to the space of vertical cycles), and the primary horizontal subspace is orthogonal to the vertical component.

The choice of $(B_3,[S])$ in section 4.4.1 is a simple generalization of [27]; $B_3 = \mathbb{P}[\mathcal{O}_{\mathbb{P}^2} \oplus \mathcal{O}_{\mathbb{P}^2}(n)]$ instead of $B_3 = \mathbb{P}[\mathcal{O}_{\mathbb{P}^2} \oplus \mathcal{O}_{\mathbb{P}^2}] = \mathbb{P}^1 \times \mathbb{P}^2$. In order to determine the flux $G^{(4)}_{\rm fix}$ generating the chirality of SU(5) unification models, the conditions for Lorentz SO(3,1) symmetry (2.1) and unbroken SU(5) symmetry (2.3) were imposed on the space of vertical four-forms $H^{2,2}_V(\hat{Z};\mathbb{R})$. As we can think of the Kähler form as being expanded in a basis consisting of divisors of the base, the section, the generic fibre class and the exceptional fibre components, these constraints also automatically make the D-term (2.2) vanish. It is legitimate, as we stated above, to search the chirality generating flux $G^{(4)}_{\rm fix}$ from $H^{2,2}_V(\hat{Z};\mathbb{R})$, because the matter surface belongs to the space of vertical four-cycles. We have seen in section 4.4.1 that the space $H^{2,2}_V(\hat{Z};\mathbb{R})$ has nine dimensions, while the conditions of unbroken SO(3,1) Lorentz and SU(5) unified symmetries result in eight independent constraints. This is true for all the cases with $-3 \leq n \leq 2$, not just the case $n = 0$ in [27]. After a straightforward computation, it turns out that

$$G^{(4)}_{\rm fix} = \lambda\left(5\hat{Y}_4 \cdot \hat{Y}_2 + (2S + (3+n)H_{\mathbb{P}^2}) \cdot (2\hat{Y}_1 - 2\hat{Y}_4 - \hat{Y}_2 + \hat{Y}_3)\right), \tag{C.2}$$

where $\lambda \in \mathbb{R}$ and $H_{\mathbb{P}^2}$ is the hyperplane divisor of the base $\mathbb{P}^2$. We have confirmed that this flux is equivalent to the one given in [25] and, in the case of $n = 0$, to the choice of [27] with $\lambda = -3\beta$, exploiting rational equivalence. The net chirality for the SU(5) **10**-$\overline{\mathbf{10}}$ representations is given by

$$N_{\rm gen} = \chi_{\mathbf{10}} = -\lambda(18-n)(3-n). \tag{C.3}$$

The choice of such chirality generating flux is quantized due to the condition $G^{(4)}_{\rm fix} \in [H^4(\hat{Z};\mathbb{Z})]_{\rm shift}$. It is not an easy task, to say the least, to determine the integral basis of $[H^4(\hat{Z};\mathbb{Z})]_{\rm shift} \cap H^{2,2}_V(\hat{Z};\mathbb{Q})$, but fortunately this task can be detoured in the cases we are dealing with. Here, a dual description in Heterotic string theory exists, and it is known

JHEP01(2015)047

n	-3	-2	-1	0	1	2
$\chi(\hat{Z})/24$	1263/4	719/2	869/2	2163/4	2713/4	847
$\frac{1}{2}(G_{\rm fix}^{(4)})^2$	315/4	125/2	95/2	135/4	85/4	10
$L_*^{\max}$	237	297	387	507	657	837
K	7557	8603	10403	12953	16253	20303

Table 6. The value of $\chi(\hat{Z})/24$ as well as $(G_{\rm fix}^{(4)})^2/2$ and L_* for $\lambda = \pm 1/2$, when L_* becomes maximal for a given n. The result of $K := \dim_{\mathbb{R}}[H_H^4(\hat{Z};\mathbb{R})]$ is copied from table 2.

that (6.1) gives rise to the net chirality (6.2). We should thus identify $\lambda_{FMW} = \lambda$, and the quantization

$$\lambda = \frac{1}{2}(1+2a), \qquad a \in \mathbb{Z} \tag{C.4}$$

follows from that of that of λ_{FMW} [25]. As discussed in [25], $G_{\rm fix}^{(4)}$ with this quantization condition satisfies $G_{\rm fix}^{(4)} \in [H^4(\hat{Z};\mathbb{Z})]_{\rm shift}$.

Now that $G_{\rm fix}^{(4)}$ is given explicitly, we are ready to compute the D3-tadpole upper bound L_*. The standard computation techniques of toric geometry allow us to compute $\int_{\hat{Z}} G_{\rm fix}^{(4)} \wedge G_{\rm fix}^{(4)}$. We find that

$$L_* = \frac{2163}{4} + \frac{125}{8}n(n+7) - \frac{5(18-n)(3-n)}{2}\lambda^2 \tag{C.5}$$

$$= \frac{2163}{4} + \frac{125}{8}n(n+7) - \frac{5N_{\rm gen}^2}{2(18-n)(3-n)}. \tag{C.6}$$

It is not obvious from the above equation whether L_* becomes integer or not, but L_* is indeed; see table 6. The computation here is essentially that of [55], although a K3-fibre is used instead of the stable degeneration limit $dP_9 \cup dP_9$, and a specific resolution of singularity is employed. The value of the D3-tadpole upper bound L_* depends on the number of generation $N_{\rm gen}$. This result is used in section 6 (and also [22]) to derive the distribution of $N_{\rm gen}$ in the landscape of F-theory flux vacua.

(Received 2 September 2014; published 1 December 2014)

The traditional idea of the Pomeron/Reggeon description for hadron scattering is now being given theoretical foundation in gravity dual descriptions, where Pomeron corresponds to an exchange of spin-$j \in 2\mathbb{Z}$ states in the graviton trajectory. Deeply virtual Compton scattering (DVCS) is essentially a two-to-two scattering process of a hadron and a photon, and hence one should be able to study nonperturbative aspects (the generalized parton distribution [GPD]) of this process by the Pomeron/Reggeon process in gravity dual. We find, however, that even one of the most developed formulations of gravity dual, Pomeron [Brower-Polchinski-Strassler-Tan (BPST), 2006], is not able to capture skewness dependence of GPD properly. Therefore, we compute Reggeon wave functions on AdS_5 so that the formalism of BPST can be generalized. These wave functions are used to determine the DVCS amplitude, bring it to the form of conformal operator product expansion/collinear factorization, and extract a holographic model of GPD, which naturally fits into the framework known as "dual parametrization," or the "(conformal) collinear factorization approach."

I. INTRODUCTION

Scattering processes of hadrons involve nonperturbative information of QCD. When it comes to scattering with the center of mass energy higher than the QCD scale, lattice computation will not have enough computation power in a near future, yet perturbative QCD is able to say something only about the hard components involved in the scattering. This is where holographic descriptions of strongly coupled gauge theories may find a role to play. Although we cannot expect gravitational "dual" descriptions to be both calculable and perfectly equivalent to the QCD of the real world at the same time, we still hope to be able to learn nonperturbative aspects of hadrons at the qualitative level, using calculable holographic dual descriptions of nearly conformal strongly coupled gauge theories.

String theory started out as the dual resonance model describing scattering amplitudes of hadrons. One of its major problems as a theory of hadrons was a "prediction" that the amplitude of the elastic scattering of two hadrons falls off exponentially, e^{Bt} in the momentum transfer squared t for some $B > 0$, although the amplitude is known in reality to fall off in a power law in $|-t|$ for hard scattering. The prediction, however, is now understood as that of string theory with a flat background metric; the amplitude of elastic scattering turns into such a power law indeed when the target space of string theory has a warped metric. At the qualitative level, string theory on a warped spacetime—holographic (gravitational dual) descriptions—can be a viable theory of hadron scattering [1–3].

The holographic technique can be used to study not just amplitudes of hadron scattering as a whole, but also to extract the information of partons within hadrons [2]. Parton distribution functions (PDFs) are defined by the inverse Mellin transformation of hadron matrix elements of gauge singlet parton-bilinear operators in QCD, and gravity dual descriptions can be used to determine matrix elements of the gauge singlet operators. The PDF extracted in this way satisfies Dokshitzer-Gribov-Lipatov-Altarelli-Parisi [(DGLAP), q^2-evolution] and Balitsky-Fadin-Kuraev-Lipatov [(BFKL), $\ln(1/x)$-evolution] equations (e.g., [4–7]); just like in perturbative QCD [8], these two evolution equations follow from how the saddle point j^* moves in the complex angular momentum j-plane integral (the inverse Mellin transform). The holographic description for the PDF and the generalized parton distribution (GPD) also shows crossover transition between this DGLAP/BFKL behavior and the Regge behavior [3] (see also [7]). Thus, the parton information studied in this way may be used to understand nonperturbative issues associated with partons in a hadron at qualitative level.

In this article, we study two-body–two-body scattering between a hadron and a photon (that is possibly virtual) in gravitational dual descriptions; $\gamma^*(q_1)+h(p_1)\to\gamma^{(*)}(q_2)+h(p_2)$. A special case of this scattering—the forward scattering with $q_1 = q_2$ and $p_1 = p_2$—has been studied extensively in the literature (e.g., [2,4–7]) for the study of deep inelastic scattering (DIS) and PDF, and some references also cover the case of nonforward elastic scattering

$[(q_1)^2 = (q_2)^2,\ (q_1 - q_2)^2 \neq 0]$. This article extends the analysis so that all kinds of skewed ($q_1^2 \neq q_2^2$) cases are covered. In hadron physics, therefore, the kinematics needed for deeply virtual Compton scattering, hard exclusive vector meson production and timelike Compton scattering processes [9] is covered in this analysis. With the full skewness dependence included in this analysis, it is also possible to use the result of this study to bridge a gap between data in such scattering processes at nonzero skewness [10] and the transverse profile of partons in a hadron, which is encoded by GPD at zero skewness [11].

From a theoretical perspective, the task of this article is to generalize the formalism of [2,3] (see also [4,6,7]) so that it can be used for two-body-to-two-body scattering that is not necessarily elastic. Pomeron/Reggeon propagators have been treated as if they were for a scalar field in [2,3,7], but they correspond to an exchange of stringy states with nonzero (arbitrarily high) spins; for the study of scattering with nonzero skewness, the polarization of a higher spin state propagator should also be treated with care (see also the approach in [12,13]).

It is a notoriously difficult problem to compute scattering of strings on a curved background geometry. We do not pretend that the generalization of the formalism in this article is something derived from string theory without a flaw. This is rather an attempt at capturing an approximately correct picture of nonperturbative aspects in hadron scattering that string theory would predict in the distant future. We are forced to rely sometimes on physics intuition —and to ignore subtleties or corrections that are not under our control—when we face situations where not enough techniques have been developed in string theory at the moment.

This article is organized as follows. We begin in Sec. II A with a review of parametrization of GPD in terms of conformal OPE (operator product expansion) because the expansion in a series of conformal primary operators becomes the key concept in using AdS/CFT correspondence (cf. [5]). After plainly stating what needs to be done in the gravity dual approach in Sec. II B, we proceed to explain our basic gravity dual setting and an idea of how to construct a scattering amplitude of our interest by using string field theory in Secs. III and IV. Section V shows the results of computing wave functions of spin-j fields on AdS_5, while a more detailed account of the derivation of wave functions is given in Appendix A. Classification of eigenmodes that turn out to be relevant for the "twist-2" operators in later sections is given in Sec. V A, and wave functions are presented as analytic functions of the complex spin (angular momentum) variable j in Sec. V B. These wave functions are organized into irreducible representations of conformal algebra in Sec. V C; the representation for spin-j primary operators contain more eigenmode components than those treated by the Pomeron exchange amplitude in the formalism of [3], indicating that more contributions are needed in the scattering amplitude with nonvanishing skewness than in the formalism of [3]. These wave functions (and propagators) are used in Sec. VI in organizing scattering amplitude on AdS_5. The amplitude obtained in this way can be cast into the form of conformal OPE, from which one can also extract GPD as a function of kinematical variables. We are not committed to a particular form of implementing confining effects in the holographic description, as discussed in Sec. V D. Some qualitative aspects of the GPD profile are examined in Sec. VII. This paper in Phys. Rev. D is based on the preprints [14].

Not surprisingly, holographic models of GPD so obtained provide a special subclass of GPD models that have been called dual parametrization or (conformal) collinear factorization approach in the QCD/hadron community [15–18]. After all, it is the combination of the dual resonance model and the AdS/CFT correspondence that are being used.

We found that interesting preprints [12,13] cover a subject that is closely related to our study in Secs. V and VI and in Appendix A. References [12,13] mainly deal with correlation functions of CFTs as functions of spacetime coordinates, whereas we deal with them in this article as functions of incoming/outgoing momenta, and confinement effects are also implemented, so that we can study hadron scattering processes.

II. OUR APPROACH: CONFORMAL OPE AND GRAVITY DUAL

A. Review: Conformal OPE of DVCS amplitude

1. Notation and conventions

Deeply virtual Compton scattering (DVCS) $\gamma^* + h \to h + \gamma$, hard exclusive vector meson production (VMP) $e + h \to e + h + V$ and timelike Compton scattering (TCS) processes $e + h \to e + h + e^+e^-$ are shown in Figs. 1(a), 1(c), and 1(d), respectively. As a part of all these processes, the photon-hadron two-body-to-two-body scattering amplitude,

$$\mathcal{M}(\gamma^* h \to \gamma^{(*)} h) = (\epsilon_1^\mu) T_{\mu\nu} (\epsilon_2^\nu)^*, \tag{1}$$

is involved.[1] This two-body-to-two-body scattering amplitude with this exclusive choice of the final states (Fig. 2) is truly nonperturbative information, and this is the subject of this article. Because the "final state" photon is required to be on-shell $q_2^2 = 0$ in DVCS and timelike[2] $q_2^2 < 0$ in VMP

[1]There are two contributions from (a) the $\gamma^* + h \to \gamma + h$ virtual Compton scattering and (b) the Bethe-Heitler process in the leptoproduction process of a photon on a target hadron h: $\ell + h \to \ell + \gamma + h$, and they interfere. They can be separated experimentally, however, by exploiting kinematical dependence and polarization [19]. It thus makes sense to focus only on the amplitude (a).

[2]We use the $(-,+++)$ metric throughout this paper.

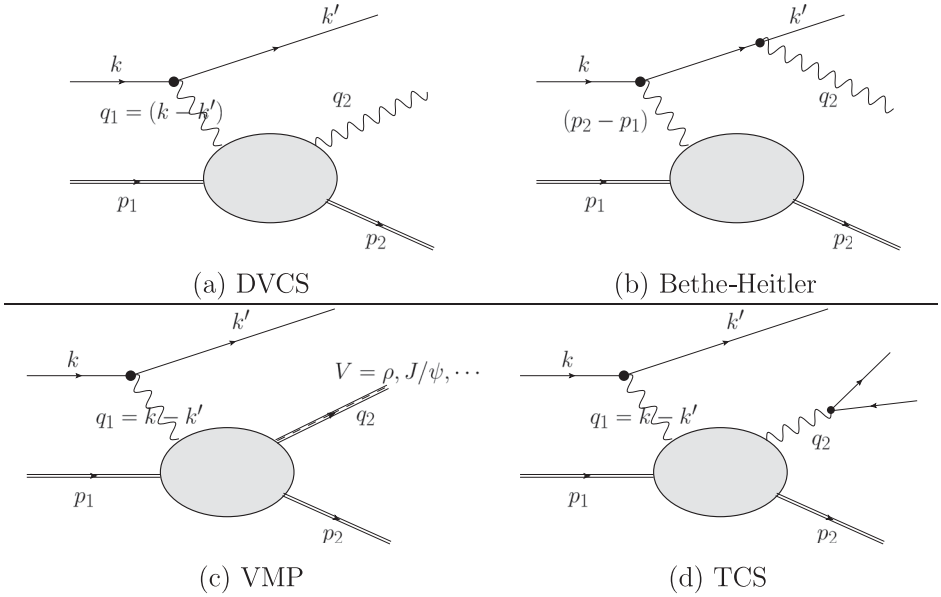

FIG. 1. Panels (a),(b) are diagrams contributing to the leptoproduction process of photon on a hadron, $\ell + h \to \ell + \gamma + h$, (c) is the exclusive vector meson production process, and, finally, (d) is the timelike Compton scattering process.

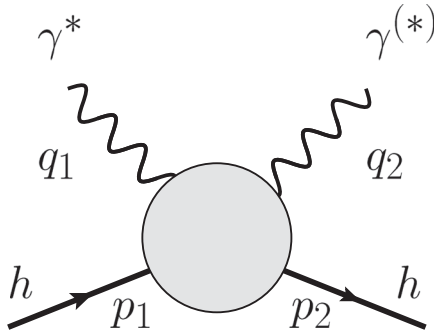

FIG. 2. Photon-hadron two-body-to-two-body scattering amplitude.

and TCS, we are interested in developing a theoretical framework to calculate this nonperturbative amplitude in the case where q_2^2 is different from spacelike $q_1^2 > 0$.

Just like in the QCD/hadron literature, we use the following notation for Lorentz invariant kinematical variables:

$$p^\mu = \frac{1}{2}(p_1^\mu + p_2^\mu), \qquad q^\mu = \frac{1}{2}(q_1^\mu + q_2^\mu),$$
$$\Delta^\mu = p_2^\mu - p_1^\mu = q_1^\mu - q_2^\mu, \tag{2}$$

$$x = \frac{-q^2}{2p\cdot q}, \qquad \eta = \frac{-\Delta\cdot q}{2p\cdot q},$$
$$s = W^2 = -(p+q)^2, \qquad t = -\Delta^2. \tag{3}$$

η is called skewness; in the scattering process of our interest, $q_1^2 = q^2 + \Delta^2/4 + q\cdot\Delta$ and $q_2^2 = q^2 + \Delta^2/4 - q\cdot\Delta$ are not the same; hence, the skewness does not vanish.

We will focus on high-energy scattering; for a typical energy scale of hadron masses/confinement scale Λ, we assume that

$$\Lambda^2 \ll q_1^2, W^2, \quad \text{while } |t| \lesssim \mathcal{O}(\Lambda). \tag{4}$$

The photon-hadron scattering amplitude (Fig. 2) in the real-world QCD (where all charged partons are fermions), the Compton tensor is given by the hadron matrix element with the insertion of two QED currents J^μ,

$$T^{\mu\nu} = i\int d^4x e^{-iq\cdot x}\langle h(p_2)|T\{J^\nu(x/2)J^\mu(-x/2)\}|h(p_1)\rangle. \tag{5}$$

For simplicity, we assume that the target hadron is a scalar and further pay attention only to the structure function V_1 appearing in the gauge-invariant decomposition[3] of the Compton tensor:

$$\begin{aligned} T^{\mu\nu} = {} & V_1 P[q_1]^{\mu\rho} P[q_2]^\nu_\rho + V_2 (p\cdot P[q_1])^\mu (p\cdot P[q_2])^\nu \\ & + V_3 (q_2\cdot P[q_1])^\mu (q_1\cdot P[q_2])^\nu \\ & + V_4 (p\cdot P[q_1])^\mu (q_1\cdot P[q_2])^\nu \\ & + V_5 (q_2\cdot P[q_1])^\mu (p\cdot P[q_2])^\nu + A\epsilon^{\mu\nu\rho\sigma} q_{1\rho} q_{2\sigma}. \end{aligned} \tag{7}$$

[3]Here, we introduced a convenient notation:

$$P[q]_{\mu\nu} = \left[\eta_{\mu\nu} - \frac{q_\mu q_\nu}{q^2}\right]. \tag{6}$$

These structure functions, $V_{1,2,3,4,5}(x,\eta,t,q^2)$, should be expressed in terms of the kinematical variables x,η, and t, and one of the primary purposes of this article is to study how the structure functions depend on the skewness η.

2. Light-cone operator product expansion

The light-cone OPE can be applied to the product of currents $T\{J^\nu J^\mu\}$ before evaluating it as a hadron matrix element. Let the expansion be

$$i\int d^4x e^{-iq\cdot x}T\{J^\nu(x/2)J^\mu(-x/2)\} = \sum_I \mathcal{C}^{\mu\nu}_{I\rho_1\cdots\rho_{j_I}}(q)\mathcal{O}_I^{\rho_1\cdots\rho_{j_I}}(0;q^2) \tag{8}$$

for some basis of local operators $\mathcal{O}_I^{\rho_1\cdots\rho_{j_I}}$ renormalized at $\mu^2=q^2$. $C^{\mu\nu}_{I\rho_1\cdots\rho_{j_I}}$'s are the corresponding Wilson coefficients renormalized at $\mu^2=q^2$. If we were to evaluate these local operators on the right-hand side with the same state for both bra and ket, $\langle h(p_2)|$ and $|h(p_1)\rangle$, with $p_2^\mu=p_1^\mu$, then the Compton tensor and its structure functions do not receive nonzero contributions from local operators that are given by the total derivative of some other local operators. In the case of our interest, however, such operators do contribute.

Let us take a series of operators in QCD that are called twist-2 operators in the weak coupling limit. The twist-2 operators in the flavor-nonsinglet sector are labeled by two integers, j,l,

$$\mathcal{O}^\alpha_{j,l} \coloneqq [(-i)^{j+l-1}\partial^{\mu_{j+1}}\cdots\partial^{\mu_{j+l}}\overline{\Psi}_a\gamma^{\mu_1}(\overleftrightarrow{D})^{\mu_2}\cdots(\overleftrightarrow{D})^{\mu_j}\lambda^\alpha_{ab}\Psi_b]_{\text{t.s.t.l.}}(0;q^2), \tag{9}$$

with an $N_F\times N_F$ flavor matrix $(\lambda^\alpha)_{ab}$. Similarly, in the flavor-singlet sector, there are two series of twist-2 operators with the label j,l, given by quark bilinear and gluon bilinear. Here, these operators are made totally symmetric and traceless (t.s.t.l) in the $j+l$ Lorentz indices so that they transform in irreducible representations of the Lorentz group $\mathrm{SO}(3,1)$, $\overleftrightarrow{D}\coloneqq\vec{D}-\overleftarrow{D}$.

Suppose that the hadron matrix element of the operator $\mathcal{O}^\alpha_{j,l}$ is given by

$$\langle h(p_2)|\mathcal{O}^\alpha_{j,l}|h(p_1)\rangle = \sum_{k=0}^{j}[\Delta^{\mu_1}\cdots\Delta^{\mu_{k+l}}p^{\mu_{k+l+1}}\cdots p^{\mu_{j+l}}]_{\text{t.s.t.l.}}A_{j,k}(t;q^2)(-2)^{j-k}; \tag{10}$$

the reduced matrix element $A^\alpha_{j,k}(t)$ is nonperturbative information and cannot be determined by perturbative QCD. If we pay attention only to Wilson coefficients $C^{\mu\nu}_{j,l,\alpha;\mu_1\cdots\mu_{j+l}}$ that are proportional to $\eta^{\mu\nu}$ and are to write them as[4]

$$\eta^{\mu\nu}\mathcal{C}^\alpha_{j,l}\frac{q_{\rho_1}\cdots q_{\rho_{j+l}}}{(q^2)^{j+l}}, \tag{11}$$

then the twist-2 flavor-nonsinglet contribution to the structure function V_1 becomes

$$V_1 \simeq \sum_{j,l}\mathcal{C}^\alpha_{j,l}\frac{1}{x^{j+l}}\sum_{k=1}^{j}A^\alpha_{j,k}(t;q^2)\eta^{k+l} =: \sum_j \mathcal{C}^\alpha_j(\vartheta)\frac{1}{x^j}A^\alpha_j(\eta,t;q^2), \tag{12}$$

where $\vartheta\coloneqq(\eta/x)$, $\mathcal{C}^\alpha_j(\vartheta)\coloneqq\sum_{l=0}^\infty\mathcal{C}^\alpha_{j,l}\vartheta^l$, and $A^\alpha_j(\eta,t)\coloneqq\sum_{k=0}^j\eta^kA^\alpha_{j,k}(t)$. If the structure function V_1 receives contributions only from even $j\in\mathbb{Z}$, then this j summation is rewritten as

$$V_1(x,\eta,t;q^2)\simeq-\int\frac{dj}{4i}\frac{1+e^{-\pi ij}}{\sin(\pi j)}\mathcal{C}^\alpha_j(\vartheta)\frac{1}{x^j}A^\alpha_j(\eta,t;q^2) \tag{13}$$

in the form of inverse Mellin transformation; here, $\mathcal{C}^\alpha_j(\vartheta;q^2)$ and $A^\alpha_j(\eta,t;q^2)$ are now meant to be holomorphic functions on j (possibly with some poles and cuts) that coincide with the original ones at $j\in2\mathbb{Z}$. Precisely the same story also holds true for the flavor-singlet sector.

Because the structure function is given by the inverse Mellin transform of a product of three factors, namely, (a) the signature factor $\mp[1\pm e^{-\pi ij}]/\sin(\pi j)$, (b) the Wilson coefficients $\mathcal{C}^\alpha_j$, and (c) the hadron matrix elements A^α_j, it can be regarded as a convolution of inverse Mellin transforms of those three factors. The inverse Mellin transform of the signature factor becomes

$$\int\frac{dj}{2\pi i}\frac{1}{x^j}\frac{\pi}{2}\frac{\mp[1\pm e^{-\pi ij}]}{\sin(\pi j)}=\frac{-1}{2}\left[\frac{1}{1-x+i\epsilon}\pm\frac{1}{1+x}\right], \tag{14}$$

which corresponds to propagation of the parton in a perturbative calculation [20], and the inverse Mellin transform of the matrix element is called the generalized parton distribution:

$$H^\alpha(x,\eta,t;\mu^2=q^2)=\int\frac{dj}{2\pi i}\frac{1}{x^j}A^\alpha_j(\eta,t;\mu^2=q^2). \tag{15}$$

GPD $H^\alpha(x,\eta,t;\mu^2)$ of a hadron h is nonperturbative information, just like the ordinary PDF, which is obtained

[4]In the leading order of QCD perturbation, $\mathcal{C}^\alpha_{j,0}=-[1+(-1)^j]$ for $j=2,4,\ldots$ and $(\lambda^\alpha)_{ab}=[\mathrm{diag}(4/9,1/9,1/9)]_{\text{t.l.}}$.

by simply setting $\eta = 0$ and $t = 0$. For a phenomenological fit of the experimental data of DVCS and VMP, some function form of the GPD needs to be assumed because of the convolution involved in the scattering amplitude [10]. Setting up a model (and assuming a function form) for the nonperturbative information in terms of $A_j(\eta, t; q^2)$ rather than the GPD itself $[H(x, \eta, t; q^2)]$ is called dual parametrization [15–18], and some phenomenological Ansätze have been proposed. In this article, we aim at deriving a qualitative form of $A_j(\eta, t)$ by using a gravitational dual (that is analytic in j), instead of assuming the form of $A_j(\eta, t)$ by hand.

3. Renormalization and OPE in dilatation eigenbasis

Remembering that the distinction between the $\gamma^* + h \to \gamma + h$ scattering amplitude and GPD originates from the factorization into the Wilson coefficients and local operators (and their matrix elements), one will notice that the GPD defined in this way should depend on the choice of the basis of local operators. Although the choice of operators $\mathcal{O}^\alpha_{j,l}$, with $j \geq 1$ and $l \geq 0$, in (9) appears to be the most natural (and intuitive) one for the twist-2 operators in the flavor-nonsinglet sector, there is nothing wrong with taking different linear combinations of these operators as a basis when the corresponding Wilson coefficients also become linear combinations of what they are for $\mathcal{O}^\alpha_{j,l}$. Given the fact that the operators $\mathcal{O}^\alpha_{j,l}$ mix with one another under renormalization, it should not be compulsory for us to stick to the basis $\mathcal{O}^\alpha_{j,l}$.

Under the perturbation of QCD, the flavor-nonsinglet twist-2 operators are renormalized under

$$\mu \frac{\partial}{\partial \mu} [\mathcal{O}_{j-m,m}(0; \mu^2)] = -[\gamma^{(j)}]_{mm'} [\mathcal{O}_{j-m',m'}(0; \mu^2)]; \tag{16}$$

because operators can mix only with those with the same number of Lorentz indices, the anomalous dimension matrix $[\gamma]$ is block diagonal in the basis of $\mathcal{O}^\alpha_{j,l}$. The $j \times j$ matrix for the operators $\mathcal{O}^\alpha_{j-m,m}$ $(m = 0, \ldots, j-1)$ is denoted by $[\gamma^{(j)}]$. This matrix is upper triangular in this basis, and the diagonal entries are given by the anomalous dimensions of the twist-2 spin-j operators without a total derivative:

$$[\gamma^{(j)}]_{mm} = \gamma(j - m). \tag{17}$$

Therefore, the eigenvalue of the anomalous dimension matrix is $\{\gamma(j-m)\}_{m=0,\ldots,j-1}$ in this diagonal block, and the corresponding operator $\overline{\mathcal{O}}^\alpha_{j-m-1,m}$ is a linear combination of operators $\mathcal{O}_{j-m',m'}$, with $m' = m, \ldots, j-1$ [21]. The corresponding Wilson coefficient $\overline{C}^\alpha_{j-m-1,m}$ for such an operator is a linear combination of $\mathcal{C}^\alpha_{j-m',m'}$, with $m' = m, \ldots, 0$. In this operator basis, matrix elements and Wilson coefficients renormalize multiplicatively, without mixing.[5]

In this new basis of local operators, the structure function becomes

$$\begin{aligned} V_1 &\simeq \sum_{n,K} \overline{C}^\alpha_{n,K} \frac{1}{x^{n+1+K}} \sum_k \overline{A}^\alpha_{n+1,k}(t; \mu^2) \eta^{K+k} \\ &=: \sum_n \overline{C}^\alpha_n(\vartheta) \frac{1}{x^{n+1}} \overline{A}^\alpha_{n+1}(\eta, t; \mu^2), \end{aligned} \tag{18}$$

where

$$\overline{C}^\alpha_n(\vartheta) = \sum_{K=0}^{\infty} \overline{C}^\alpha_{n,K} \vartheta^K, \tag{19}$$

and $\overline{A}^\alpha_{n+1,k}(t; \mu^2)$ is the reduced matrix element of the operator[6] $\overline{\mathcal{O}}^\alpha_{n,0}(0; \mu^2)$. The structure function is therefore written as yet another inverse Mellin transform,

$$V_1 \simeq -\int \frac{dj}{4i} \frac{1 + e^{-\pi i j}}{\sin(\pi j)} \overline{C}^\alpha_{j-1}(\vartheta) \frac{1}{x^j} \overline{A}^\alpha_j(\eta, t; \mu^2). \tag{20}$$

Yet another GPD can also be defined by using $\overline{A}^\alpha$ instead of $A^\alpha_j(\eta, t; q^2)$:

$$\overline{H}^\alpha(x, \eta, t; \mu^2) = \int \frac{dj}{2\pi i} \frac{1}{x^j} \overline{A}^\alpha_j(\eta, t; \mu^2). \tag{21}$$

When it comes to the description of the $\gamma^* + h \to \gamma + h$ scattering amplitude as a whole, it does not matter which operator basis is used. In order to talk about the distribution of partons in the transverse directions in a hadron, we only need GPD at $\eta = 0$. The newly defined GPD $\overline{H}$ does just as good a job as the H defined in (15); they are the same at $\eta = 0$.

Even within the dual parametrization approach, it has been advantageous to use this operator basis because it becomes much easier to implement a phenomenological assumption (a function form) of $\overline{A}^\alpha_j(\eta, t; \mu^2)$ that is consistent with renormalization group flow [15].

[5] In reality, the anomalous dimension matrix depends on the coupling constant α_s, and α_s changes over the scale. Thus, the eigenoperator of the renormalization/dilatation also changes over the scale. In scale invariant theories (and in theories with only slow running in α_s), however, this multiplicative renormalization is exact or a good approximation (cf. [22]).

[6] Just like $\mathcal{O}_{j,l} = (-i\partial)^l \mathcal{O}_{j,0}$, there is a relation $\bar{\mathcal{O}}_{n,K} = (-i\partial)^K \bar{\mathcal{O}}_{n,0}$ in the new basis. This is why all the hadron matrix elements of $\bar{\mathcal{O}}_{n,K}$ can be parametrized by $\bar{A}_{n+1,k}$, just like those of $\mathcal{O}_{j,l}$ are by $A_{j,k}$. Here, n corresponds to the conformal spin, which is sometimes denoted by j in the literature. In this article, however, we maintain $j = n + 1$.

4. Conformal OPE

Although the hadron matrix element is essentially nonperturbative and is not calculable within perturbative QCD, more discussion has been made of the Wilson coefficients $\overline{C}^{\alpha}_{n,K}$. They still have to be calculated order by order in perturbation theory, if one is interested strictly in the QCD of the real world. If one is interested in gauge theories that are more or less "similar" to QCD, however, stronger statements can be made for a system with higher symmetry: conformal symmetry. One can think of $\mathcal{N}=4$ super Yang-Mills theory or $\mathcal{N}=1$ supersymmetric $\mathrm{SU}(N)\times\mathrm{SU}(N)$ gauge theory of [23] as an example of theories with exact (super)conformal symmetry. The QED probe in the real-world QCD can be replaced by gauging global symmetries [such as (a part of) SU(4) R symmetry of $\mathcal{N}=4$ super Yang-Mills theory and $\mathrm{SU}(2)\times\mathrm{SU}(2)\times\mathrm{U}(1)$ symmetry of [23]]. By applying the conformal symmetry, one can derive stronger statements on the Wilson coefficients of primary operators appearing in the OPE.

Suppose that we are interested in the OPE of two primary operators, A and B, that are both scalar under SO(3,1). If we take the basis of local operators for the expansion to be primary operators $\overline{\mathcal{O}}_n$ (with j_n Lorentz indices and an l_n scaling dimension) and their descendants $\partial^K\overline{\mathcal{O}}_n$ (with j_n+K Lorentz indices), then in the OPE,

$$T\{A(x)B(0)\}=\sum_n\left(\frac{1}{x^2}\right)^{\frac{1}{2}(l_A+l_B-l_n+j_n)}\sum_{K=0}^{\infty}c_{n,K}\frac{x^{\rho_1}\cdots x^{\rho_{j_n+K}}}{(x^2)^{j_n+K}}\times[\partial^K\overline{\mathcal{O}}_n(0)]_{\rho_1\cdots\rho_{j_n+K}}. \tag{22}$$

The conformal symmetry determines all the coefficients of the descendants $c_{n,K}$ ($K\geq 1$) in terms of that of the primary operator, $c_{n,0}=:c_n$. Ignoring the mixture of nontraceless contributions, one finds that [24]

$$T\{A(x)B(0)\}\simeq\sum_n\left(\frac{1}{x^2}\right)^{\frac{1}{2}(l_A+l_B-l_n+j_n)}x^{\rho_1}\cdots x^{\rho_{j_n}}c_n\times{}_1F_1\left(\frac{l_A-l_B+l_n+j_n}{2},l_n+j_n;x\cdot\partial\right)\times[\overline{\mathcal{O}}_n(0)]_{\rho_1\cdots\rho_{j_n}}. \tag{23}$$

A question of real interest to us is the OPE of conserved currents J^ν and J^μ. They are not scalars of SO(3,1), but the same logic as in [24] can be used also to show that, in the terms with Wilson coefficients proportional to $\eta^{\mu\nu}$,

$$T\{J^\nu(x)J^\mu(0)\}\simeq\eta^{\mu\nu}\sum_n\left(\frac{1}{x^2}\right)^{3-\frac{\tau_n}{2}}x^{\rho_1}\cdots x^{\rho_{j_n}}c_n\times{}_1F_1\left(\frac{l_n+j_n}{2},l_n+j_n;x\cdot\partial\right)\times[\overline{\mathcal{O}}_n(0)]_{\rho_1\cdots\rho_{j_n}}+\cdots, \tag{24}$$

where $\tau_n:=l_n-j_n$ is the twist, a mixture of the nontraceless (and hence higher twist) contributions is ignored, and terms with Wilson coefficients without $\eta^{\mu\nu}$ are all omitted here. The scaling dimension of conserved currents $l_A=l_B=3$ has been used. The momentum space version of the OPE is [25]

$$i\int d^4x\,e^{-iq_2\cdot x}T\{J^\nu(x)J^\mu(0)\}\simeq\eta^{\mu\nu}\sum_n\frac{(2\pi)^2\Gamma(\frac{l_n+j_n-2}{2})}{4^{2-\frac{\tau_n}{2}}\Gamma(3-\frac{\tau_n}{2})}c_n\frac{(-2i)^{j_n}q_2^{\rho_1}\cdots q_2^{\rho_{j_n}}}{(q_2^2)^{\frac{\tau_n}{2}-1}(q_2^2)^{j_n}}\times{}_2F_1\left(\frac{l_n+j_n}{2},\frac{l_n+j_n}{2}-1,l_n+j_n;\frac{-2iq_2\cdot\partial}{q_2^2}\right)\overline{\mathcal{O}}_n(0)+\cdots, \tag{25}$$

or, equivalently [18],

$$i\int d^4(x-y)e^{-iq\cdot(x-y)}T\{J^\nu(x)J^\mu(y)\}\simeq\eta^{\mu\nu}\sum_n\frac{(2\pi)^2\Gamma(\frac{l_n+j_n-2}{2})}{4^{2-\frac{\tau_n}{2}}\Gamma(3-\frac{\tau_n}{2})}c_n\frac{(-2i)^{j_n}q^{\rho_1}\cdots q^{\rho_{j_n}}}{(q^2)^{\frac{\tau_n}{2}-1}(q^2)^{j_n}}\times{}_2F_1\left(\frac{l_n+j_n-2}{4},\frac{l_n+j_n}{4},\frac{l_n+j_n}{2};\left(\frac{iq\cdot\partial}{q^2}\right)^2\right)\overline{\mathcal{O}}_n\left(\frac{x+y}{2}\right)+\cdots. \tag{26}$$

Either in the form of (25) or (26), the primary operators $\overline{\mathcal{O}}_n$ and the corresponding coefficients c_n are renormalized multiplicatively.

B. AdS/CFT approach

In AdS/CFT correspondence, type IIB string theory on $\mathrm{AdS}_5\times W$ with a five-dimensional Einstein manifold W corresponds to a gauge theory on $\mathbb{R}^{3,1}$ with an exact conformal symmetry; theories with an exact conformal symmetry, however, are qualitatively different from the QCD in the real world. But the type IIB string on a geometry that is close to $\mathrm{AdS}_5\times W$, except with the confining end in the infrared, may be used to extract a qualitative lesson on strongly coupled gauge theories with confinement, which are not qualitatively different from the QCD.

In a dual pair of a conformal field theory (CFT) and a string theory on a background $AdS_5 \times W$, primary operators of the CFT are in one-to-one correspondence with string states on AdS_5, and their correlation functions can be calculated by using the wave functions of the string states on AdS_5. When the background geometry is changed from $AdS_5 \times W$ to some warped geometry that is nearly AdS_5 with an end in the infrared, then the wave functions might be used to calculate matrix elements of the corresponding "primary" operators in an almost conformal theory. The correspondence between the operators and string states can be made precise, because they are both classified in terms of the representation of the conformal algebra, which is shared by both of the dual theories.

In order to determine GPD $\overline{H}$ in gravitational dual descriptions, it is therefore sufficient to determine wave functions of string states corresponding to the primary operators of interest. Although there is plenty of literature discussing the correspondence between the (superconformal) primary operators and string states at the supergravity level, it is known that the flavor-singlet twist-2 operators (labeled by the spin j) correspond to the stringy excitations with arbitrary high spin j that are in the same trajectory as the graviton [3,26]. Our task is, therefore, to determine the wave functions of such string states. Needless to say, one has to fix all of the gauge degrees of freedom associated with string component fields (not just the general coordinate invariance associated with the graviton) before working out the mode decomposition. Furthermore, wave functions need to be grouped together properly so that they form an irreducible representation of the conformal group in order to establish correspondence with a primary operator of the gauge theory side, which also forms an irreducible representation of the conformal group, along with its descendants.

It will be clear by the end of this article that all such technical work is necessary and essential for the purpose of extracting skewness dependence of GPD.

There are two different (but equivalent) ways to study the DVCS $\gamma^* + h \to \gamma^{(*)} + h$ amplitude and GPD in gravitational dual descriptions. One is to determine the hadron matrix elements of spin-j primary operators by using appropriate wave functions; GPD $\overline{H}$ is obtained by the inverse Mellin transform of the matrix elements. Using the Wilson coefficients that are governed by the conformal symmetry [see (26)], the DVCS amplitude will also be obtained. Conversely, the other way is to calculate disc/sphere amplitude directly, with the vertex operators given (approximately) by using the wave functions associated with the target hadron (see Secs. III and IV). We will identify the structure of conformal OPE in the expression for the $\gamma^* + h \to \gamma^{(*)} + h$ scattering amplitude in gravity dual [see (160), (163), (178)], with the Wilson coefficient for the twist-2 operators precisely as predicted by conformal symmetry (26). That also makes it possible to read out hadron matrix elements, and to extract the GPD. In these approaches, one can hope to work also for higher twist contributions, in principle, but we are not ambitious enough to do that in this article. In this article, we will proceed with the latter approach.

III. GRAVITY DUAL SETTINGS

A number of warped solutions to the type IIB string theory have been constructed, and they are believed to be dual to some strongly coupled gauge theories. When the geometry is close to $AdS_5 \times W$ with some five-dimensional Einstein manifold W, with weak running of the anti–de Sitter (AdS) radius along the holographic radius, the corresponding gauge theory will also have approximate conformal symmetry, and the gauge coupling constant runs slowly. If the $AdS_5 \times W$ geometry has a smooth end at the infrared as in [27], then the dual gauge theory will end up with confinement. Gravitational backgrounds in the type IIB string theory with the properties we stated above all provide a decent framework for studying qualitative aspects of nonperturbative information associated with gluons/Yang-Mills theory on $3+1$ dimensions.

In studying the $h + \gamma^* \to h + \gamma$ scattering process in a gravitational dual, we need a global symmetry to be gauged weakly, just like QED for QCD. In type IIB D-brane constructions of gauge theories that have a gravity dual, U(1) subgroups of an R symmetry or a flavor symmetry on D7-branes can be used as the models of the electromagnetic U(1) symmetry. Therefore, we have in mind gravity dual models on a background that is approximately $AdS_5 \times W$ with a nontrivial isometry group on W, or with a D7-brane configuration on it, as in [2].

Our interest, however, is not so much in writing down an exact mathematical expression based on a particular gravity dual model that is equivalent to a particular strongly coupled gauge theory, but more in extracting qualitative information of partons in hadrons of confining gauge theories in general. It is, therefore, more suitable for this purpose to use a simplified setup that carries common (and essential) features of the type IIB models that we described above. Throughout this article, we assume a pure $AdS_5 \times W$ metric background,

$$ds^2 = G_{MN}dx^M dx^N = g_{mn}dx^m dx^n + R^2 (g_W)_{ab} d\theta^a d\theta^b, \tag{27}$$

$$g_{mn}dx^m dx^n = e^{2A(z)}(\eta_{\mu\nu}dx^\mu dx^\nu + dz^2), \quad e^{2A(z)} = \frac{R^2}{z^2}; \tag{28}$$

that is, we ignore the running effect, and we do not specify the five-dimensional manifold W. The dilaton vacuum expectation value is simply assumed to be constant, $e^\phi = g_s$. A confining effect—the infrared end of this

geometry—can be introduced, for example, by sharply cutting off the AdS_5 space at $z = \Lambda^{-1}$ (hard wall models), or by similar alternatives (soft wall models). We are not committed to a particular implementation of the infrared cutoff in this article (see the discussion in Sec. V D), except in a couple of places where we write down some concrete expressions for illustrative purposes (Secs. VII A and VII D). The energy scale Λ associated with (any form of implementation of) the infrared cutoff corresponds to the confining energy scale in the dual gauge theories. When we consider (a simplified version of the) models with D7-branes for flavor, we assume that the D7-brane world volume wraps on a three-cycle on W and extends all the way down to the infrared end of the holographic radius z; i.e., all of $0 \le z \le \Lambda^{-1}$. This corresponds to assuming massless quarks. In this article, we will not pay attention to physics where spontaneous chiral symmetry breaking is essential.

As we stated earlier, we would like to work out the $h + \gamma^* \to h + \gamma^{(*)}$ scattering amplitude by using the gravity dual models. This is done by summing up sphere/disc amplitudes, along with those with higher genus world sheets. We will restrict our attention to kinematical regions where saturation is not important (i.e., large q^2 and/or not too small x, and large N_c). That allows us to focus only on sphere/disc amplitudes, with the insertion of four vertex operators corresponding to the incoming and outgoing hadron h and (possibly virtual) photon γ.

As a string-based model of the target hadron h [that is SO(3,1) scalar], we have in mind either a scalar "glueball"[7] that has nontrivial R-charge, or a scalar meson made of matter fields. The former corresponds to a vertex operator [in the $(-1,-1)$ picture]

$$V(p) = :e^{ip_\mu \cdot X^{\hat{\mu}}} \psi^m \tilde{\psi}^n g_{mn} \Phi(Z; m_n) Y(\Theta):, \qquad (29)$$

where $Y(\Theta)$ is a "spherical harmonics" on W, and the latter to

$$V(p) = :e^{ip_\mu \cdot X^{\hat{\mu}}} \psi \Phi(Z; m_n):, \qquad (30)$$

where ψ corresponds to the D7-brane fluctuations in its transverse directions. $\Phi(Z)$ is the wave function on AdS_5, with the argument promoted to the field on the world sheet [3]. The vertex operators above are approximate expressions in the $(\alpha'/R^2) \sim 1/\sqrt{\lambda}$ expansion (e.g., [28]) in a theory formulated with a nonlinear σ model given by (27). If we are to employ the hard wall implementation of the infrared boundary, with the AdS_5 metric in the bulk without modification, then the wave function $\Phi(Z; m_n)$ is of the form

$$\sqrt{t_h}\Phi(z; m_n) = 2\Lambda z^2 \frac{J_{\ell_\phi - 2}(j_{\ell_\phi - 2, n}\Lambda z)}{|J'_{\ell_\phi - 2}(j_{\ell_\phi - 2, n})|}. \qquad (31)$$

[7]By glueball, we only mean a bound state of fields in super Yang-Mills theory.

This wave function is that of the nth lightest hadron corresponding to some scalar operator with conformal dimension ℓ_ϕ; the hadron mass $m_n = j_{\ell_\phi - 2, n}\Lambda$ is given by the nth zero of the Bessel function $J_{\ell_\phi - 2}$. We will comment on the normalization factor $\sqrt{t_h}$ in later sections, though it disappears from the expression for physical observables.

The "photon" current in the correlation function/matrix element $T^{\nu\mu}$ in the gauge theory description corresponds to the insertion of vertex operators associated with non-normalizable wave functions, rather than with the normalizable wave functions (31) for the target hadron state. If we are to employ an R-symmetry current as the string-based model of the QED current, then the corresponding closed string vertex operator is

$$V(q) = :e^{iq_\mu \cdot X^{\hat{\mu}}} v_a(\Theta) A_m(Z; q)(\psi^a \tilde{\psi}^m + \psi^m \tilde{\psi}^a):, \qquad (32)$$

with some Killing vector $v_a \partial/\partial\theta^a$ on W. The vertex operator in the case of a D7-brane U(1) current is

$$V(q) = :e^{iq_\mu \cdot X^{\hat{\mu}}} A_m(Z; q) \psi^m:. \qquad (33)$$

The wave function $A_m(Z; q)$ on AdS_5 is of the form

$$A_\mu(z; q) = \left[\delta_\mu^{\hat{\kappa}} - \frac{q_\mu q^{\hat{\kappa}}}{q^2}\right] \epsilon_\kappa(q)(qz) K_1(qz) + q_\mu \frac{q^{\hat{\kappa}} \epsilon_\kappa(q)}{2q^2} (qz)^2 K_2(qz), \qquad (34)$$

$$A_z(z; q) = -i\partial_z \frac{q^{\hat{\kappa}} \epsilon_\kappa(q)}{2q^2} (qz)^2 K_2(qz). \qquad (35)$$

Here, q stands for $\sqrt{q^2}$, although it sometimes imply four-momentum q^μ, depending on the local context in this article. The rationale for our choice of the terms proportional to $(q \cdot \epsilon)$ will be explained later on in Appendix A.4, but those terms should not be relevant in the final result because of the gauge invariance of $T^{\nu\mu}$. When the infrared boundary is implemented by the hard wall, $K_1(qz)$ should be replaced by $K_1(qz) + [K_0(q/\Lambda)/I_0(q/\Lambda)]I_1(qz)$, and $K_2(qz)$ by an arbitrary linear combination of $K_2(qz)$ and $I_2(qz)$.

It is not as easy to calculate the sphere/disc amplitudes in practice, however. It has been considered that the parton contributions to $\gamma^* + h \to \gamma^{(*)} + h$ scattering are given by an amplitude with states in the leading trajectory with arbitrary high spin being exchanged [3]. These fields are not scalar on AdS_5 but come with multiple degrees of freedom associated with polarizations. Such polarization of higher spin fields propagating on AdS_5 needs to be treated properly—including such issues as covariant derivatives and kinetic mixing among different polarizations (diagonalization of the Virasoro generator L_0)—in gravity dual

descriptions in order to be able to discuss the skewness dependence of the GPD/DVCS amplitude. The direct impact of the curved background geometry can be implemented through the nonlinear σ model on the world sheet, but one has to define the vertex operators as a composite operator properly in such an interacting theory. The Ramond-Ramond background is an essential ingredient in making the warped background metric stable, yet a nonzero Ramond-Ramond background cannot be implemented in the Neveu-Schwarz-Ramond (NSR) formalism.

Instead of using a world-sheet calculation in the NSR formalism when implementing the effect of a curved background (27), we use string field theory action on flat space in this article and make it covariant. Because the gravity dual setup of our interest is in type IIB string theory, we are thus supposed to use superstring field theory for closed string and open string modes. In order to avoid technical complications associated with the interacting superstring field theories, however, we employ a sort of toy-model approach by using the cubic string field theory for bosonic string theory.

In our toy-mode approach, we deal with the cubic string field theory on AdS_5 ($\times$ some internal compact manifold), and ignore instability of the background geometry. The probe photon in this toy-model gravity dual setup will be the massless vector state of bosonic string theory with the wave function (34), (35). The target hadron can be any scalar states, (say, the tachyon) with the wave function (31). We are to construct a toy-model amplitude of the $h+\gamma^*\to h+\gamma^{(*)}$ scattering by using the two-to-two scattering of the massless photon and some scalar in bosonic string theory on the AdS_5 background. In short, this is to maintain the spirit of the setup in [2,3] and use the bosonic cubic string field theory to compute and obtain something concrete, from which qualitative lessons are to be extracted for the setup of our interest.

One of the costs of this approach (without the technical complexity of interacting superstring field theory) is that we have to restrict our attention to the Reggeon exchange (flavor-nonsinglet) amplitude because the cubic bosonic string field theory deals with open strings, not the closed (i.e., flavor neutral) string. The amplitude constructed in this way is certainly not faithful to the equations of type IIB string theory, either. Since our motivation is not in constructing yet another exact solution to superstring theory, however, we still expect that this (flavor-nonsinglet) toy-mode amplitude in bosonic string still maintains some fragrance of hadron scattering amplitude to be calculated in superstring theory. This discussion continues in Sec. VII C.

IV. CUBIC STRING FIELD THEORY

Section IV A summarizes the technical details of cubic string field theory that we will need in later sections. We then proceed in Sec. IV B to explain an idea of how to reproduce disc amplitude only from string field theory t-channel amplitude, using photon-tachyon scattering on a flat spacetime background as an example. This idea of constructing amplitude is generalized in Sec. VI for scattering on a warped spacetime, and we will see that this construction of the amplitude allows us to cast the amplitude almost immediately into the form of conformal OPE (25), (26).

A. Action of the cubic SFT on a flat spacetime

The action of the cubic string field theory (SFT) is given by [29]

$$S=-\frac{1}{2\alpha'}\int\left(\Phi*Q_B\Phi+\frac{2}{3}g_o\Phi*\Phi*\Phi\right), \quad (36)$$

$$=-\frac{1}{2\alpha'}\left(\Phi\cdot Q_B\Phi+\frac{2g_o}{3}\Phi\cdot\Phi*\Phi\right), \quad (37)$$

where g_o is a coupling constant of mass dimension $(1-D/2)$, where $D=26$ is the spacetime dimensions of bosonic string theory.[8] Q_B is the Becchi-Rouet-Stora-Tyutin (BRST) operator, and $*$ and $\cdot$ are the star product and inner product of the string fields, respectively; all of the technical details we need for this article are summarized below in this section, but more information is found, e.g., in [29,30]. The string field Φ is, as a ket state, expanded in terms of the Fock states as in

$$\begin{aligned}\Phi=|\Phi\rangle=&\phi(x)|{\downarrow}\rangle+(A_M(x)\alpha_{-1}^M+C(x)b_{-1}+\overline{C}(x)c_{-1})|{\downarrow}\rangle\\&+\left(f_{MN}(x)\frac{1}{\sqrt{2}}\alpha_{-1}^M\alpha_{-1}^N+ig_M(x)\frac{1}{\sqrt{2}}\alpha_{-2}^M\right.\\&\left.+h(x)b_{-1}c_{-1}+\cdots\right)|{\downarrow}\rangle,\end{aligned} \quad (38)$$

with component fields $\phi, A_M, C, \overline{C}, f_{MN}, g_M, h, \ldots$; we have already chosen the Feynman-Siegel gauge here. We will eventually be interested only in the states with a vanishing ghost number, $N_{\rm gh}=0$, because states with a nonzero ghost number do not appear in the t-channel/s-channel exchange for the disc amplitude.

The Hilbert space of one string state is spanned by the Fock states given (in this gauge) by

$$\prod_{a=1}^{h_a}\alpha_{-n_a}^{M_a}\prod_{b=1}^{h_b}b_{-l_b}\prod_{c=1}^{h_c}c_{-m_c}|{\downarrow}\rangle, \quad (39)$$

with $1\le n_1\le n_2\le\cdots\le n_{h_a}$, $1\le l_1<l_2<\cdots<l_{h_b}$, and $1\le m_1<m_2<\cdots<m_{h_c}$. Let us use $Y:=\{\{n_a\}\text{'s},\{l_b\}\text{'s},\{m_c\}'s\}$ as the label distinguishing

[8]The sign of the interaction term is just a matter of convention, because field redefinition for all of the component fields $\Phi\to-\Phi$ is always possible. Under this redefinition, however, the covariant derivative can be either $\partial_m-i\rho(A_\mu)$ or $\partial_m+i\rho(A_m)$. The sign convention above is for $\partial_m-i\rho(A_m)$, following the convention of Sec. 6.5 of Polchinski's textbook.

different Fock states of string on a flat spacetime. The mass of these Fock states is determined by

$$\alpha' k^2 + (N^{(Y)} - 1) = 0, \quad N^{(Y)} = \sum_{a=1}^{h_a} n_a + \sum_{b=1}^{h_b} l_b + \sum_{c=1}^{h_c} m_c. \tag{40}$$

A component field corresponding to a Fock state may be further decomposed into a multiple irreducible representation of the Lorentz group, but at least the rank-h_a totally symmetric traceless tensor representation is always contained. The Fock states of particular interest to us are the ones in the leading trajectory: $Y = \{1^N, 0, 0\}$, so that all the n_a's are 1, $h_b = h_c = 0$, and $N^{(Y)} = h_a$. The totally symmetric traceless tensor component field of these states is denoted by $(N!)^{-1/2} A^{(Y)}_{M_1 \cdots M_{h_a}}$.

The kinetic term—the first term of (36), (37)—is written down in terms of the component fields as follows:

$$-\frac{1}{2\alpha'} \Phi \cdot Q_B \Phi = \frac{1}{2} \int d^{26}x \, \mathrm{tr} \Big[\phi(x) \Big(\partial^2 + \frac{1}{\alpha'} \Big) \phi(x) + A_M(x) \partial^2 A^M(x) + f_{MN}(x) \Big(\partial^2 - \frac{1}{\alpha'} \Big) f^{MN}(x) + g_M(x) \Big(\partial^2 - \frac{1}{\alpha'} \Big) g^M(x) - h(x) \Big(\partial^2 - \frac{1}{\alpha'} \Big) h(x) + \cdots \Big]. \tag{41}$$

The totally symmetric tensor component field of the Fock states in the leading trajectory $Y = \{1^N, 0, 0\}$ has a kinetic term

$$\frac{1}{2} \int d^{26}x \, \mathrm{tr} \Big[A^{M_1 \ldots M_j} \Big(\partial^2 - \frac{N-1}{\alpha'} \Big) A_{M_1 \ldots M_j} \Big]. \tag{42}$$

The cubic string field theory action in the Feynman-Siegel gauge has two nice properties: First, the kinetic terms of those Fock states do not mix in the flat spacetime background, and second, the second derivative operators are simply given by the d'Alembertian operator, without complicated restrictions or mixing among various polarizations in the component fields.

The second term of the action (36), (37) gives rise to interactions involving three component fields. Interactions involving Fock states with small excitation level N are [30]

$$\begin{aligned} &-\frac{1}{2\alpha'} \frac{2g_o}{3} \Phi \cdot \Phi * \Phi \\ &= -\int d^{26}x \frac{g_o \lambda_{\mathrm{sft}}}{3\alpha'} \hat{E} (\mathrm{tr}[\phi^3(x)] \\ &\quad + \sqrt{\frac{8\alpha'}{3}} \mathrm{tr} \Big[(-iA_M)(\phi \overset{\leftrightarrow}{\partial}{}^M \phi) \Big] \\ &\quad - \frac{8\alpha'}{9\sqrt{2}} \mathrm{tr}[f_{MN} (\phi \overset{\leftrightarrow}{\partial}{}^M \overset{\leftrightarrow}{\partial}{}^N \phi)] - \frac{5}{9\sqrt{2}} \mathrm{tr}[f^M_M \phi^2] \\ &\quad + \frac{2\sqrt{\alpha'}}{3} \mathrm{tr}[(\partial_M g^M) \phi^2] - \frac{11}{9} \mathrm{tr}[h\phi^2]) + \cdots, \end{aligned} \tag{43}$$

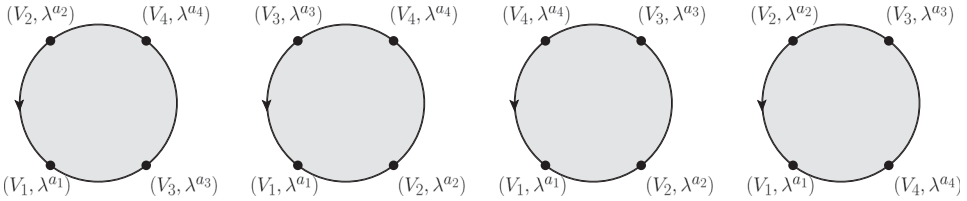
where $\lambda_{\mathrm{sft}} = 3^{9/2}/2^6$ [31], $\overset{\leftrightarrow}{\partial^M} = (\overleftarrow{\partial^M} - \overrightarrow{\partial^M})$, and

$$\hat{E} = \exp \Big[-2\alpha' \ln \Big(\frac{2}{3^{3/4}} \Big) (\partial^2_{(1)} + \partial^2_{(2)} + \partial^2_{(3)}) \Big]. \tag{44}$$

The $\partial^2_{(1,2,3)}$ designates the taking of derivatives of the first, second, and third fields.[9]

Interactions involving totally symmetric leading trajectory states are also of interest to us. The tachyon-tachyon–$Y = \{1^N, 0, 0\}$ cubic coupling with N derivatives is given by

$$-\frac{g_o \lambda_{\mathrm{sft}}}{\alpha'} \int d^{26}x \, \hat{E} \, \mathrm{tr} \Big[A^{(Y)}_{M_1 \cdots M_N} (\phi (-i \overset{\leftrightarrow}{\partial}{}^{M_1}) \cdots (-i \overset{\leftrightarrow}{\partial}{}^{M_N}) \phi) \Big] \Big(\frac{8\alpha'}{27} \Big)^{\frac{N}{2}} \frac{1}{\sqrt{N!}} \tag{45}$$



in the interaction part of the action. The photon (level-1 state)-photon–$Y = \{1^N, 0, 0\}$ coupling in the cubic string field theory includes

$$-\frac{g_o \lambda_{\mathrm{sft}}}{\alpha'} \int d^{26}x \, \hat{E} \, \mathrm{tr} \Big[A^{(N)}_{M_1 \cdots M_N} (A_L (-i \overset{\leftrightarrow}{\partial}{}^{M_1}) \cdots (-i \overset{\leftrightarrow}{\partial}{}^{M_N}) A_K) \Big(\frac{8\alpha'}{27} \Big)^{\frac{N}{2}} \eta^{KL} \frac{16}{27} \frac{1}{\sqrt{N!}} + \cdots \Big], \tag{46}$$

where we kept only the terms that have N derivatives and are proportional to η^{KL}, as they are necessary in deriving (61).

[9] Concretely,

$$\begin{aligned} &\hat{E} A(x) B(x) C(x) \\ &\quad = \Big[\Big(\frac{27}{16} \Big)^{\frac{\alpha'}{2}\partial^2} A(x) \Big] \Big[\Big(\frac{27}{16} \Big)^{\frac{\alpha'}{2}\partial^2} B(x) \Big] \Big[\Big(\frac{27}{16} \Big)^{\frac{\alpha'}{2}\partial^2} C(x) \Big]. \end{aligned}$$

FIG. 3. Disc amplitudes with two photon vertex operators (V_1 and V_2) and two tachyon vertex operators (V_3 and V_4) inserted. Kinematical amplitudes given by the disc amplitudes above are multiplied by the Chan-Paton factors $\mathrm{tr}[\lambda^{a_1}\lambda^{a_3}\lambda^{a_4}\lambda^{a_2}]$ in (a), $\mathrm{tr}[\lambda^{a_1}\lambda^{a_2}\lambda^{a_4}\lambda^{a_3}]$ in (b), $\mathrm{tr}[\lambda^{a_1}\lambda^{a_2}\lambda^{a_3}\lambda^{a_4}]$ in (c) and $\mathrm{tr}[\lambda^{a_1}\lambda^{a_4}\lambda^{a_3}\lambda^{a_2}]$ in (d), respectively. The two disc amplitudes (a),(b) become $\mathcal{M}_{\mathrm{Ven}}(s,t)$, while (c),(d) become $\mathcal{M}_{\mathrm{Ven}}(u,t)$.

B. Cubic SFT scattering amplitude and t-channel expansion

Before proceeding to study the $h+\gamma^*\to h+\gamma^{(*)}$ scattering amplitude by using the cubic string field theory on the warped spacetime background, let us remind ourselves how to obtain t-channel operator product expansion from the amplitude calculation based on string field theory, by using tachyon-photon scattering on the flat spacetime as an example.

Let us consider the disc amplitude of tachyon-photon scattering. The vertex operators labeled by $i=1,2$, $V_i=:\epsilon_M^i\partial X^M e^{ik_i\cdot X}:$ are for photon incoming ($i=1$) and outgoing ($i=2$) states, which come with Chan-Paton matrices λ^{a_i}. Tachyon incoming ($i=3$) and outgoing ($i=4$) states correspond to vertex operators $V_i=:e^{ik_i\cdot X}:$ with Chan-Paton matrices λ^{a_i}. The photon-tachyon scattering amplitude $A+\phi\to A+\phi$ in bosonic open string theory (Veneziano amplitude) is given by[10]

$$\mathcal{M}_{\mathrm{Ven}}(s,t)=-\left(\frac{g_o^2}{\alpha'}\right)\frac{\Gamma(-\alpha' t-1)\Gamma(-\alpha' s-1)}{\Gamma(-\alpha'(s+t)-1)}\epsilon_M(k_2)\epsilon_N(k_1)\left\{\left[\eta^{MN}-\frac{k_1^M k_2^N}{k_1\cdot k_2}\right](\alpha' s+1)\right.$$
$$\left.+2\alpha'\left(\left[p^M-k_1^M\frac{k_2\cdot p}{k_1\cdot k_2}\right]-\frac{k_2^M}{2}\right)\left(\left[p^N-k_2^N\frac{k_1\cdot p}{k_2\cdot k_1}\right]-\frac{k_1^N}{2}\right)(\alpha' t+1)\right\},\tag{47}$$

which is to be multiplied by the Chan-Paton factor $\mathrm{Tr}[\lambda^{a_2}\lambda^{a_4}\lambda^{a_3}\lambda^{a_1}+\lambda^{a_4}\lambda^{a_2}\lambda^{a_1}\lambda^{a_3}]$ [see Figs. 3(a) and 3(b)]. If the Chan-Paton matrices of a pair of incoming and outgoing vertex operators, λ^{a_1} and λ^{a_2}, commute with each other,[11] then the Chan-Paton factors from Figs. 3(c) and 3(d) are the same, and the total kinematical part of the amplitude for this Chan-Paton factor becomes $\mathcal{M}_{\mathrm{Ven}}(s,t)+\mathcal{M}_{\mathrm{Ven}}(u,t)$.

Let us stay focused on $\mathcal{M}_{\mathrm{Ven}}(s,t)$ alone for now. The amplitude proportional to η^{MN} can be expanded, as is well known, as a sum only of t-channel poles[12]:

$$\frac{g_o^2}{\alpha'}\frac{\Gamma(-\alpha' t-1)\Gamma(-\alpha' s)}{\Gamma(-\alpha'(s+t)-1)}=\frac{g_o^2}{\alpha'}\int_0^1 dx\, x^{-\alpha' t-2}(1-x)^{-\alpha' s-1},\tag{48}$$

$$=\frac{g_o^2}{\alpha'}\sum_{N=0}^{\infty}\frac{-1}{\alpha' t-(N-1)}\frac{(\alpha' s+1)\cdots(\alpha' s+N)}{N!}.\tag{49}$$

The Veneziano amplitude (47) can also be obtained in cubic string field theory [32]. In the cubic SFT, the scattering amplitude consists of two pieces, a collection of t-channel exchange diagrams and s-channel diagrams (Fig. 4):

$$\mathcal{M}_{\mathrm{Ven}}(s,t)=\sum_Y\mathcal{M}_Y^{(t)}(s,t)+\sum_Y\mathcal{M}_Y^{(s)}(s,t).\tag{50}$$

Infinitely many one string states (39) with zero ghost number ($h_b=h_c$)—labeled by Y—can be exchanged in the t channel or the s channel, and the corresponding contributions are in the form of

$$\mathcal{M}_Y^{(t)}=\frac{f_Y^{(t)}(s,t)}{-\alpha' t-1+N^{(Y)}},\qquad \mathcal{M}_Y^{(s)}=\frac{f_Y^{(s)}(t,s)}{-\alpha' s-1+N^{(Y)}},\tag{51}$$

[10]Here, $p:=(k_3-k_4)/2$, the averaged momentum of the tachyon before and after the scattering, just like in (2).

[11]Just like in the case where both λ^{a_1} and λ^{a_2} are an $N_F\times N_F$ matrix $\mathrm{diag}(2/3,-1/3,-1/3)$.

[12]It is also possible to expand this as a sum of s-channel poles only; that is the celebrated s-t duality of the Veneziano amplitude.

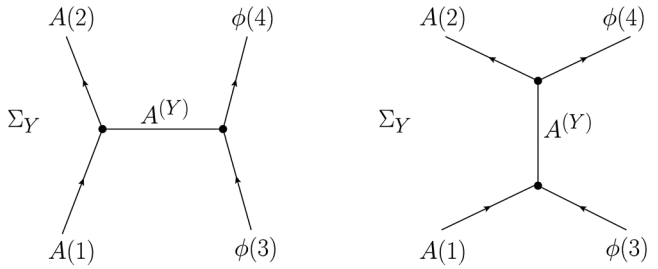

FIG. 4. Two types of diagrams contribute to the photon-tachyon scattering amplitude $\mathcal{M}_{\rm Ven}(s,t)$ in cubic string field theory: the t-channel exchange of one string states labeled by Y (left panel) and the s-channel exchange (right panel).

where $f_Y^{(t)}$ and $f_Y^{(s)}$ are regular functions at finite s and t; $N^{(Y)}$ is the excitation level (40) of a component field $A^{(Y)}$.

Because both the world-sheet calculation (47), (49) and the cubic SFT calculation (50), (51) are the same thing, $\mathcal{M}_{\rm Ven}(s,t)$ in both approaches should be exactly the same functions of (s,t). Therefore, for an arbitrary given value of s, the residue of all the poles in the complex t plane should be the same. We also know that the Veneziano amplitude can be expanded purely in the infinite sum of t-channel poles with t-independent residues. This means that the full Veneziano amplitude (47) can be reproduced just from the t-channel cubic SFT amplitude[13] $\sum_Y \mathcal{M}_Y^{(t)}(s,t)$ through the following procedure:

$$\sum_Y \frac{f_Y^{(t)}(s,t)}{-\alpha' t - 1 + N^{(Y)}} \to \sum_Y \frac{f_Y^{(t)}(s,(N^{(Y)}-1)/\alpha')}{-\alpha' t - 1 + N^{(Y)}} = \mathcal{M}_{\rm Ven}(s,t). \tag{52}$$

To see that this prescription really works, let us take a look at the amplitudes of t-channel exchange of one string states with small excitation level $N^{(Y)} = 0, 1, 2$. Focusing on the amplitude of $A + \phi \to A + \phi$ proportional to η^{MN}, we find that the tachyon exchange in the t channel [Fig. 5(a)] gives rise to the amplitude [33]

$$\mathcal{M}_\phi^{(t)}(s,t) = \left(\frac{g_o \lambda_{\rm sft}}{\alpha'}\right)^2 \left(\frac{2}{3^{3/4}}\right)^{-2\alpha' t - 2\alpha' t + 4} \frac{-1}{t + 1/\alpha'} = \frac{g_o^2}{\alpha'}\left(\frac{27}{16}\right)^{\alpha' t + 1} \frac{-1}{\alpha' t + 1}, \tag{53}$$

which is obtained simply by using the ϕ-ϕ-ϕ vertex rule (43) and the A-A-ϕ vertex rule (45). The prescription (52) turns this amplitude into

[13]The t-channel and s-channel amplitudes of the cubic SFT, $\sum_Y \mathcal{M}_Y^{(t)}$ and $\sum_Y \mathcal{M}_Y^{(s)}$, correspond to the integration over $[0, 1/2]$ and $[1/2, 1]$, respectively, in (48) [32]. Thus, $\sum_Y \mathcal{M}_Y^{(s)}$ does not contain a pole in t.

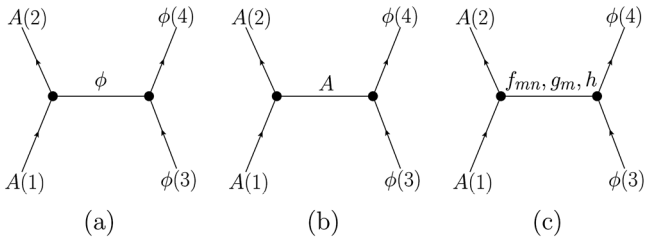

FIG. 5. t-channel exchange diagrams for $A + \phi \to A + \phi$ scattering in cubic string field theory. The tachyon ($N = 0$), photon ($N = 1$), and level-2 states are exchanged in diagrams (a), (b), and (c), respectively.

$$\to \mathcal{M}_\phi(s,t) = \frac{g_o^2}{\alpha'} \frac{-1}{\alpha' t + 1}, \tag{54}$$

which reproduces the $N = 0$ term of (49).

The t-channel exchange of level $N^{(Y)} = 1$ excited states can also be calculated in the cubic string field theory [Fig. 5(b)]. The amplitude proportional to η^{MN} is

$$\mathcal{M}_A^{(t)}(s,t) = \frac{g_o^2}{\alpha'}\left(\frac{27}{16}\right)^{\alpha' t} \frac{-1}{\alpha' t}\left[\frac{\alpha'(s-u)}{2}\right], \tag{55}$$

where $(s-u) = (k_{(1)} - k_{(2)}) \cdot (k_{(4)} - k_{(3)})$. Using the relation $\alpha'(s+t+u) = -2$ in the tachyon-photon scattering to eliminate u in favor of s and t, and following the prescription (52)—which is to exploit $\alpha' t = 0$ in the numerator—this amplitude is replaced by [33]

$$\longrightarrow \mathcal{M}_A(s,t) = \frac{g_o^2}{\alpha'} \frac{-(\alpha' s + 1)}{\alpha' t}. \tag{56}$$

Once again, this reproduces the level $N = 1$ contribution to the Veneziano amplitude (49).

A similar calculation for level-2 state exchange can be carried out [Fig. 5(c)]. Using the vertex rule in (43) for the level-2–ϕ-ϕ couplings, and also the interactions among level-2–A-A couplings in the literature, the cubic SFT t-channel amplitude is given by [33]

$$\mathcal{M}_f^{(t)}(s,t) = \frac{g_o^2}{\alpha'}\left(\frac{27}{16}\right)^{\alpha' t - 1} \frac{-1}{\alpha' t - 1} \times \left[\frac{(\alpha'(s-u))^2}{8} - \frac{5(\alpha' t + 2)}{16 \cdot 2} + \frac{490}{16^2 \cdot 2}\right], \tag{57}$$

$$\mathcal{M}_g^{(t)}(s,t) = \frac{g_o^2}{\alpha'}\left(\frac{27}{16}\right)^{\alpha' t - 1} \frac{-1}{\alpha' t - 1}\left[-\frac{36\alpha' t}{16^2}\right], \tag{58}$$

$$\mathcal{M}_h^{(t)}(s,t) = \frac{g_o^2}{\alpha'}\left(\frac{27}{16}\right)^{\alpha' t - 1} \frac{-1}{\alpha' t - 1}\left[-\frac{11^2}{16^2}\right]. \tag{59}$$

After using $\alpha' u = -\alpha'(s+t) - 2$ to eliminate u in favor of s and t, and further following the prescription (52) ($\alpha' t \to 1$

in the numerator), one will see that the level $N^{(Y)}=2$ amplitude turns into

$$\begin{aligned}&\to(\mathcal{M}_f+\mathcal{M}_g+\mathcal{M}_h)(s,t)\\&=\frac{g_o^2}{\alpha'}\frac{-1}{\alpha' t-1}\left[\frac{(\alpha' s)^2+3(\alpha' s)+2}{2}\right].\end{aligned}\tag{60}$$

Once again, this is precisely the same as the $N=2$ contribution to the Veneziano amplitude (49).

Contributions from the t-channel exchange of states in the leading trajectory can also be examined systematically. Using the vertex rule (45), (46) involving the states in the leading trajectory ($Y=\{1^N,0,0\}$), one finds that the amplitude proportional to η^{MN} is

$$\mathcal{M}^{(t)}_{\{1^N,0,0\}}\simeq\frac{g_o^2}{\alpha'}\left(\frac{27}{16}\right)^{\alpha' t-(N-1)}\frac{-1}{\alpha' t-(N-1)}\frac{(\alpha'(s-u)/2)^N}{N!},\tag{61}$$

where we maintained only the terms with the highest power of either s or u. After using the kinematical relation $\alpha'(s+t+u)+2=0$ to eliminate u in favor of s and t, and following the prescription (52) [$\alpha' t\to(N-1)$ in the numerator], we obtain the large-(α's) leading power contribution to the Nth term of (49) with the correct coefficient.

We have, therefore, seen that the prescription (52) allows us to use the t-channel exchange amplitude in the cubic string field theory to construct the full disc scattering amplitude. In Sec. VI, this prescription is extended for the disc scattering amplitudes on a spacetime with a curved background metric, which is the situation of real interest in the context of hadron scattering.

V. MODE DECOMPOSITION ON AdS_5

Let us now proceed to work out mode decomposition of the totally symmetric (traceless) component field on the warped spacetime. The correspondence between the primary operators of the conformal field theory on the (UV) boundary and wave functions on AdS_5 is made clear in this section. The Pomeron/Reggeon wave functions are obtained as a *holomorphic* function of the spin variable j since we need to do so for the further inverse Mellin transformation. The wave functions will then also be used to construct the scattering amplitude of $h+\gamma^*\to h+\gamma^{(*)}$ and GPD in Secs. VI and VII.

Let the bilinear (free) part of the (bulk) action of a rank-j tensor field on AdS_5 be[14]

$$\begin{aligned}S_{\text{eff kin}}=&-\frac{1}{2}\frac{t_{Ay}}{R^3}\int d^4x\int dz\sqrt{-g(z)}g^{m_1n_1}\cdots g^{m_jn_j}\\&\times\left[g^{m_0n_0}(\nabla_{m_0}A^{(y)}_{m_1\cdots m_j})(\nabla_{n_0}A^{(y)}_{n_1\cdots n_j})\right.\\&\left.+\left(\frac{c_y}{R^2}+\frac{N^{(y)}_{\text{eff}}}{\alpha'}\right)A^{(y)}_{m_1\cdots m_j}A^{(y)}_{n_1\cdots n_j}\right],\end{aligned}\tag{62}$$

where we assume that kinetic mixing between different fields is either absent or sufficiently small. Here, the dimensionless parameter $N^{(y)}_{\text{eff}}$ is $N^{(Y)}-1$ for an $N^{(Y)}\in\mathbf{Z}_{\geq 0}$ for bosonic open string ($j\leq N^{(Y)}$), which would be $4(N^{(Y)}-1)$ for an $N^{(Y)}\in\mathbf{Z}_{\geq 1}$ for closed string ($j\leq 2N^{(Y)}$). This field is regarded as a reduction of some field with spherical harmonics on the internal manifold,[15] and hence $j\leq h_a$, in general. Another dimensionless coefficient c_y may contain a contribution from the "mass" associated with the spherical harmonics over the internal manifold and may also include the ambiguity (which is presumably of order unity) associated with making d'Alembertian of the flat metric background covariant.[16] The combination $(c_y/R^2+N^{(y)}_{\text{eff}}/\alpha')$ is denoted by M^2_{eff}.

The equation of motion (in the bulk part)[17] then becomes

$$g^{m_1m_2}(\nabla_{m_1}\nabla_{m_2}A^{(y)}_{n_1\cdots n_j})-\left(\frac{c_y}{R^2}+\frac{N^{(y)}_{\text{eff}}}{\alpha'}\right)A^{(y)}_{n_1\cdots n_j}=0.\tag{64}$$

Solutions to this equation of motion can be obtained from solutions of the following eigenmode equation,[18]

$$\nabla^2A_{m_1\cdots m_j}=-\frac{\mathcal{E}}{R^2}A_{m_1\cdots m_j},\tag{65}$$

[14]The dimensionless constant t_{Ay} is something like N_c^2 for a mode obtained by a reduction of closed string component fields in higher dimensions. More comments on t_{Ay} for open string states is found in footnote 27.

[15]The internal manifold would be a five-dimensional one, W, for closed string modes in type IIB, and a three-cycle one for open string states on the flavor D7-branes. For sufficiently small x, however, amplitudes of exchanging modes with nontrivial spherical harmonics on these internal manifolds are relatively suppressed, and we are not interested very much.

[16]The ambiguity in c_y/R^2 includes insertion of the curvature tensor,

$$\begin{aligned}([\nabla_M,\nabla_N])^{Q'}_{Q}&=-\Gamma^{Q'}_{QN,M}+\Gamma^{Q'}_{QM,N}+\Gamma^{L}_{QM}\Gamma^{Q'}_{LN}-\Gamma^{L}_{QN}\Gamma^{Q'}_{LM}\\&=\frac{\delta^{Q'}_M g_{QN}-\delta^{Q'}_N g_{QM}}{R^2},\end{aligned}\tag{63}$$

which vanishes in flat space. Depending on details of how it is inserted, the value of c_y may not be the same for all the individual irreducible components of SO(4,1) in a rank-j tensor field $A_{m_1\cdots m_j}$.

[17]There is also an IR boundary part of the equation motion. We will come back to this issue in Sec. V D.

[18]The differential operator $\nabla^2:=g^{mn}\nabla_m\nabla_n$ is Hermitian under the measure $d^4xdz\sqrt{-g(z)}g^{m_1n_1}\cdots g^{m_jn_j}$.

by imposing the on-shell condition

$$\frac{(\mathcal{E}+c_y)}{\sqrt{\lambda}}+N^{(y)}_{\rm eff}=0 \qquad (\text{i.e.,}\quad \mathcal{E}+R^2M^2_{\rm eff}=0). \tag{66}$$

We will work out the eigenmode decomposition for rank-j tensor fields in the following, where we have to work only for a separate j, without referring to the mass parameter.[19]

The eigenmode wave functions are used not just for a construction of solutions to the equation of motions, but also in constructing the Reggeon exchange contributions to the $h+\gamma^*\to h+\gamma^{(*)}$ scattering amplitude. The propagator is proportional to

$$\frac{-i}{\frac{\mathcal{E}+c_y}{\sqrt{\lambda}}+N^{(y)}_{\rm eff}-i\epsilon}\frac{\alpha' R^3}{t_{Ay}}. \tag{67}$$

The mode equation for a rank-j tensor field $A_{m_1\cdots m_j}$ on AdS_5 is further decomposed into those of irreducible representations of SO(4,1). For simplicity of argument, we deal only with the mode equations for the totally symmetric (and traceless) rank-j tensor fields. Namely,

$$A_{m_1\cdots m_j}=A_{m_{\sigma(1)}\cdots m_{\sigma(j)}} \quad \text{for } {}^\forall\sigma\in\mathfrak{S}_j. \tag{68}$$

We call them spin-j fields.

The eigenmode equation (65) for a totally symmetric spin-j field can be decomposed into $j+1$ pieces, labeled by $k=0,\ldots,j$:

$$\begin{aligned}&((R^2\Delta_j)-[(2k+1)j-2k^2+3k])A_{z^k\mu_1\cdots\mu_{j-k}}\\&\quad+2zk\partial^{\hat\rho}A_{z^{k-1}\rho\mu_1\cdots\mu_{j-k}}+k(k-1)A^{\hat\rho}_{z^{k-2}\rho\mu_1\cdots\mu_{j-k}}\\&\quad-2z(D[A_{z^{k+1}\ldots}])_{\mu_1\cdots\mu_{j-k}}+(E[A_{z^{k+2}\ldots}])_{\mu_1\cdots\mu_{j-k}}\\&=-\mathcal{E}A_{z^k\mu_1\cdots\mu_{j-k}}.\end{aligned} \tag{69}$$

Here,

$$A_{z^k\mu_1\cdots\mu_{j-k}}\coloneqq A_{\underbrace{z\cdots z}_{k}\mu_1\cdots\mu_{j-k}} \tag{70}$$

and can be regarded as a rank-$(j-k)$ totally symmetric tensor of the SO(3,1) Lorentz group. The SO(3,1) indices with $\hat{}$ in the superscript, such as $\hat\rho$ in $\partial^{\hat\rho}$, are raised by the four-dimensional (4D) Minkowski metric $\eta^{\rho\sigma}$ from a subscript σ, not by the five-dimensional (5D) warped metric g^{mn}. $D[a]$ and $E[a]$ are operations creating totally symmetric rank-$(r+1)$ and rank-$(r+2)$ tensors of SO(3,1), respectively, from a totally symmetric rank-r tensor of SO(3,1), a:

$$(D[a])_{\mu_1\cdots\mu_{r+1}}\coloneqq\sum_{i=1}^{r+1}\partial_{\mu_i}a_{\mu_1\cdots\check{\mu_i}\cdots\mu_{r+1}}, \tag{71}$$

$$(E[a])_{\mu_1\cdots\mu_{r+2}}\coloneqq 2\sum_{p<q}\eta_{\mu_p\mu_q}a_{\mu_1\cdots\check{\mu_p}\cdots\check{\mu_q}\cdots\mu_{r+2}}. \tag{72}$$

The differential operator Δ_j in the first term is defined, as in [3], by

$$\begin{aligned}R^2\Delta_j&\coloneqq R^2z^{-j}\left[\left(\frac{z}{R}\right)^5\partial_z\left[\left(\frac{R}{z}\right)^3\partial_z\right]\right]z^j+R^2\left(\frac{z}{R}\right)^2\partial^2,\\&=z^2\partial_z^2+(2j-3)z\partial_z+j(j-4)+z^2\partial^2.\end{aligned} \tag{73}$$

The eigenmode equation (65), (69) is a generalization of the "Schrödinger equation" of [3] determining the Pomeron wave function. As we will see, the single-component Pomeron wave function discussed in [3], etc. corresponds to (93)—that of the $(n,l,m)=(0,0,0)$ eigenmode in our language, and the Schrödinger equation to (90), (A10); there are other eigenmodes, whose wave functions are to be determined in the following.

In the following sections, V A and V B, we simply state the results of the eigenmode decomposition of (65), (69) for spin-j fields. A more detailed account is given in Appendix A.

A. Eigenvalues and eigenmodes for $\Delta^\mu=0$

Because of the $(3+1)$-dimensional translational symmetry in ∇^2, solutions to the eigenmode equations can be classified by the eigenvalues of the generators of translation, $(-i\partial_\mu)$. Until the end of Sec. V B, we will focus on eigenmodes in the form of

$$A_{m_1\cdots m_j}(x,z)=e^{i\Delta\cdot x}A_{m_1\cdots m_j}(z;\Delta) \tag{74}$$

and study the eigenmode equation (65) separately for different eigenvalues Δ^μ.

The eigenmode equation for $\Delta^\mu=0$ and that for $\Delta^\mu\neq 0$ are qualitatively different and need separate study. The eigenmodes for $\Delta^\mu\neq 0$ will be presented in Sec. V B (and Appendix A.2); we begin in Sec. V A (and Appendix A.1) with the eigenmode equation for $\Delta^\mu=0$, which is also regarded as an approximation of the eigenmode equation for $\Delta^\mu\neq 0$ in the asymptotic UV boundary region (at the least, $\Delta z\ll 1$ and z may be as small as R).

For now, we relax the traceless condition on the spin-j field $A_{m_1\cdots m_j}$ ($m_i=0,1,\ldots,3,z$), and we just assume that the rank-j tensor field $A_{m_1\cdots m_j}$ is totally symmetric.[20]

[19] There are many states with the same value of j, but with different c_y and $N^{(y)}_{\rm eff}$.

[20] This only makes the following presentation more far-reaching; in the end, it is quite easy to identify which eigenmodes fall into the traceless part within $A_{m_1\cdots m_j}$. See (82)–(84) at the end of Sec. V A.

Consider the following decomposition of the space of z-dependent field configuration $A_{m_1\cdots m_j}(z;\Delta=0)$:

$$A_{z^k\mu_1\cdots\mu_{j-k}}(z;\Delta^\mu=0)=\sum_{N=0}^{[(j-k)/2]}(E^N[a^{(k,N)}])_{\mu_1\cdots\mu_{j-k}};\qquad(75)$$

here, $(a^{(k,N)}(z;\Delta^\mu=0))_{\mu_1\cdots\mu_{j-k-2N}}$ is a rank-$(j-k-2N)$ totally symmetric tensor of SO(3,1), and it satisfies the 4D-traceless condition

$$\eta^{\hat\mu_1\hat\mu_2}a^{(k,N)}_{\mu_1\cdots\mu_{j-k-2N}}=0.\qquad(76)$$

Thus, the field configuration can be described by $a^{(k,N)}$'s with $0\le k\le j$, $0\le N\le[(j-k)/2]$. These components form groups labeled by $n=0,\ldots,j$, where the nth group consists of $a^{(k,N)}$'s, with $k+2N=n$; they are all rank-$(j-n)$ totally symmetric tensors of SO(3,1); let us call the subspace spanned by the components in this nth group the nth subspace. The eigenmode equation for $\Delta^\mu=0$ becomes block diagonal under the decomposition into these subspaces labeled by $n=0,\ldots,j$ [see (A3) in the appendix]. Therefore, the eigenmode equation for $\Delta^\mu=0$ can be studied separately for the individual diagonal blocks.

The nth diagonal block contains $[n/2]+1$ components, and hence there are $[n/2]+1$ eigenmodes. Let $\mathcal{E}_{n,l}$ $(l=0,\ldots,[n/2])$ be the eigenvalues in the nth diagonal block. The corresponding eigenmode wave function is of the form

$$(a^{(k,N)}(z;\Delta^\mu=0))_{\mu_1\cdots\mu_{j-n}}=c_{k,l,n}(\epsilon^{(n,l)})_{\mu_1\cdots\mu_{j-n}}z^{2-j-i\nu},\qquad(77)$$

where $\epsilon^{(n,l)}$ is a z-independent, k-independent rank-$(j-n)$ tensor of SO(3,1) ($c_{k,l,n}\in\mathbb{R}$). In the eigenmode equation for $\Delta^\mu=0$, the eigenmode wave functions are all in a simple power of z, and the power is parametrized by $i\nu$ ($\nu\in\mathbb{R}$). The eigenvalues $\mathcal{E}_{n,l}$ are functions of ν; once the mass-shell condition (66) is imposed, the eigenmodes turn into solutions of the equation of motion and $i\nu$ is determined by the mass parameter.

The eigenmodes with smaller (n,l) are as follows:

$$\mathcal{E}_{0,0}=(j+4+\nu^2),\quad a^{(0,0)}(z)_{\mu_1\cdots\mu_j}=\epsilon^{(0,0)}_{\mu_1\cdots\mu_j}z^{2-j-i\nu},\qquad(78)$$

$$\mathcal{E}_{1,0}=(3j+5+\nu^2),\qquad a^{(1,0)}(z)_{\mu_1\cdots\mu_{j-1}}=\epsilon^{(1,0)}_{\mu_1\cdots\mu_{j-1}}z^{2-j-i\nu},\qquad(79)$$

$$\mathcal{E}_{2,0}=(5j+4+\nu^2),\quad\begin{pmatrix}a^{(0,1)}(z)_{\mu_1\cdots\mu_{j-2}}\\ a^{(2,0)}(z)_{\mu_1\cdots\mu_{j-2}}\end{pmatrix}=\begin{pmatrix}1\\-4j\end{pmatrix}\epsilon^{(2,0)}_{\mu_1\cdots\mu_{j-2}}z^{2-j-i\nu},\qquad(80)$$

$$\mathcal{E}_{2,1}=(j+2+\nu^2),\quad\begin{pmatrix}a^{(0,1)}(z)_{\mu_1\cdots\mu_{j-2}}\\ a^{(2,0)}(z)_{\mu_1\cdots\mu_{j-2}}\end{pmatrix}=\begin{pmatrix}1\\2\end{pmatrix}\epsilon^{(2,1)}_{\mu_1\cdots\mu_{j-2}}z^{2-j-i\nu}.\qquad(81)$$

Empirically, the j dependence of the eigenvalues in the nth diagonal block appears to be $\mathcal{E}_{n,l}=((2n+1-4l)j+\nu^2+O(1))$ $(l=0,\ldots,[n/2])$ [see (A12)–(A27) in the Appendix for more samples of the eigenvalues], and we promote this j dependence as a rule of the labeling of the eigenmodes with l.

The eigenmode with $l=0$ is found in any one of the diagonal blocks ($n=0,\ldots,j$). Its eigenvalue is

$$\mathcal{E}_{n,0}=(2n+1)j+2n-n^2+4+\nu^2,\qquad(82)$$

and

$$c_{2\bar k,0,2\bar n}=(-)^{\bar k}4^{\bar k}\frac{\bar n!}{(\bar n-\bar k)!}\frac{(j-\bar n+1)!}{(j-\bar n-\bar k+1)!},\quad(n=2\bar n,\bar k=0,\ldots,\bar n),\qquad(83)$$

$$c_{2\bar k+1,0,2\bar n+1}=(-)^{\bar k}4^{\bar k}\frac{\bar n!}{(\bar n-\bar k)!}\frac{(j-\bar n)!}{(j-\bar n-\bar k)!},\quad(n=2\bar n+1,\bar k=0,\ldots,\bar n).\qquad(84)$$

These $(n,l)=(n,0)$ eigenmodes are characterized by the 5D-traceless condition

$$g^{m_1m_2}A_{m_1\cdots m_j}=0.$$

Thus, the eigenmodes within the 5D-traceless (and totally symmetric) component—the spin-j field—for $\Delta^\mu=0$ are labeled simply by $n=0,\ldots,j$.

B. Mode decomposition for nonzero Δ_μ

1. Diagonal block decomposition for the $\Delta^\mu\neq0$ case

The eigenmode equation (65), (69) is much more complicated in the case of $\Delta^\mu\neq0$ because of the second and fourth terms in (69). The eigenmode equation is still made block diagonal for an appropriate decomposition of the space of field $A_{m_1\cdots m_j}(z;\Delta^\mu)$.

Consider a decomposition

$$A_{z^k\mu_1\cdots\mu_{j-k}}(z;\Delta^\mu)=\sum_{s=0}^{j-k}\sum_{N=0}^{[s/2]}(\tilde E^N D^{s-2N}[a^{(k,s,N)}])_{\mu_1\cdots\mu_{j-k}},\qquad(85)$$

where a new operation $a\mapsto\tilde E[a]$ on a totally symmetric SO(3,1) tensor a,

$$(\tilde{E}[a])_{\mu_1\cdots\mu_{r+2}} := 2\sum_{p<q}\left(\eta_{\mu_p\mu_q}-\frac{\partial_{\mu_p}\partial_{\mu_q}}{\partial^2}\right)a_{\mu_1\cdots\check{\mu_p}\cdots\check{\mu_q}\cdots\mu_{r+2}}, \tag{86}$$

is used. $a^{(k,s,N)}$'s are totally symmetric, 4D-traceless [i.e., (76)] rank-$(j-k-s)$ tensor fields of SO(3,1) that satisfy an additional condition, the 4D-transverse condition:

$$\partial^{\hat{\rho}}(a^{(k,s,N)})_{\rho\mu_2\cdots\mu_{j-k-s}} = i\Delta^{\hat{\rho}}(a^{(k,s,N)})_{\rho\mu_2\cdots\mu_{j-k-s}} = 0. \tag{87}$$

The space of field configuration $A_{m_1\cdots m_j}(z;\Delta^\mu)$ is now decomposed into $a^{(k,s,N)}$'s, with $0\le k\le j$, $0\le s\le j-k$, $0\le N\le[s/2]$; these components form groups labeled by $m=0,\ldots,j$, where the mth group consists of $a^{(k,s,N)}$'s, with $k+s=m$; they are all rank-$(j-m)$, totally symmetric 4D-traceless and 4D-transverse tensors of SO(3,1); let us call the subspace spanned by the components in this mth group the mth subspace. The eigenmode equation for $\Delta^\mu\neq 0$ becomes block diagonal under the decomposition into these subspaces labeled by $m=0,\ldots,j$. The eigenmode equation for the mth sector is given by (A39) in Appendix A.2. The mth subspace should have

$$\sum_{s=0}^{m}([s/2]+1) \tag{88}$$

eigenmodes.

Eigenvalues $\mathcal{E}$ are determined in terms of the characteristic exponent in the expansion of the solution in the power series of z. Let the first term in the expansion be $z^{2-j-i\nu}$; the eigenvalues are functions of ν then. Because the indicial equation at the regular singular point $z\simeq 0$ allows us to determine the eigenvalues in terms of ν, the eigenvalues in the case of $\Delta^\mu\neq 0$ cannot be different from the ones we have already known in the $\Delta^\mu=0$ case. In the mth diagonal block, the eigenvalues consist of $\mathcal{E}_{n,l}$, with $0\le n\le m$, $0\le l\le[n/2]$.

To summarize, the eigenmodes in the totally symmetric rank-j tensor field of SO(4,1) are labeled by (n,l,m) and Δ^μ and ν. Their eigenvalues $\mathcal{E}_{n,l}$ depend only on n and l (with $0\le n\le j$ and $0\le l\le[n/2]$) and ν. Corresponding eigenmodes are denoted by

$$\begin{aligned}A(x,z)^{n,l,m;\Delta,\nu}_{z^k\mu_1\cdots\mu_{j-k}} &= e^{i\Delta\cdot x}A^{n,l,m}_{z^k\mu_1\cdots\mu_{j-k}}(z;\Delta^\mu,\nu)\\ &= e^{i\Delta\cdot x}\sum_{N=0}^{[s/2]}\tilde{E}^N D^{s-2N}[\epsilon^{(n,l,m)}]\frac{b^{(j-m)}_{s,N}}{\Delta^{s-2N}}\Psi^{(j);s,N}_{i\nu;n,l,m}(-\Delta^2,z).\end{aligned} \tag{89}$$

$\epsilon^{(n,l,m)}$ is a (z-independent) totally symmetric 4D-traceless 4D-transverse rank-$(j-m)$ tensor of SO(3,1), and all the s's appearing in the expression above are understood as $s=m-k$. $b^{(r)}_{s,N}$ is a constant whose definition is given in (A38) in the Appendix.

2. Single-component Pomeron wave function

The Pomeron wave function that has been discussed in the literature (e.g., [3]) does not look as awful as (89). To our knowledge, the Pomeron wave function in the literature in the context of hadron high-energy scattering has been a single component one, $\Psi_{i\nu}(t,z)$. How is $A^{n,l,m}_{m_1\cdots m_j}(z;\Delta^\mu,\nu)$ related to $\Psi_{i\nu}(-\Delta^2;z)$?

In the block diagonal decomposition of the eigenmode equation, there is only one subspace where the diagonal block is 1×1. That is the $m=0$ subspace, which consists only of $a^{(0,0,0)}$. The eigenmode equation is

$$\left[\Delta_j-\frac{j}{R^2}\right]a^{(0,0,0)}(z;\Delta^\mu) = -\frac{\mathcal{E}}{R^2}a^{(0,0,0)}(z;\Delta^\mu). \tag{90}$$

This equation, as well as (A10) in the $\Delta^\mu=0$ case, corresponds to the Schrödinger equation in [3] determining the Pomeron wave function. It should be noted, however, that we consider that ∇^2 is the operator relevant to the eigenmode decomposition[21] rather than Δ_j; furthermore, the operator ∇^2 and Δ_j has a simple relation $\nabla^2=\Delta_j-j/R^2$ only on this $m=0$th subspace of a totally symmetric rank-j tensor field of SO(4,1).

The eigenvalue is

$$\mathcal{E}_{0,0} = (j+4+\nu^2), \tag{91}$$

when we define the first term in the power series expansion of z to be $z^{2-j-i\nu}$. The eigenmode wave function is

$$a^{(0,0,0)}(z;\Delta^\mu)_{\mu_1\cdots\mu_j} = \epsilon^{(0,0,0)}_{\mu_1\cdots\mu_j}\Psi^{(j)}_{i\nu}(-\Delta^2,z), \tag{92}$$

$$\Psi^{(j)}_{i\nu}(-\Delta^2,z) := \frac{2}{\pi}\sqrt{\frac{\nu\sinh(\pi\nu)}{2R}}e^{(j-2)A}K_{i\nu}(\Delta z), \tag{93}$$

where $e^{2A(z)}=(R/z)^2$ is the warp factor introduced in (28). The normalization factor is determined [3][22] so that it satisfies the normalization condition[23]

[21] Thus, the propagator (67) uses the eigenvalue of ∇^2, rather than that of Δ_j. The eigenvalue $\mathcal{E}$ of ∇^2 in the $m=0$th subspace is $(j+4+\nu^2)$ as in (91), instead of $(4+\nu^2)$. Reference [3] uses a mode $h_{mn}\propto z^{-2}(\eta_{\mu\nu},\delta_{zz})$ of the spin-2 field to fix the details of (65), (66) and (90). This $h_{mn}\propto z^{-2}(\eta_{\mu\nu},\delta_{zz})$ mode, however, corresponds to the $(n,l)=(2,1)$ mode of the spin-$j=2$ field in (A17), rather than the 5D-traceless 5D-transverse mode $(n,l)=(0,0)$. The eigenvalue $\mathcal{E}_{2,1}=(2+j+\nu^2)$ with $j=2$ becomes $(4+\nu^2)$, though.

[22] The Pomeron wave function in [7] was of the form (124), which becomes (93) in the limit of $\Lambda\to 0$, while we keep z and Δ^μ fixed.

[23] The normalization condition is generalized to (99) later on.

$$\int d^4x \int dz \sqrt{-g(z)} e^{-2jA} [e^{i\Delta\cdot x} \Psi^{(j)}_{i\nu}(-\Delta^2, z)] \times [\Psi^{(j)}_{i\nu'}(-\Delta'^2, z) e^{-i\Delta'\cdot x}] = (2\pi)^4 \delta^4(\Delta - \Delta')\delta(\nu - \nu'). \tag{94}$$

The single component Pomeron/Reggeon wave function $\Psi^{(j)}_{i\nu}(-\Delta^2, z)$ is now understood as $\Psi^{(j);0,0}_{i\nu;0,0,0}(-\Delta^2, z)$.

3. 5D-traceless 5D-transverse Modes

The eigenmode equation (65) for a totally symmetric rank-j tensor field of SO(4,1) should be closed within its 5D-traceless component. The subspace of 5D-traceless component is characterized by the 5D-traceless condition

$$g^{m_1 m_2} A_{m_1 \cdots m_j}(z; \Delta^\mu) = 0. \tag{95}$$

The fact that the Hermitian operator ∇^2 maps this subspace to itself implies that the eigenmode equation of ∇^2 is block diagonal, when the space of (not-necessarily-5D-traceless) $A_{m_1\cdots m_j}$ is decomposed into the sum of the 5D-traceless subspace and its orthogonal complement. The collection of the eigenmodes with $l = 0$ corresponds to the subspace of 5D-traceless field configuration.

Similarly, one can think of a subspace of field configuration satisfying both the 5D-traceless condition (95) and the 5D-transverse condition

$$g^{nm_1} \nabla_n A_{m_1 m_2 \cdots m_j} = 0. \tag{96}$$

Obviously this is a subspace of the subspace of the 5D-traceless modes we discussed above. Since the Hermitian operator ∇^2 on AdS_5 maps this new subspace also to itself, the eigenmode equation of ∇^2 should also become block diagonal when the subspace of 5D-traceless modes is decomposed into this new subspace and its orthogonal complement.

As we will see in Appendix A.3, there is only one such mode satisfying this set of conditions (95), (96) in each one of the mth diagonal block. Thus, the combination of the 5D-traceless and 5D-transverse conditions allows us to determine an eigenmode completely. This mode turns out to be $(n, l, m) = (0, 0, m)$ (for $0 \le m \le j$). Put differently, the eigenmodes with the eigenvalue $\mathcal{E}_{n,l} = \mathcal{E}_{0,0} = (j + 4 + \nu^2)$ are characterized by the traceless and transverse conditions on AdS_5.

The eigenmode wave functions of the 5D-traceless transverse modes $(n, l, m) = (0, 0, m)$ are (see Appendix A.3)

$$\Psi^{(j);s,N}_{i\nu;0,0,m}(-\Delta^2, z) = \sum_{a=0}^{N} (-)^a {}_N C_a \left(\frac{z^3 \partial_z z^{-3}}{\Delta}\right)^{s-2a} [(z\Delta)^m \Psi^{(j);0,0}_{i\nu;0,0,0}(-\Delta^2, z)] \times N_{j,m}. \tag{97}$$

$N_{j,m}$ is a dimensionless normalization constant. We choose it to be[24]

$$N^{-2}_{j,m} = {}_j C_m \frac{\Gamma(j + 1 - i\nu)}{\Gamma(j + 1 - m - i\nu)} \frac{\Gamma(j + 1 + i\nu)}{\Gamma(j + 1 - m + i\nu)} \frac{\Gamma(3/2 + j - m)}{2^m \Gamma(3/2 + j)} \frac{\Gamma(2 + 2j)}{\Gamma(2 + 2j - m)}, \tag{98}$$

so that the eigenmode wave functions are normalized as in

$$\int d^4x \int_0 dz \sqrt{-g(z)} g^{m_1 n_1} \cdots g^{m_j n_j} A^{n,l,m;\Delta,\nu}_{m_1\cdots m_j}(x, z) A^{n',l',m';\Delta',\nu'}_{n_1\cdots n_j}(x, z) = (2\pi)^4 \delta^4(\Delta + \Delta')\delta(\nu - \nu')\delta_{n,n'}\delta_{l,l'}\delta_{m,m'} [\epsilon^{(n,l,m)}(\Delta)] \cdot [\epsilon^{(n',l',m')}(\Delta')]. \tag{99}$$

Here, $[\epsilon^{(n,l,m)}] \cdot [\epsilon'^{(n,l,m)}] := \epsilon^{(n,l,m)}_{\mu_1\cdots\mu_{j-m}} \epsilon'^{(n,l,m)}_{\nu_1\cdots\nu_{j-m}} \eta^{\hat{\mu}_1\hat{\nu}_1} \cdots \eta^{\hat{\mu}_{j-m}\hat{\nu}_{j-m}}$.

4. Propagator

The propagator of the totally symmetric rank-j tensor field (respectively, the spin-j field) on AdS_5 is given by summing up propagators of the (n, l, m) modes [respectively, the (n, l, m) modes with $l = 0$]. For the purpose of writing down the propagator of a given (n, l, m) eigenmode, it is convenient to introduce the following notation:

$$A^{n,l,m;\Delta,\nu}_{m_1\cdots m_j}(x, z) = [A^{n,l,m;\Delta,\nu}_{m_1\cdots m_j}(x, z)]^{\hat{\kappa}_1\cdots\hat{\kappa}_{j-m}} \epsilon^{(n,l,m)}_{\kappa_1\cdots\kappa_{j-m}} = e^{i\Delta\cdot x} [A^{n,l,m}_{m_1\cdots m_j}(z; \Delta^\mu, \nu)]^{\hat{\kappa}_1\cdots\hat{\kappa}_{j-m}} \epsilon^{(n,l,m)}_{\kappa_1\cdots\kappa_{j-m}}. \tag{100}$$

With this notation, the propagator of the (n, l, m) mode is given by

[24]Note that $N_{j,m} = 1$, if $m = 0$.

$$G(x,z;x',z')^{(n,l,m)}_{m_1\cdots m_j;n_1\cdots n_j} = \int \frac{d^4\Delta}{(2\pi)^4}\int_0^\infty d\nu \frac{-iP^{(j-m)}_{\rho_1\cdots\rho_{j-m};\sigma_1\cdots\sigma_{j-m}}}{\frac{\mathcal{E}_{n,l}+c}{\sqrt{\lambda}}+N_{\rm eff}-i\epsilon}\frac{\alpha' R^3}{t_y} \times [A^{n,l,m;\Delta,\nu}_{m_1\cdots m_j}(x,z)]^{\hat\rho_1\cdots\hat\rho_{j-m}}[A^{n,l,m;-\Delta,\nu}_{n_1\cdots n_j}(x',z')]^{\hat\sigma_1\cdots\hat\sigma_{j-m}}. \quad (101)$$

Here, $P^{(j-m)}_{\rho_1\cdots\rho_{j-m};\sigma_1\cdots\sigma_{j-m}}$ is a polarization tensor generalizing $\eta_{\rho\sigma}-\partial_\rho\partial_\sigma/\partial^2$; when an orthogonal basis $\epsilon_a(q)\cdot\epsilon_b(-q)=\delta_{a,b}D_a$ of rank-r 4D-traceless 4D-transverse tensors is given,

$$P^{(r)}_{\mu_1\cdots\mu_r;\nu_1\cdots\nu_r} := \sum_a \frac{1}{D_a}\epsilon(q)_{a;\mu_1\cdots\mu_r}\epsilon(-q)_{a;\nu_1\cdots\nu_r}. \quad (102)$$

An alternative characterization of this $P^{(r)}_{\mu_1\cdots\mu_r;\nu_1\cdots\nu_r}$ is given by a combination of the following two conditions: one is

$$P^{(r)}_{\mu_1\cdots\mu_r;\nu_1\cdots\nu_r}\epsilon_a^{\hat\nu_1\cdots\hat\nu_r} = \epsilon_{a;\mu_1\cdots\mu_r}, \quad (103)$$

and the other is that $P^{(r)}_{\mu_1\cdots\mu_r;\nu_1\cdots\nu_r}$ also be a totally symmetric 4D-transverse 4D-traceless tensor with respect to $(\mu_1\cdots\mu_r)$ for any choice of $(\nu_1\cdots\nu_r)$. Its explicit form (A74), given in the Appendix, is useful for practical computations.

C. Representation in the dilatation eigenbasis

It is an essential process in the application of the AdS/CFT correspondence to classify solutions to the equation of motions on the gravity dual background (AdS_5) into irreducible representations of the conformal group SO(4,2) (or possibly its supersymmetric extension). In the CFT description, primary operators are in one-to-one correspondence with (highest weight) irreducible representations of the conformal group, and it is believed that one can establish a one-to-one correspondence between (i) a primary operator in the CFT description and (ii) a group of solutions to the equation of motion forming an irreducible representation in the gravity dual description. Once this correspondence is given, hadron matrix elements of the primary operators in a (nearly conformal) field theory can be calculated by using the corresponding solutions to the equations of motion (the wave functions) on AdS_5. Note that the hadron matrix elements of the primary operators are all that remain unknown in the formulation of conformal operator product expansion (26).

Let P_μ, K_μ, $L_{\mu\nu}$, and D denote the generators of the unitary operators of the conformal group transformation on the Hilbert space. They satisfy the following commutation relations:

$$[D,P_\mu]=iP_\mu, \qquad [P_\rho,L_{\mu\nu}]=i(\eta_{\rho\mu}P_\nu-\eta_{\rho\nu}P_\mu), \quad (104)$$

$$[D,K_\mu]=-iK_\mu, \quad [K_\rho,L_{\mu\nu}]=i(\eta_{\rho\mu}K_\nu-\eta_{\rho\nu}K_\mu), \quad (105)$$

$$[P_\mu,K_\nu]=-2i(\eta_{\mu\nu}D+L_{\mu\nu}), \quad (106)$$

$$[L_{\mu\nu},L_{\rho\sigma}]=i(\eta_{\nu\rho}L_{\mu\sigma}-\eta_{\nu\sigma}L_{\mu\rho}-\eta_{\mu\rho}L_{\nu\sigma}+\eta_{\mu\sigma}L_{\nu\rho}). \quad (107)$$

When such a conformal symmetry exists in a conformal field theory in $3+1$ dimensions, these generators have a representation as differential operators on fields on $\mathbb{R}^{3,1}$; these differential operators are denoted by $\mathcal{P}_\mu$, $\mathcal{K}_\mu$, $\mathcal{L}_{\mu\nu}$, and $\mathcal{D}$. The generators and the differential operators on a CFT are in the following relation:

$$[\mathcal{O}(x),P_\mu]=\mathcal{P}_\mu\mathcal{O}(x), \qquad [\mathcal{O}(x),K_\mu]=\mathcal{K}_\mu\mathcal{O}(x),$$
$$[\mathcal{O}(x),D]=\mathcal{D}\mathcal{O}(x),\ldots, \quad (108)$$

and these differential operators acts on primary operators as follows:

$$\mathcal{D}\overline{\mathcal{O}}_n(x)=-i(x\cdot\partial+l_n)\overline{\mathcal{O}}_n(x), \quad (109)$$

$$\mathcal{L}_{\mu\nu}\overline{\mathcal{O}}_n(x)=(i(x_\mu\partial_\nu-x_\nu\partial_\mu)+[S_{\mu\nu}])\overline{\mathcal{O}}_n(x), \quad (110)$$

$$\mathcal{P}_\mu\overline{\mathcal{O}}_n(x)=-i\partial_\mu\overline{\mathcal{O}}_n(x), \quad (111)$$

$$\mathcal{K}_\mu\overline{\mathcal{O}}_n(x)=(-i(2x_\mu x\cdot\partial-x^2\partial_\mu)-i2l_nx_\mu-x^\nu[S_{\mu\nu}])\overline{\mathcal{O}}_n(x), \quad (112)$$

where l_n is the scaling dimension of the operator $\overline{\mathcal{O}}_n$ and $[S_{\mu\nu}]$ a finite dimensional representation of SO(3,1) generators satisfying the same commutation relation as $L_{\mu\nu}$'s. Thus, for a primary operator $\overline{\mathcal{O}}_n(x)$, $\overline{\mathcal{O}}_n(x=0)$ plays the role of the highest weight state

$$[\overline{\mathcal{O}}_n(0),K_\mu]=0, \qquad [\overline{\mathcal{O}}_n(0),D]=-il_n\overline{\mathcal{O}}_n(0); \quad (113)$$

all other states in the highest weight state representation—descendants—are generated by applying $[\bullet,P_\mu]$ multiple times; the whole representation, therefore, is spanned by a collection of

$$\{\overline{\mathcal{O}}_n(0),\partial_\mu\overline{\mathcal{O}}_n(0),\partial_\mu\partial_\nu\overline{\mathcal{O}}_n(0),\ldots\}; \quad (114)$$

it is also equivalent to a collection of $\overline{\mathcal{O}}(x=x_0)$, with arbitrary $x_0\in\mathbb{R}^{3,1}$.

In the preceding sections, we have worked on solutions to the eigenmode equation on AdS_5; once the mass-shell condition (66) is imposed, they become solutions to the equation of motion. They are obtained as an eigenmode of the spacetime translation in $3+1$ dimensions, $(-i\partial^\mu)=\Delta^\mu$. Under the conformal group SO(4,2), which contains Lorentz SO(3,1) symmetry, however, an irreducible representation has to include solutions with all kinds of eigenvalues Δ^μ.

In the case of a scalar field on AdS_5, one can think of the following linear combination $G(x,z;x_0;R_0)$ (for some $R_0\ll\Delta^{-1}$):

$$G(x,z;x_0)=\frac{i}{\pi^2}\frac{\Gamma(l_n)}{\Gamma(l_n-2)}R_0^{l_n-4}\left(\frac{z}{z^2+(x-x_0)^2}\right)^{l_n}$$
$$=\int\frac{d^4\Delta}{(2\pi)^4}e^{i\Delta\cdot(x-x_0)}\frac{(\Delta z)^2K_{l_n-2}(\Delta z)}{(\Delta R_0)^2K_{l_n-2}(\Delta R_0)}. \quad (115)$$

The factor $[e^{i\Delta\cdot x}(\Delta z)^2K_{l_n-2}(\Delta z)]$ in the integrand on the right-hand side is a solution to the equation of motion of a scalar field on AdS_5 whose mass square $M_{\rm eff}^2$ is given by $l_n-2=i\nu=\sqrt{4+M_{\rm eff}^2R^2}$. The coefficient of the linear combination, $e^{-i\Delta\cdot x_0}[(\Delta R_0)^2K_{l_n-2}(\Delta R_0)]^{-1}$, is chosen so that the integrand behaves as

$$e^{i\Delta\cdot(x-x_0)}\left(\frac{z}{R_0}\right)^{4-l_n} \quad (116)$$

at $0\le z\ll\Delta^{-1}$. The space of solutions to the equation of motion $G(x,z;x_0)$ parametrized by $x_0\in\mathbb{R}^{3,1}$ is alternatively spanned by derivatives of $G(x,z;x_0)$ with respect to x_0^μ at $x_0^\mu=0$. It is easy to see that this basis,

$$\{G(x,z;0),\partial_\mu^{(x_0)}G(x,z;0),\partial_\mu^{(x_0)}\partial_\nu^{(x_0)}G(x,z;0),\ldots\}, \quad (117)$$

is an eigenbasis under the action of dilatation, $\mathcal{D}:=i(z\partial_z+x\cdot\partial)$, and their weights are $-il_n,-i(l_n+1),-i(l_n+2),\ldots$, respectively. Correspondence between scalar field wave functions on AdS_5 and scalar primary operators of the dual CFT is established in this way [34].

Let us now generalize the discussion above slightly to construct an analogue of $G(x,z;x_0)$ for a spin-j field $A_{m_1\cdots m_j}$ on AdS_5, from which the dilatation eigenbasis is constructed. To this end, note that all of the $(0,0,m)$ modes $(m=0,\ldots,j)$ have the leading $z^{2-j-i\nu}$ term in the power series expansion only in the $A_{z^0\mu_1\cdots\mu_j}$ component, not in any other $A_{z^k\mu_1\cdots\mu_{j-k}}$ components[25] with $k>0$. It is possible to choose $\epsilon^{(0,0,m)}(\Delta^\mu)$ properly so that

$$\sum_{m=0}^{j}[A^{0,0,m;\Delta,\nu}_{\mu_1\cdots\mu_j}(x,z)]^{\hat\kappa_1\cdots\hat\kappa_{j-m}}\epsilon^{(0,0,m)}_{\kappa_1\cdots\kappa_{j-m}}e^{-i\Delta\cdot x_0}$$
$$\simeq e^{i\Delta\cdot(x-x_0)}\left(\frac{z}{R_0}\right)^{2-j-i\nu}\epsilon_{\mu_1\cdots\mu_j} \quad (118)$$

in the region near the UV boundary $z\ll\Delta^{-1}$, where $\epsilon_{\mu_1\cdots\mu_j}$ is a Δ^μ-independent 4D-traceless totally symmetric rank-j tensor of SO(3,1); the condition on $\epsilon^{(0,0,m)}(\Delta^\mu)$ is

$$\epsilon_{\mu_1\cdots\mu_j}=\left(\frac{R_0}{R}\right)^{2-j}K_{i\nu}(\Delta R_0)\frac{2}{\pi}\sqrt{\frac{\nu\sinh(\pi\nu)}{2R}}$$
$$\times\sum_{m=0}^{j}\frac{N_{j,m}\Gamma(m-j-i\nu)}{\Gamma(-j-i\nu)}$$
$$\times\sum_{N=0}^{[m/2]}\frac{b_{m,N}^{(j-m)}}{\Delta^{m-2N}}(\tilde E^N D^{m-2N}[\epsilon^{(0,0,m)}])_{\mu_1\cdots\mu_j}. \quad (119)$$

[25]Use (97).

It is possible to invert this relation by using (A37) and writing down $\epsilon^{(0,0,m)}(\Delta^\mu)$ in terms of $\epsilon_{\mu_1\cdots\mu_j}$, though we will not present the result here. What really matters to us is that $\epsilon^{(0,0,m)}(\lambda\Delta)=\epsilon^{(0,0,m)}(\Delta)\lambda^{i\nu}$. With $\epsilon^{(0,0,m)}$'s satisfying the condition above, one can see that the following linear combination of solutions to the equation of motion,

$$G_{m_1\cdots m_j}(x,z;x_0)$$
$$:=\int\frac{d^4\Delta}{(2\pi)^4}\sum_{m=0}^{j}[A^{0,0,m;\Delta,\nu}_{m_1\cdots m_j}(x,z)]^{\hat\kappa_1\cdots\hat\kappa_{j-m}}\epsilon^{(0,0,m)}$$
$$\times(\Delta)_{\kappa_1\cdots\kappa_{j-m}}e^{-i\Delta\cdot x_0}, \quad (120)$$

has a property

$$G_{m_1\cdots m_j}(\lambda x,\lambda z;\lambda x_0)=\lambda^{-(2+j+i\nu)}G_{m_1\cdots m_j}(x,z;x_0). \quad (121)$$

$i\nu$ is determined by the mass parameter on AdS_5 once the mass-shell condition (66) is imposed. Therefore, $G_{m_1\cdots m_j}(x,z;0)$ is an eigenstate of dilatation, and so are the derivatives of $G_{m_1\cdots m_j}(x,z;x_0)$ with respect to x_0^μ at $x_0^\mu=0$. All of the derivatives combined forms of a dilatation eigenbasis in the space of solutions with the equation of motion of a spin-j field.

It is now clear that the eigenmodes with $(n,l,m)=(0,0,m)$ $(0\le m\le j)$ and arbitrary Δ^μ as a whole—modes that satisfy the 5D-traceless and 5D-transverse conditions (95), (96)—form an irreducible representation of the conformal group. If one is interested purely in the matrix element of a spin-j primary operator $\mathcal{O}_n(x_0=0)$ of an approximately conformal gauge theory, then the matrix element can be calculated by using the wave function $G_{m_1\cdots m_j}(x,z;0)$. Note that the $m=0$ mode alone—where the Pomeron/Reggeon wave function has a single component, as in [3]—cannot reproduce all of the matrix elements associated with matrix elements of spin-j primary operators.

D. Confinement effect

1. Top-down approach

QCD in the real world is not a conformal gauge theory, but it has a mass gap in the hadron spectrum due to confinement. Confinement of a nearly conformal strongly coupled gauge theory is realized in its gravitational dual description in the form of a nearly AdS geometry with a minimum value in the warp factor.

Klebanov-Strassler geometry of type IIB string theory [27] will be one of the most popular background geometries of this kind. The Klebanov-Strassler geometry is not dual to a confining gauge theory that is asymptotically free, however; it is dual to a gauge theory that is confining in the infrared, but its 't Hooft couplings become stronger and stronger toward ultraviolet. Such geometries as Klebanov-Strassler are not truly dual to the QCD of the real world, but

one will still be able to learn a lot from studying the mode decomposition on such geometries.

Mode decomposition can be carried out once we know the background configuration and the action of the bilinear fluctuations around the background; we do not need interactions of stringy fields. Thus, it will be a doable task, at least at the supergravity level. Reduction over the $W_5 = T^{1,1}$ geometry has been worked out in the literature, and one is left to translate the smoothness condition of mode functions at the tip of the deformed warped conifold into the language of boundary conditions on a warped $(4+1)$-dimensional spacetime.[26] The authors do not find a reason not to work on it, except that it will take extra time to do so.

In this article, however, we set a higher priority in getting a broader perspective on the subject ranging from string theory to hadron physics, and we avoid taking too much time to solve technical problems in string theory. Instead, we discuss, in the following, two temporary approaches of implementing the confinement effects; one is an effective-theory model building approach and the other is a phenomenological approach. We will proceed with the phenomenological approach in the following sections, although we understand that the topdown approach above will eventually replace/back up/verify the phenomenological approach to be adopted in this article. The following "effective theory model building approach" is not used in this article, but we present it here because it helps us understand the physical meaning (the hidden assumptions) of the phenomenological approach.

2. Effective theory model building approach

The hard wall model and its variations are introduced in order to mimic the presence of a minimum value of the warped factor, mass gap, and nearly AdS background geometry. It remains simple enough so that analytic results are obtained in a relatively short amount of time, though we cannot discuss the stability of the geometry or the theoretical consistency of string theory.

With this philosophy in mind, one could think of implementing the confining effect in the form of

$$S = \int d^4x \int_0^{1/\Lambda} dz \sqrt{-g(z)}\mathcal{L}_{\rm bulk} + \int d^4x \sqrt{-g}|_{z=1/\Lambda}\mathcal{L}_{\rm bdry}, \tag{122}$$

where the background geometry remains AdS_5 and the holographic radius z is cut off at $z = \Lambda^{-1}$. Note that different choices of $\mathcal{L}_{\rm bdry}$ lead to a different physics; to be more precise, different choices of $(\mathcal{L}_{\rm bulk}, \mathcal{L}_{\rm bdry})$ modulo partial integration should be regarded as different models. It is reasonable to have such freedom in the choice of effective-theory models because we know that there is more than one holographic background of type IIB string theory that is dual to confining gauge theories. Such constraints as SO(3,1) symmetry unbroken global symmetry of a strongly coupled gauge theory, however, are very weak in constraining $\mathcal{L}_{\rm bdry}$.

Once a model is fixed, the Euler-Lagrange equation of this theory includes not only the equation of motion in the bulk (64)=(65), (66), but also the boundary conditions at $z = 1/\Lambda$. Different models (i.e., different $\mathcal{L}_{\rm bdry}$) predict different Pomeron/Reggeon wave functions.

We require that SO(3,1) symmetry is preserved even in $\mathcal{L}_{\rm bdry}$. Boundary conditions might introduce mixing between the eigenmode decomposition determined in the bulk, in principle, but the unbroken SO(3,1) symmetry excludes mixing between SO(3,1)-irreducible tensors of different ranks. This observation still does not exclude mixing among (n,l,m) modes of a spin-j totally symmetric field on AdS_5 with a common m, but different (n,l)'s.

3. Phenomenological approach

As an alternative approach, one can think of a phenomenological approach, which is to start from a small number of parameters and let the physical consequences constrain those parameters. When one finds that reasonable physical consequences cannot be available under a given set of parameters, then a few more parameters will be introduced so that more freedom is available.

As one of the simplest trial parametrizations of the confining effect, we make the following changes in the mode functions $\Psi^{(j);0,0}_{i\nu;0,0,m}(\Delta, z)$:

$$K_{i\nu}(\Delta z) \to \left[K_{i\nu}(\Delta z) + \frac{\pi}{2}\frac{c^{(j)}_{i\nu;0,0,m}}{\sin(\pi i\nu)} I_{i\nu}(\Delta z)\right] =: \text{“}K_{i\nu}(\Delta z)\text{”}. \tag{123}$$

$c^{(j)}_{i\nu;0,0,m}$'s, which may depend on Δ^2 and Λ, are the parameters we introduce. An implicit assumption here is that the confining effect does not introduce mixing among modes with different (n,l,m)'s. Under this assumption, however, the parametrization above does not lose any generality; once the ratio between the $K_{i\nu}(\Delta z)$ wave and $I_{i\nu}(\Delta z)$ is given for $\Psi^{(j);0,0}_{i\nu;0,0,m}(-\Delta^2, z)$, there is no freedom left for the other $\Psi^{(j);s,N}_{i\nu;0,0,m}(-\Delta^2, z)$ functions $((s,N) \neq (0,0))$ of the same $(n,l,m) = (0,0,m)$ mode because the relation among them is completely fixed by the equation of motion in the bulk. In Sec. VII A, we will carry out a test of whether this simple parametrization works well or not.

When the infrared boundary is introduced in the holographic background geometry, the normalization of the

[26] Such geometries typically are in the form of $\mathbb{R}^{3,1} \times W'_n$, which nearly remains constant around the tip of the throat $r = 0$, and a shrinking $(5-n)$ cycle with the metric $ds^2 = dr^2 + r^2(d\Omega_{5-n})^2$. For simplicity, let $n = 4$ and $d\Omega_1 = d\theta$. A scalar field $\phi(r,\theta)$ with smooth configuration in the coordinate $(r\cos\theta, r\sin\theta)$ is decomposed into $\sum_k e^{ik\theta}\phi_k(r)$ when the mode $\phi_k(r)$ needs to be in the form of $r^k \times \text{fcn}(r^2)$. Thus, $\partial_r[r^{-k}\phi_k(r)] = 0$ at $r = 0$.

Pomeron/Reggeon wave function also needs to be changed. In the case of the $(n,l,m)=(0,0,0)$ mode, with the Dirichlet boundary condition at the IR boundary $z=1/\Lambda$, for example, the wave function $\Psi^{(j);0,0}_{i\nu;0,0,0}=\Psi^{(j)}_{i\nu}(-\Delta^2,z)$ was given the following normalization [3,7]:

$$\Psi^{(j)}_{i\nu}(-\Delta^2,z)=e^{(j-2)A}\frac{2}{\pi}\sqrt{\frac{\nu\sinh(\pi\nu)}{2R}}\sqrt{\frac{I_{i\nu}(x_0)}{I_{-i\nu}(x_0)}}\times\left[K_{i\nu}(\Delta z)-\frac{K_{i\nu}(x_0)}{I_{i\nu}(x_0)}I_{i\nu}(\Delta z)\right], \tag{124}$$

with an extra factor $\sqrt{I_{i\nu}(x_0)/I_{-i\nu}(x_0)}$, where $x_0\coloneqq\Delta/\Lambda$. This result is generalized as follows. By repeating the same argument as in Appendix A.3.a, one finds that the normalization factor $N_{j,m}$ should be replaced by

$$N_{j,m}\to N_{j,m}\times\frac{1}{\sqrt{1-c^{(j)}_{i\nu;0,0,m}}}. \tag{125}$$

The Dirichlet boundary condition for the $m=0$ mode above corresponds to $(1-c^{(j)}_{i\nu;0,0,0})=[I_{-i\nu}(x_0)/I_{i\nu}(x_0)]$; the modified normalization (124) is a special case of (125). The mode functions are defined, so far, for $\nu\geq\mathbb{R}$ since the eigenvalue $\mathcal{E}_{0,0}=4+j+\nu^2$ depends only on ν^2. When the mode function is analytically continued to the $\nu<0$ region, the mode function for $-\nu$ should be the same as $+\nu$. From this observation, it follows that

$$(1-c^{(j)}_{-i\nu;0,0,m})=(1-c^{(j)}_{i\nu;0,0,m})^{-1}. \tag{126}$$

VI. ORGANIZING THE SCATTERING AMPLITUDE ON AdS_5

A. "Effective" string field action on AdS_5

If we are to start from type IIB string theory in ten dimensions with a background that is approximately $AdS_5\times W_5$ (except near the infrared boundary), one can think of an effective theory on AdS_5 after carrying out spherical harmonics mode decomposition on W_5. As we have already discussed in Sec. V how to construct propagators in such an effective theory, we would now like to construct the scattering amplitude.

For this purpose, we need interaction among string fields, and we turn to cubic string field theory, which we reviewed already in Sec. IV. This allows us to write down a concrete expression for the scattering amplitude. Clearly the biggest drawback of this approach is in the fact that no stable background geometry $AdS_5\times W_{21}$ is known in bosonic string theory for a 21-dimensional internal manifold W_{21}. In the following, we will construct an effective action on AdS_5 by carrying out dimensional reduction of the cubic string field theory action, as if there exists an $AdS_5\times W_{21}$ solution to bosonic string theory. This is not meant to claim that we obtain such an action as an effective theory of bosonic string theory, but to use it as a starting point in constructing a toy-model scattering amplitude of a hadron and a (virtual) photon that may still carry some fragrance of interaction structure in superstring theory.

Let us start off by clarifying the relation between the normalization of string component fields in (38), (41), (42) and that of the component fields in (62). All of the component fields in (38) are normalized so that they have canonically normalized kinetic terms in the action in the 26-dimensional spacetime. Now, we make them dimensionless by the redefinition $\phi\to g_o^{-1}\phi$, $A_M\to g_o^{-1}A_M$, etc. All of the terms in the cubic string field theory—both the kinetic terms and the interactions—will then have $(1/g_o^2)$ as an overall factor. When a mode decomposition of the following form is assumed for the component in this new normalization,

$$\phi(x,z,\theta)=\sum_y\phi^{(y)}(x,z)Y_y(\theta),$$
$$A_M(x,z,\theta)=\begin{cases}\sum_y A^{(y)}_m(x,z)Y_y(\theta) & M=m=0,\ldots,3,z\\ 0 & M=5,\ldots,25.\end{cases} \tag{127}$$

Similarly decomposition holds for spin-h_a fields $A_{M_1\cdots M_{h_a}}(x,z,\theta)$; we take spherical harmonics $Y_y(\theta)$ (labeled by y) to be dimensionless, so that the component fields on AdS_5 such as $\phi^{(y)}(x,z)$, $A^{(y)}_m(x,z)$, $A^{(y)}_{m_1\cdots m_{h_a}}(x,z)$ are also dimensionless.

The overall coefficient of the effective action on AdS_5 then becomes a dimension-$(+3)$ parameter

$$\frac{\mathrm{vol}(W_{21})}{2(g_o)^2}\times\mathcal{O}(1), \tag{128}$$

which is to be identified with the overall coefficient $t_y/(2R^3)$ in (62). Reduction of interaction terms (43), (45), (46) also yields the same overall factor (128), apart from possibly one order factor coming from the overlap integration of spherical harmonics over the internal manifold. Because the amplitudes from exchanging states with higher spherical harmonics are suppressed in small-x DIS and DVCS (e.g., [7]), we will be interested only in the interactions involving $\phi^{(y)}$-$\phi^{(y)}$–(intermediate states) and $A^{(y)}_m$-$A^{(y)}_m$–(intermediate states) cubic couplings, with the intermediate states having spherical harmonics $Y(\theta)=1$. The overall factor of the cubic interactions then becomes precisely the same as that of the kinetic terms of $\phi^{(y)}$ and $A^{(y)}_m$.

For this reason, we write down the following interaction terms for the effective action on AdS_5:

$$S_{\text{eff int}} = -\frac{t_{\phi y}\lambda_{\text{sft}}}{3\alpha' R^3}\int d^4x dz\sqrt{-g(z)}\hat{E} \times\left(3\,\text{tr}[\phi_y^2\phi] + \sqrt{\frac{8\alpha'}{3}}\text{tr}[(-iA_m)(\phi_y\overleftrightarrow{\nabla}^m\phi_y)] - \frac{8\alpha'}{9\sqrt{2}}\text{tr}[f_{mn}(\phi_y\overleftrightarrow{\nabla}^m\overleftrightarrow{\nabla}^n\phi_y)] - \frac{5}{9\sqrt{2}}\text{tr}[f_m^m\phi_y^2] + \frac{2\sqrt{\alpha'}}{3}\text{tr}[(\nabla_m g^m)\phi_y^2] - \frac{11}{9}\text{tr}[h\phi_y^2]\right) + \cdots. \tag{129}$$

Fields without a label y are to be used for the intermediate states exchanged in the t channel (in the sense that we explained in Sec. IV B); ϕ_y are for the incoming and outgoing states. Partial derivatives have been replaced by covariant derivatives on AdS_5. Similarly, all other interactions, such as (45), (46) in 26 dimensions, also give rise to their corresponding cubic interactions on AdS_5. Certainly such a choice of effective action on AdS_5 will be one of the most likely (and simple) setups that may still maintain some aspects of scattering amplitude in string theory, although top-down justification is not given.

We will only sum t-channel amplitudes where $Y_y(\theta) = 1$ modes of the stringy states in the leading Reggeon/Pomeron trajectory are exchanged, because that constitutes the dominant contribution in small-x scattering. Thus, three-point interactions of such modes with incoming and outgoing tachyon states are necessary, which we write down as follows,

$$\Delta S_{\text{eff int}} = -\frac{t_h\lambda_{\text{sft}}}{R^3\alpha'}\int d^4x dz\sqrt{-g(z)}\hat{E} \times\text{tr}[A^{(Y)}_{m_1\cdots m_N}(\phi\overleftrightarrow{\nabla}^{m_1}\cdots\overleftrightarrow{\nabla}^{m_N}\phi)]\left(\frac{8\alpha'}{27}\right)^{\frac{N}{2}}\frac{(-i)^N}{\sqrt{N!}}, \tag{130}$$

by keeping only the $Y_y(\theta) = 1$ modes and replacing the derivatives in (45) by covariant derivatives. The normalization constant $t_{\phi y}$ for the target hadron kinetic term is now simply written as t_h, as we will have to pay attention only to the individual choices of target hadrons [the individual choices of $Y_y(\theta)$] in the external states. Similarly, we also need interaction of the same group of modes with the incoming and outgoing photon states, which we write down as follows:

$$\Delta S_{\text{eff int}} = -\frac{t_\gamma\lambda_{\text{sft}}}{R^3\alpha'}\int d^4x dz\sqrt{-g(z)}\hat{E} \times\text{Tr}\left[A^{(N)}_{m_1\cdots m_N}(A_l(-i\overleftrightarrow{\nabla}^{m_1}) \cdots(-i\overleftrightarrow{\nabla}^{m_N})A_k)\left(\frac{8\alpha'}{27}\right)^{\frac{N}{2}}\frac{g^{kl}\frac{16}{27}}{\sqrt{N!}} + \cdots\right], \tag{131}$$

following the same procedure by starting from (46). We have retained only the terms that have N derivatives and are proportional to η^{kl}, as they are necessary in determining the twist-2 contributions to the structure function V_1. Since we need the normalization constant t_{Ay} of the kinetic term of the external state only for the spherical harmonics $Y(\theta) = 1$, we no longer need to refer to the choice of spherical harmonics; t_{Ay} is therefore rewritten as t_γ.

B. External states wave function

The vertex operator insertions in the world-sheet calculation are replaced by appropriate external state wave functions in amplitude calculations based on string field theories.

First, the insertions of a vertex operator of the form (33) for the U(1) currents on flavor D7-branes are replaced by wave functions for the massless vector field in bosonic string theory. We use the wave functions for the incoming state $\gamma^*(q_1)$ and the outgoing state $\gamma^{(*)}(q_2)$:

$$A^{\text{in}}_m(x_\gamma, z_\gamma) = R\int\frac{d^4q_1}{(2\pi)^4}e^{iq_1\cdot(x_\gamma-(\overline{x}-(\Delta x)/2)}A_m(z_\gamma; q_1), \tag{132}$$

$$A^{\text{out}}_m(x_\gamma, z_\gamma) = R\int\frac{d^4q_2}{(2\pi)^4}e^{-iq_2\cdot(x_\gamma-(\overline{x}+(\Delta x)/2))}A_m(z_\gamma; q_2), \tag{133}$$

where $A_m(z; q)$ on the right-hand sides are the wave functions given in (35). A factor R is inserted here because we adopted a normalization convention, so that $A^{(\text{in/out})}_m(x, z)$ on AdS_5 is dimensionless.[27] The arguments of the electromagnetic current insertions $T\{J^\nu(x)J^\mu(y)\}$—coordinates in boundary theory x and $y \in \mathbb{R}^{3,1}$—are now denoted by $\overline{x} + (\Delta x)/2$ and $\overline{x} - (\Delta x)/2$, respectively.

[27] $A_m(x, z)$ is often normalized so that it has mass dimension $(+1)$, and hence this factor R is not then necessary. In a case in which the gauging of a global symmetry of a strongly coupled gauge theory is realized in the form of a flavor D7-brane, the natural reduction of the 7-brane action on a three-cycle leads to the form of

$$S_{\text{eff}} \sim -\frac{N_c}{R}\int d^4x dz\sqrt{-g(z)}F_{mn}F^{mn}; \tag{134}$$

the external state wave function (132), (133) without the factor R can be used in such cases. In the presentation adopted in this section, where a bosonic string is used and the gauge field is assigned zero mass dimension (like other higher spin fields), the factor R is included in (132), (133) and the kinetic term of $F_{mn}F^{mn}$ has the coefficient t_γ/R^3 instead. Thus, we can think of t_γ as something like N_c.

The vertex operators (30) for the target hadron are replaced by wave functions of the form

$$\phi^{\rm in}(x_h,z_h)=e^{ip_1\cdot x_h}\Phi(z_h;m_n),$$
$$\phi^{\rm out}(x_h,z_h)=e^{-ip_2\cdot x_h}\Phi(z_h;m_n), \tag{135}$$

where $\Phi(z;m)$'s on the right-hand sides are the wave function given by (31). The first one is for the incoming state and the second for the outgoing hadron.

C. Leading trajectory contribution to the Compton tensor

When the target hadron is to be identified with some Kaluza-Klein state of the tachyon of bosonic string theory, then $\ell_\phi-2=\sqrt{4+M_{\rm eff}^2R^2}=\sqrt{4+c-\sqrt{\lambda}}$ is not real valued for $\lambda\gg1$. We treat this $\ell_\phi-2$ as if it were real valued, until the last moment. Since our true interest is in the scattering amplitude in type IIB string theory, or in hadron scattering in the real world, this problem is absent in such situations, and we do not bother about this issue.

Let us combine all the pieces together to organize an amplitude of photon-tachyon scattering given by a t-channel exchange of a leading trajectory spin-j state reduced to AdS_5, with $Y_y(\theta)=1$. Such an amplitude—denoted by $i\mathcal{M}^{(t)}_{(N_{\rm eff}=j,j)}$—consists of a t-channel exchange of all the eigenmodes labeled by (n,l,m). We will further focus on contributions from $(n,l,m)=(0,0,m)$. It is given by

$$\begin{aligned}i\mathcal{M}^{(t)}_{(j,j);(0,0,m)}\simeq{}&\frac{-it_\gamma}{R^3\alpha'}\int d^4x_\gamma dz_\gamma\sqrt{-g(z_\gamma)}J^{\gamma\gamma}_{k_1\cdots k_j;pq}g^{pq}(g^{k_1r_1}\cdots g^{k_jr_j})(z_\gamma)\left(\frac{\alpha'}{2}\right)^{j/2}e^{-2A(z_\gamma)}\\&\times\frac{-it_h}{R^3\alpha'}\int d^4x_h dz_h\sqrt{-g(z_h)}J^{hh}_{l_1\cdots l_j}(g^{l_1s_1}\cdots g^{l_js_j})(z_h)\left(\frac{\alpha'}{2}\right)^{j/2}e^{-2A(z_h)}\\&\times\frac{1}{j!}\left(\frac{27}{16}\right)^{\alpha' t-(j-1)}[e^{2A(z_\gamma)}e^{2A(z_h)}G^{(0,0,m)}(x_\gamma,z_\gamma;x_h,z_h)_{r_1\cdots r_j;s_1\cdots s_j}];\end{aligned} \tag{136}$$

just like in the amplitude calculation in Sec. IV B, this amplitude is meant to be the coefficient of $\mathrm{Tr}[\lambda^{\gamma 2}\lambda^{\gamma 1}\lambda^{h1}\lambda^{h2}]$. $J^{\gamma\gamma}$ and J^{hh} (above) are given by the external state wave functions as follows:

$$J^{\gamma\gamma}_{k_1\cdots k_j;pq}(x_\gamma,z_\gamma)=(-i)^j[A_p^{\rm out}\overleftrightarrow{\nabla}_{k_1}\cdots\overleftrightarrow{\nabla}_{k_j}A_q^{\rm in}](x_\gamma,z_\gamma), \tag{137}$$

$$J^{hh}_{l_1\cdots l_j}(x_h,z_h)=(-i)^j[\phi^{\rm in}\overleftrightarrow{\nabla}_{l_1}\cdots\overleftrightarrow{\nabla}_{l_j}\phi^{\rm out}](x_h,z_h). \tag{138}$$

Here, $\phi^{\rm in/out}(x_h,z_h)$ are both of mass dimension (-1), and $A_m^{\rm in/out}(x_\gamma,z_\gamma)$ is of mass dimension $(+3)+\dim[\epsilon_\mu]$. From this expression, one can see that the first line has mass dimension $(+6)+2\times\dim[\epsilon_\mu]$, the second line (-2), and the last line 0. Thus, $i\mathcal{M}^{(t)}_{(j,j);(0,0,m)}$ is a function of p_1^κ, p_2^κ, $\bar{x}^\kappa$ and Δx^κ of mass dimension $4+2\times\dim[\epsilon_\mu]$. This is precisely the property expected for

$$(i)^2\langle h(p_2)|T\{J^\nu(\bar{x}+(\Delta x)/2)J^\mu(\bar{x}-(\Delta x)/2)\}|h(p_1)\rangle\epsilon_\mu^1\epsilon_\nu^{2*}. \tag{139}$$

Its Fourier transform with respect to $(\Delta x)^\mu$ becomes $(iT^{\mu\nu})\times e^{-i\bar{x}\cdot(p_2-p_1)}$.

If we carry out an integration over d^4x_γ, d^4x_h, and $d^4(\Delta x)$ first, then the three integration variables Δ^μ in (101) and $q_{1,2}$ in (132), (133) are determined in terms of the input $p_{1,2}^\mu$ and q^μ; we have $\Delta^\mu:=(p_2-p_1)^\mu$, $q_2^\mu=(q-\Delta/2)^\mu$ and $q_1:=(q+\Delta/2)^\mu$. As a result, it follows that

$$\begin{aligned}[T^{\mu\nu}\epsilon_\mu^1\epsilon_\nu^{2*}]^{(t)}={}&\int d^4(\Delta x)e^{-iq\cdot(\Delta x)}\mathcal{M}^{(t)}_{(j,j);(0,0,m)}|_{\bar{x}=0}\\\simeq{}&\frac{t_\gamma}{R^3\alpha'}\int dz_\gamma\sqrt{-g(z_\gamma)}\bar{J}^{\gamma\gamma}_{k_1\cdots k_j;pq}R^2g^{pq}(g^{k_1r_1}\cdots g^{k_jr_j})\left(\frac{\alpha'}{2}\right)^{j/2}\frac{t_h}{R^3\alpha'}\int dz_h\sqrt{-g(z_h)}\bar{J}^{hh}_{l_1\cdots l_j}(g^{l_1s_1}\cdots g^{l_js_j})\left(\frac{\alpha'}{2}\right)^{j/2}\\&\times\frac{1}{j!}\left(\frac{27}{16}\right)^{\alpha' t-(j-1)}\frac{R^3\alpha'}{t_{(j,j,1)}}\int_0^\infty d\nu\frac{P^{(j-m)}_{\rho_1\cdots\rho_{j-m};\sigma_1\cdots\sigma_{j-m}}}{\frac{\mathcal{E}_{0,0}+c_y}{\sqrt{\lambda}}+N_{\rm eff}-i\epsilon}[A^{0,0,m}_{r_1\cdots r_j}(z_\gamma;-\Delta,\nu)]^{\hat{\rho}_1\cdots\hat{\rho}_{j-m}}[A^{0,0,m}_{s_1\cdots s_j}(z_h;\Delta,\nu)]^{\hat{\sigma}_1\cdots\hat{\sigma}_{j-m}},\end{aligned} \tag{140}$$

where

$$\bar{J}^{\gamma\gamma}_{k_1\cdots k_j;pq}(z_\gamma)=(-i)^j[A_p(z_\gamma;-q_2)\overleftrightarrow{\nabla}_{k_1}\cdots\overleftrightarrow{\nabla}_{k_j}A_q(z_\gamma;q_1)], \tag{141}$$

$$\overline{J}^{hh}_{l_1\cdots l_j}(z_h) = (-i)^j[\Phi(z_h;p_1)\overleftrightarrow{\nabla}_{l_1}\cdots\overleftrightarrow{\nabla}_{l_j}\Phi(z_h;-p_2)]. \tag{142}$$

Although momentum vectors are used in the second arguments of the external state wave functions A and Φ here, instead of their Lorentz-invariant momentum square, this is only to remind ourselves of the sign when ∇'s act on the wave functions.

The expression (140) is meant to be a part of the t-channel contribution to the Compton tensor $[T^{\mu\nu}\epsilon^1_\mu\epsilon^{2*}_\nu]^{(t)}$, and we should obtain the full contribution to the Compton tensor $[T^{\mu\nu}\epsilon^1_\mu\epsilon^{2*}_\nu]$ after employing the prescription (52). At least this prescription tells us to set the factor $(27/16)^{[\alpha' t-(j-1)]}$ in the fourth line to $(27/16)^{\mathcal{O}(1/\sqrt{\lambda})}\simeq 1$.

Now, we claim that this is the only necessary change under this prescription, so far as the amplitude of $(0,0,m)$-mode exchange is concerned.

To see this, remember that, prior to applying the prescription (52), we need to rewrite the residues of the t-channel poles in terms only of the Mandelstam variables s and t, not of u. Let us take the expression $[\Phi_h\overleftrightarrow{\nabla}_m\Phi_h]g^{mn}[A_\gamma\overleftrightarrow{\nabla}_n A_\gamma]$ as an example which captures the feature of contraction of SO(4,1) indices in (140). In the scattering $\phi(P_1)+A(Q_1)\to\phi(P_2)+A(Q_2)$, with $P_{1,2}$ and $Q_{1,2}$ "momenta" $\sim$ derivatives in five dimensions, $(s-u)\sim(P_1+P_2)\cdot(Q_1+Q_2)$ is converted to $(2s+t)$ in the following steps:

$$\begin{aligned}(P_1+P_2)\cdot(Q_1+Q_2) &= (2P_1+(P_2-P_1))\cdot(Q_1+Q_2),\\ &= (2P_1)\cdot(Q_1+Q_2)+(Q_1-Q_2)\cdot(Q_1+Q_2) = (2P_1)\cdot(2Q_1+(Q_2-Q_1))+(Q_1)^2-(Q_2)^2,\\ &= (2P_1)\cdot(2Q_1+(P_1-P_2))+(Q_1)^2-(Q_2)^2 = (4P_1\cdot Q_1)+(-2P_1\cdot P_2)+2(P_1)^2+(Q_1)^2-(Q_2)^2;\end{aligned}$$

each one of the steps above is regarded as either one of partial integration in $dx_\gamma dz_\gamma$, one in $dx_h dz_h$, or a rewriting of (P_2-P_1) by (Q_1-Q_2) or vice versa. The last procedure is to pass a derivative on one side of the propagator to the other. Because of the 5D-transverse condition characterizing the $(0,0,m)$ modes, such terms proportional to ∇ drop out from the amplitudes exchanging the $(0,0,m)$ modes. Noting that the prescription (52) modifies the $-2(P_1\cdot P_2)\sim t$ term above into the propagator mass, and that this term appeared only after passing a derivative ∇ through the propagator, we see that the term which would have been affected by the prescription (52) has indeed already dropped out.

1. Casting the amplitude into the form of OPE

So far, the (virtual) photon and the target hadron have been treated equally in the scattering amplitude. We are interested, however, in the $h+\gamma^*\to h+\gamma^{(*)}$ scattering in the regime of generalized Bjorken scaling, where

$$|(q^2)|,(q\cdot p),|(q_1\cdot\Delta)|,|(q_2\cdot p)|\gg|\Delta^2|,m_h^2,\Lambda^2, \tag{143}$$

while the ratio among $(q\cdot p)$, (q^2), and $(q\cdot\Delta)$—namely, x and η—is kept finite. It is, thus, desirable to rewrite the scattering amplitude (the structure functions) in a form that fits to the conformal OPE. To do this, we follow a prescription that has been used in the study of DIS in holographic models.

Let us focus on the following factors that appear in the third and fourth lines of (140):

$$\int_0^\infty d\nu[A^{0,0,m}_{r_1\cdots r_j}(z_\gamma;-\Delta,\nu)]^{\hat\rho_1\cdots\hat\rho_{j-m}}\times[A^{0,0,m}_{s_1\cdots s_j}(z_h;\Delta,\nu)]^{\hat\sigma_1\cdots\hat\sigma_{j-m}}\times[\cdots]. \tag{144}$$

The last factor $[\cdots]$ denotes the remaining ν dependence (denominator) in the integrand; we need to remember only that $\mathcal{E}_{0,0}=(4+j+\nu^2)$, and hence it is even under the change $\nu\to-\nu$.

We begin with the case $m=0$. The expression (144) for the $m=0$ case becomes

$$\begin{aligned}&\int_0^\infty d\nu[\Psi^{(j);0,0}_{i\nu;0,0,0}(-\Delta^2;z_\gamma)][\Psi^{(j);0,0}_{i\nu;0,0,0}(-\Delta^2;z_h)]\times[\cdots],\\ &=\frac{2}{\pi^2 R}\int_0^\infty d\nu\frac{\nu\sinh(\pi\nu)}{(1-c^{(j)}_{i\nu;0,0,0})}[e^{(j-2)A(z_\gamma)}\text{“}K_{i\nu}(\Delta z_\gamma)\text{”}]\\ &\quad\times[e^{(j-2)A(z_h)}\text{“}K_{i\nu}(\Delta z_h)\text{”}]\times[\cdots]\end{aligned} \tag{145}$$

multiplied by a factor $[\delta^{\hat\rho_1}_{r_1}\cdots\delta^{\hat\rho_j}_{r_j}\delta^{\hat\sigma_1}_{s_1}\cdots\delta^{\hat\sigma_j}_{s_j}]$. Using the fact that $K_{i\nu}(x)=i\pi/2\times(I_{i\nu}(x)-I_{-i\nu}(x))/[\sinh(\pi\nu)]$, the ν integral above can be rewritten as

$$\frac{1}{\pi R}\int_{-\infty}^{+\infty}d\nu i\nu[e^{(j-2)A(z_\gamma)}I_{i\nu}(\Delta z_\gamma)][\text{“}K_{i\nu}(\Delta z_h)\text{”}e^{(j-2)A(z_h)}]\times[\cdots], \tag{146}$$

where we used the relation (126). This expression is more convenient than (145); this is because (i) the z_γ integration is dominated in the region $qz_\gamma\lesssim 1$ because of the photon external state wave functions containing $K_1(q_{1,2}z)$, (ii) $I_{i\nu}(\Delta z_\gamma)$ decreases rapidly toward positive $i\nu$ for $qz_\gamma\lesssim 1$ and $q\gg\Delta$ [a generalized Bjorken scaling (143)], and (iii) the rapidly decreasing $I_{i\nu}(\Delta z_\gamma)$ in the lower half of the

complex ν plane allows us to close the ν integration contour through the large-radius lower half complex ν plane (see [7] and the literature therein).

It is straightforward to generalize this treatment for all other $m \neq 0$ modes. Note that the Pomeron/Reggeon wave function $[A^{0,0,m}_{m_1\cdots m_j}(z;\Delta,\nu)]^{\hat\rho_1\cdots\hat\rho_{j-m}}$ for $m \neq 0$ is obtained from that of $m = 0$ by multiplying $(\Delta z)^m$ and $N_{j,m}$ (which is even in ν), applying differential operators in z and manipulating Lorentz indices. Obviously the order of such manipulations on the wave function and the procedure from (145) to (146) can be exchanged.

Therefore, the contribution to the Compton tensor from the leading trajectory spin-j state $(0,0,m)$ mode is

$$
\begin{aligned}
(T^{\mu\nu}\epsilon^1_\mu\epsilon^{2*}_\nu)_{(j,j);(0,0,m)} \simeq{}& \frac{1}{j!}\frac{t_\gamma\sqrt{\lambda}}{t_y\pi}\left(\frac{\alpha'}{2}\right)^j\int_{-\infty}^{+\infty}d\nu\,\frac{P^{(j-m)}_{\rho_1\cdots\rho_{j-m};\sigma_1\cdots\sigma_{j-m}}}{\frac{\mathcal{E}_{0,0}+c_y}{\sqrt{\lambda}}+N_{\rm eff}-i\epsilon}\,i\nu\\
&\times\frac{R^2}{R^3}\int dz_\gamma\sqrt{-g(z_\gamma)}\overline{J}^{\gamma\gamma}_{k_1\cdots k_j;pq}g^{pq}(g^{k_1r_1}\cdots g^{k_jr_j})[\overline{\overline{A}}^{0,0,m}_{r_1\cdots r_j}(z_\gamma;-\Delta,\nu)]^{\hat\rho_1\cdots\hat\rho_{j-m}}\\
&\times\frac{t_h}{R^3}\int dz_h\sqrt{-g(z_h)}\overline{J}^{hh}_{l_1\cdots l_j}(g^{l_1s_1}\cdots g^{l_js_j})[\overline{A}^{0,0,m}_{s_1\cdots s_j}(z_h;\Delta,\nu)]^{\hat\sigma_1\cdots\hat\sigma_{j-m}},
\end{aligned}
\tag{147}
$$

where $\overline{A}$ and $\overline{\overline{A}}$ are obtained from A by removing the factor $(2/\pi)\sqrt{[\nu\sinh(\pi\nu)/2R]}$ in (93) first, then replacing $K_{i\nu}(\Delta z_h)$ by "$K_{i\nu}(\Delta z_h)$" in $\overline{A}(z_h)$, while replacing $K_{i\nu}(\Delta z_\gamma)$ by $I_{i\nu}(\Delta z_\gamma)$ in $\overline{\overline{A}}(z_\gamma)$. Short distance (stringy) parameters such as AdS radius R and string length $\sqrt{\alpha'}$ can be eliminated from this expression of the Compton tensor so that it is written purely in terms of parameters of strongly coupled gauge theory/hadron physics;

$$
\begin{aligned}
(T^{\mu\nu}\epsilon^1_\mu\epsilon^{2*}_\nu)_{(j,j);(0,0,m)} \simeq{}& \frac{1}{j!}\frac{t_\gamma\sqrt{\lambda}}{t_y\pi}\left(\frac{1}{2\sqrt{\lambda}}\right)^j\int_{-\infty}^{+\infty}d\nu\,\frac{P^{(j-m)}_{\rho_1\cdots\rho_{j-m};\sigma_1\cdots\sigma_{j-m}}}{\frac{\mathcal{E}_{0,0}+c_y}{\sqrt{\lambda}}+N_{\rm eff}-i\epsilon}\,i\nu\\
&\times\int_0\frac{dz_\gamma}{z_\gamma}[A_p(z_\gamma;q_2)(-i\overleftrightarrow{\nabla})^j_{k_1\cdots k_j}A_q(z_\gamma;q_1)]\delta^{\hat p\,\hat q}z^j[\delta^{\hat k_1\hat r_1}\cdots\delta^{\hat k_j\hat r_j}][e^{(2-j)A}\overline{\overline{A}}^{0,0,m}_{r_1\cdots r_j}(z_\gamma;-\Delta,\nu)]^{\hat\rho's}\\
&\times t_h\int_0\frac{dz_h}{z_h^3}[\Phi(-i\overleftrightarrow{\nabla})^j_{l_1\cdots l_j}\Phi]z^j[\delta^{\hat l_1\hat s_1}\cdots\delta^{\hat l_j\hat s_j}][e^{(2-j)A}\overline{A}^{0,0,m}_{s_1\cdots s_j}(z_h;\Delta,\nu)]^{\hat\sigma's}.
\end{aligned}
\tag{148}
$$

Each line of this expression has zero mass dimension, hence $T^{\mu\nu}$ is also of zero mass dimension, as expected from the Fourier transform of the matrix element (139).

The leading twist contribution to the Compton tensor $T^{\mu\nu}$ should be obtained by summing up the amplitudes of exchanging the spin-j field in the leading trajectory, with $m = 0,\ldots,j$ also being summed. It is known in the literature that, for each spin j, the second line of (149) becomes something close to the Wilson coefficient of the OPE, and the third line of (149) something close to the operator matrix element. We will elaborate more on it, with a particular emphasis on the role played by the summation over m. For now, we define

$$
\begin{aligned}
C^{0,0,m} :={}& \int_0\frac{dz}{z}\left[A_p(z;-q_2)(-i\overleftrightarrow{\nabla})^j_{k_1\cdots k_j}A_q(z;q_1)\right]\times\left[\frac{(2\Lambda)^{i\nu-j}}{\Delta^{i\nu}}\Gamma(i\nu+1)\right]\\
&\times\delta^{\hat p\,\hat q}z^j\left[\delta^{\hat k_1\hat r_1}\cdots\delta^{\hat k_j\hat r_j}\right]\left[e^{(2-j)A}\overline{\overline{A}}^{0,0,m}_{r_1\cdots r_j}(z;-\Delta,\nu)\right]^{\hat\rho_1\cdots\hat\rho_{j-m}}\epsilon^{(0,0,m)}_{\rho_1\cdots\rho_{j-m}}
\end{aligned}
$$

and

$$
\Gamma^{0,0,m} := t_h\int_0^{1/\Lambda}\frac{dz}{z^3}\left[\Phi(-i\overleftrightarrow{\nabla})^j_{l_1\cdots l_j}\Phi\right]z^j\times\left[\left(\frac{\Delta}{2\Lambda}\right)^{i\nu}\frac{\Lambda^j}{\Gamma(i\nu)}\right]\times\left[\delta^{\hat l_1\hat s_1}\cdots\delta^{\hat l_j\hat s_j}\right]\left[e^{(2-j)A}\overline{A}^{0,0,m}_{s_1\cdots s_j}(z;\Delta,\nu)\right]^{\hat\sigma_1\cdots\hat\sigma_{j-m}}\epsilon^{(0,0,m)}_{\sigma_1\cdots\sigma_{j-m}}
\tag{149}
$$

separately. The factor $[\Gamma(i\nu+1)(2\Lambda)^{i\nu-j}/\Delta^{i\nu}]$ in $C^{0,0,m}$ and a similar factor in $\Gamma^{0,0,m}$ are introduced so that $C^{0,0,m}$ and $\Gamma^{0,0,m}$ correspond to the OPE Wilson coefficients and hadron matrix elements, respectively, renormalized at $\mu_F \sim \Lambda$, as we will see later.

We will focus on the spin-even contribution to a flavor-nonsinglet component of the structure function V_1 in (7). The V_1 structure function is picked up here, only because it is computed a little more easily than other structure functions. We will not touch flavor-singlet components in this article, apart from a brief discussion in Sec. VII C; this is because the cubic SFT with a Chan-Paton factor in Sec. IV is not an adequate tool to study the singlet components. The coefficient $C^{0,0,m}$ above is decomposed, just like $T^{\mu\nu}\epsilon_\mu^1\epsilon_\nu^{2*}$ is; the spin-j (with $j \in 2\mathbb{Z}$) contribution to the structure function $V_1^{+,\alpha}$—spin even (+) and flavor nonsinglet (α)—is denoted by $C^{0,0,m}_{V_1;+,\alpha}$.

2. Amplitude of the ($m = 0$)-mode exchange

We first study $V_1^{+,\alpha}$ from the $m = 0$-mode exchange. With the Reggeon wave function given by $\Psi^{(j);0,0}_{i\nu;0,0,0}(t,z) = \Psi^{(j)}_{i\nu}(t,z)$ in (93), this $m = 0$ contribution is expected to be the closest to what has been studied in the literature (such as [3,4,6,7]). Indeed, we reproduce the expression known in the literature, but with a little refinement, in (163).

Note first that the Reggeon wave functions $\overline{\overline{A}}^{0,0,m=0}_{r_1\cdots r_j}$ and $\overline{A}^{0,0,m=0}_{s_1\cdots s_j}$ are nonzero only when all the r_i's and s_i's are in the $3+1$ Minkowski directions $(r_1\cdots r_j) = (\rho_1\cdots\rho_j)$ and $(s_1\cdots s_j) = (\sigma_1\cdots\sigma_j)$; furthermore, the wave function is 4D-transverse and 4D-traceless totally symmetric tensors of SO(3,1).

This makes it much easier to evaluate the matrix element $\Gamma^{0,0,m=0}$. Because

$$(\nabla^k\Phi)_{\sigma_1\cdots\sigma_k} = \partial_{\sigma_1}\cdots\partial_{\sigma_k}\Phi + [\text{terms proportional to } \eta_{\sigma_a\sigma_b}], \tag{150}$$

only

$$[\Phi(z;p_1)(-i\overleftrightarrow{\nabla})^j\Phi(z;-p_2)]_{\sigma_1\cdots\sigma_j} \coloneqq \sum_{k=0}^{j} {}_jC_k[(i\nabla)^{j-k}\Phi(z;p_1)]_{\sigma_{k+1}\cdots\sigma_j}[(-i\nabla)^k\Phi(z,-p_2)]_{\sigma_1\cdots\sigma_k}$$
$$\to (-1)^j(p_1+p_1)_{\sigma_1}\cdots(p_1+p_2)_{\sigma_j}\Phi(z;p_1)\Phi(z;-p_2) \tag{151}$$

contributes to $\Gamma^{0,0,m=0}$:

$$\Gamma^{0,0,m=0} = \left[\epsilon^{(0,0,0)}_{\sigma_1\cdots\sigma_j}(-1)^j(p_1+p_2)^{\hat\sigma_1}\cdots(p_1+p_2)^{\hat\sigma_j}\right]\overline{g}^{0,0,0}(j,i\nu,\Delta), \tag{152}$$

$$\overline{g}^{0,0,0}(j,i\nu,\Delta) \coloneqq \int_0^{1/\Lambda}\frac{dz}{z^3}(\Lambda z)^j t_h(\Phi(z;m_h))^2\frac{\{\text{“}K_{i\nu}(\Delta z)\text{”}\}}{[(\frac{\Delta}{2\Lambda})^{-i\nu}\Gamma(i\nu)]}; \tag{153}$$

note here that the confinement effect has been included in the form of (i) introducing a cut in the holographic radius $z_h \le 1/\Lambda$ and (ii) $K_{i\nu}(\Delta z_h)$ is modified to $K_{i\nu}(\Delta z_h)$ in (123). The expression of $\overline{g}^{0,0,0}$ here, or that of $\Gamma^{0,0,m}$ in (149), implicitly ignores the possibility of $\mathcal{L}_{\text{bdry}} \neq 0$. For practical purposes, though, this may not be a big deal, since Ref. [6] reports that such confinement effects do not play a significant role quantitatively for most of the kinematical region.

Let us also evaluate the Wilson coefficient $C^{0,0,m=0}$. The expression

$$[A_p(z;-q_2)(-i\overleftrightarrow{\nabla})^jA_q(z;q_1)_q]_{\rho_1\cdots\rho_j}\delta^{\hat p\,\hat q} \coloneqq \sum_{k=0}^{j}{}_jC_k[(i\nabla)^{j-k}A(z;-q_2)]_{\rho_{k+1}\cdots\rho_j p}[(-i\nabla)^kA(z;q_1)]_{\rho_1\cdots\rho_k q}\delta^{\hat p\,\hat q} \tag{154}$$

appearing in $C^{0,0,m=0}$ can be evaluated by using the fact that

$$(\nabla^kA)_{\rho_1\cdots\rho_k\kappa} \equiv (\partial_{\rho_1}\cdots\partial_{\rho_k}A_\kappa) - \sum_{a=1}^{k}\frac{\eta_{\mu_a\kappa}}{z}(\partial_{\rho_1}\cdots\check\partial_{\rho_a}\cdots\partial_{\rho_k}A_z) - \sum_{1\le a<b\le k}\frac{\eta_{\rho_a\kappa}}{z^2}(\partial_{\rho_1}\cdots\check\partial_{\rho_a}\cdots\check\partial_{\rho_b}\cdots\partial_{\rho_k}A_{\rho_b}), \tag{155}$$

$$(\nabla^kA)_{\rho_1\cdots\rho_kz} \equiv (\partial_{\rho_1}\cdots\partial_{\rho_k}A_z) + \frac{1}{z}\sum_{a=1}^{k}(\partial_{\rho_1}\cdots\check\partial_{\rho_a}\cdots\partial_{\rho_k}A_{\rho_a}) \tag{156}$$

modulo terms proportional to $\eta_{\rho_c\rho_d}$. As we will focus only on the structure function $V_1^{+,\alpha}$, we can further drop the terms with A_z in (155), (156). Then the expression above becomes

$$[\eta^{\mu\nu}\epsilon_\mu^1\epsilon_\nu^{2*}](q_1+q_2)_{\rho_1}\cdots(q_1+q_2)_{\rho_j}$$
$$+\frac{2}{z^2}\sum_{a\neq b}\epsilon(-q_2)_{\rho_a}\epsilon(q_1)_{\rho_b}(q_1+q_2)_{\rho_1}\cdots{}_{\check\rho_a\check\rho_b}\cdots(q_1+q_2)_{\rho_j} \tag{157}$$

multiplied by $[(q_1z)K_1(q_1z)][(q_2z)K_1(q_2z)]$.

There are two remaining tasks in evaluating the $(m=0)$-mode contribution to the $V_1^{+,\alpha}$ structure function: (a) one is to carry out the z_γ integral and (b) the other is to sum $C^{0,0,0}\Gamma^{0,0,0}$ for different polarizations of $\epsilon^{(0,0,0)}$. As for the z_γ integral, the integrand sharply falls off[28] at $z_\gamma \approx q^{-1}$ because of the photon wave functions of the form $[(q_i z)K_{i\nu}(q_i z)]$. The z_γ integral in $C^{0,0,m}$ over the holographic radius $z_\gamma \in [0,\Lambda^{-1}]$ therefore comes mainly from a very small fraction of it, $\Lambda/q \ll 1$, in the regime of generalized Bjorken scaling (143). It is then all right to make an approximation that

$$I_{i\nu}(\Delta z_\gamma) \approx \frac{1}{\Gamma(i\nu+1)}\left(\frac{\Delta z_\gamma}{2}\right)^{i\nu}[1+\mathcal{O}(\Delta/q)]$$
$$\text{when } (\Delta z_\gamma) \lesssim \Delta/q \ll 1, \tag{158}$$

and also to replace the range of integral $z_\gamma \in [0,\Lambda^{-1}]$ to $[0,+\infty)$, as in the literature; the error caused by this approximation is only in the higher order in (Δ/q), and the twist-$(2+\gamma(j))$ contribution is still obtained properly. The integral is then cast into the form of (B1) with $\delta = j+i\nu$ for the first line of (157) [respectively $\delta = j+i\nu-2$ for the second line of (157)] and $\vartheta = \eta/x$; thus we can use the analytic expression (B3), (B5) in the Appendix.

The other task, (b) tensor computations, is carried out in Appendix A.6. Using the results of (A77) and (A81), one finds that the contribution to $(C^{0,0,0}_{V_1;+,\alpha})_{m=0}$ from the second line of (157) is roughly

$$\frac{q^2\Delta^2}{(q\cdot\Delta)(p\cdot q)} \ll 1 \tag{159}$$

times smaller than the contribution from the first line of (157) in the generalized Bjorken scaling regime (143), and hence it is ignored, when only the twist-$[2+\gamma(j)]$ contributions are retained.

Combining all of the above, the spin-$j \in 2\mathbb{Z}$ contribution is

$$(V_1^{+,\alpha})_{j,m=0} \approx \frac{\sqrt{\lambda}}{\Gamma(j+1)\pi}\frac{t_\gamma}{t_y}\int_{-\infty}^{+\infty} d\nu \frac{1}{\frac{4+j+\nu^2+c_j}{\sqrt{\lambda}}+j-1-i\epsilon} \times C_1(j+i\nu,\vartheta)\left(\frac{\Lambda}{q}\right)^{i\nu-j} \times \left(\frac{1}{\sqrt{\lambda}x}\right)^j \overline{g}^{0,0,0}(j,i\nu,\Delta)\hat{d}_j([\eta]), \tag{160}$$

where C_1 is given in (B5) and $\hat{d}_j$ is a polynomial of degree j in the argument

$$[\eta] := \eta \times \sqrt{\frac{-4p^2}{\Delta^2}} = \eta\sqrt{\frac{4m_h^2+\Delta^2}{\Delta^2}} \tag{161}$$

and is given in terms of Legendre polynomial, as in (A79).

Now that all of the factors of the spin-j contribution to $V_1^{+,\alpha}$ are given as analytic functions of j, it is possible to convert the sum over the (spin-$j \in 2\mathbb{N}$) string states in the leading trajectory to a contour integral in the complex angular momentum plane:

$$(V_1^{+,\alpha})_{m=0} = -\int \frac{dj}{4i}\frac{1+e^{\pi i j}}{\sin(\pi j)}(V_1^{+,\alpha})_{j,m=0}, \tag{162}$$

with the contour in the j plane moving just below the real positive axis toward the left, and then just above the real positive axis toward the right. The integration contour in the ν plane is deformed so that it picks up the residue of the pole in the lower complex ν plane coming from the t-channel propagation of strings. Thus,

$$(V_1^{+,\alpha})_{m=0} \approx -\int \frac{dj}{4i}\frac{1+e^{\pi i j}}{\sin(\pi j)}\frac{t_\gamma/t_y}{\Gamma(j+1)}\frac{\lambda}{i\nu_j} \times C_1\left(j+i\nu_j,\frac{\eta}{x}\right)\left(\frac{\Lambda}{q}\right)^{\gamma(j)} \times \left(\frac{1}{\sqrt{\lambda}x}\right)^j \overline{g}^{0,0,0}(j,i\nu_j,\Delta)\hat{d}_j([\eta]), \tag{163}$$

where $\gamma(j) = i\nu_j - j$ and $i\nu_j \geq 0$ is a function of j determined by the on-shell condition

$$j-1+\frac{4+j+\nu^2+c_j}{\sqrt{\lambda}} = 0. \tag{164}$$

This is the result known in [2–7], etc.; under an assumption that $\overline{g}^{0,0,0}(j,i\nu_j,\Delta)$ does not grow too rapidly for a large $\mathrm{Re}(j)$ to cancel the large factor $\Gamma(j+1)$ in the denominator, the integration contour in the j plane can be deformed toward the left in the j plane, as in the classical Watson-Sommerfeld transformation; this is how the non-converging $j \in 2\mathbb{N}$ sum of the OPE is rendered well defined for physical kinematics $x<1$. The integrand forms a saddle point due to the two factors $(1/x)^j$ and $(\Lambda/q)^{\gamma(j)}$;

[28] In DVCS, VMP, and TCS, the incoming photon has spacelike momentum q_1, although the outgoing photon may be either on shell or timelike. The sharp cutoff in the z_γ integral comes from the wave function of the incoming photon. Since the wave function of the outgoing photon remains a Hankel function even for VMP and TCS, rather than $I_{i\nu}(qz_\gamma)$, the approximation of replacing the integration interval $z_\gamma \in [0,\Lambda^{-1}]$ by $z_\gamma \in [0,\infty)$ remains valid. In such applications, $\vartheta > 1$, and the expressions (B1) and (B5) should be understood through analytic continuation. The authors thank the Physical Review D referee for bringing this issue to our attention.

let j_* in the complex j plane be where the saddle point is.[29] The integrand also has poles in the j plane. The hadron matrix element $\overline{g}^{0,0,0}$ contains $c^{(j)}_{i\nu_j;0,0,0}$ in its definition, and $c^{(j)}_{i\nu;0,0,0}$ may have a pole in the j plane [3].[30] The saddle point value j_* has a larger real part than any one of the poles, where $\ln(q/\Lambda)$ is large relatively to $\ln(1/x)$; the j integral is well approximated by the saddle point value of the integrand and yields the DGLAP regime. When $\ln(1/x)$ is large relatively to $\ln(q/\Lambda)$, however, one of the poles may have a real part larger than $\mathrm{Re}(j_*)$. Then the integral is approximated by the residue at such a leading pole. In this way, the string-theory result $(V_1^{+,\alpha})_{m=0}$ goes back and forth between the DGLAP phase and Regge phase, depending on the kinematical variables x, (q^2/Λ^2) and $t=-\Delta^2$ [3,7].

The derivation of (163) was not just a review of preceding works, however. First, the integration over z_γ yields a function $C_1(j+i\nu_j,\eta/x)$, which has precisely the same form as the one expected from the conformal OPE; comparing (25), (26) and (B3), (B5), one finds that they agree, under the identification

$$[(l_n+j_n-2)=2j_n+(\tau_n-2)]\Leftrightarrow[(j+i\nu_j)=2j+\gamma(j)]. \tag{165}$$

The expression (163) is indeed regarded as conformal OPE contributions from twist-$\tau_n=(2+\gamma(j))$ operators.

Second, the η dependence of the $m=0$ contribution is now worked out. As we will see later in Sec. VII, it comes in a form that fits very well with what has been known as dual parametrization of GPD [15]. One will also notice that the argument of the degree-j polynomial $\hat{d}_j([\eta])$ is $[\eta]$ in (161), rather than η. This means that the coefficients of the η^2 term and higher diverge in the $t=-\Delta^2\to 0$ limit. This indicates that it is essential to sum the $m\neq 0$ modes to obtain results that are physically sensible. We will address this issue in Sec. VII A.

We have considered amplitudes from a t-channel exchange of states that (a) are in the leading trajectory and (b) have 5D-traceless and 5D-transverse polarizations, and that have used the prescription (52), so that we obtained the contributions that correspond to the twist-$[2+\gamma(j)]$ operators in the conformal OPE. When the amplitudes with a t-channel exchange of other modes are included, cancellation due to BRST symmetry is at work among some of them, but other physical contributions remain. Computation of those contributions will shed a light on the higher twist contributions to the DVCS amplitudes. To do this, however, we need wave functions of modes other than the $(n,l,m)=(0,0,m)$ modes, and detailed knowledge on the interaction terms in the string field theory more than (130), (131); furthermore, the prescription (52)—the process carried out just before Sec. VI C 1—becomes more complicated for modes other than the $(0,0,m)$ modes. After all of this, one then has to work out which operators in QCD correspond to which group of modes in the t-channel exchange in the gravity dual calculation. Although this is an interesting question, we do not address that problem in this article.

3. Preparation

Let us move on to the amplitudes of $m\geq 1$-mode exchange. We begin with deriving a few general properties of those amplitudes, which makes the subsequent computations less tedious.

First, we observe that the hadron matrix element $\Gamma^{0,0,m}$ vanishes for any odd value of m. To see that this statement is true, we use the following property of $J^{hh}_{l_1\cdots l_j}$:

$$\begin{aligned}&\Phi(z,p_1)\overleftrightarrow{\nabla}_{\{l_1}\cdots\overleftrightarrow{\nabla}_{l_j\}}\Phi(z,-p_2)\\&\quad=(-1)^j\Phi(z,-p_2)\overleftrightarrow{\nabla}_{\{l_1}\cdots\overleftrightarrow{\nabla}_{l_j\}}\Phi(z,p_1);\end{aligned} \tag{166}$$

this is true in a process where the initial state hadron $h(p_1)$ continues to be the same hadron $h(p_2)$ in the final state, so that $-(p_1)^2=-(p_2)^2=m_h^2$. This property is used below to study when $J^{hh}_{z^k\lambda_{k+1}\cdots\lambda_j}\overline{A}^{z^k\lambda_{k+1}\cdots\lambda_j}$ vanishes for various $k=0,\ldots,m$.

For an even j, the SO(3,1) indices of $J^{hh}_{z^k\lambda_{k+1}\cdots\lambda_j}$ are provided by an even number of $(p_1+p_2)_\lambda$'s and even (respectively odd) number of Δ_λ's when k is even (respectively odd). The hadron matrix element $\Gamma^{0,0,m}$ receives a nonvanishing contribution from $J^{hh}_{z^k\lambda_{k+1}\cdots\lambda_j}\overline{A}^{z^k\hat{\lambda}_{k+1}\cdots\hat{\lambda}_j}$ (no sum in k) only when the D operator (71) is used for an even (respectively odd) number of times in the Reggeon wave function (89). This means that s is even (respectively odd), and hence $\Gamma^{0,0,m}$ can be nonzero only when $m=k+s$ is even.

For an odd j, the SO(3,1) indices of $J^{hh}_{z^k\lambda_{k+1}\cdots\lambda_j}$ are provided by an odd number of $(p_1+p_2)_\lambda$'s and an even (respectively odd) number of Δ_λ's when k is even (respectively odd). Thus, the matrix element $\Gamma^{0,0,m}$ receives a nonzero contribution only when an even (respectively odd) number of the D operator is used in (89). This means, once again, that s is even (respectively odd), and hence $\Gamma^{0,0,m}$ can be nonzero only when $m=k+s$ is even. This statement for an odd j is not more than a side remark, though, since we focus on the spin-even contribution $\propto[1+e^{-\pi ij}]/\sin(\pi j)$ in this article.

[29] The saddle point value j_* is determined by $\frac{\partial\gamma(j)}{\partial j}|_{j=j_*}=\frac{\ln(1/x)}{\ln(q/\Lambda)}$.

[30] For example, imagine a case $(1-c^{(j)}_{i\nu;0,0,0})=[I_{-i\nu}(\Delta/\Lambda)/I_{i\nu}(\Delta/\Lambda)]$; the factor $c^{(j)}_{i\nu_j;0,0,0}$ has poles $j=\alpha_{\mathbb{R},n}(t)$ $(n=1,2,\ldots)$ in the j plane given by the condition $j_{i\nu_j,n}=\sqrt{t}/\Lambda$; $j_{\mu,n}$'s are the nth zero of the Bessel function J_μ.

Second, $\Gamma^{0,0,m}$ can always be written in the form of

$$\Gamma^{0,0,m} = [(-2)^{j-m}(p^{\hat{\sigma}_1}\cdots p^{\hat{\sigma}_{j-m}})\cdot\epsilon^{(0,0,m)}_{\sigma_1\cdots\sigma_{j-m}}] \times \overline{g}^{0,0,m}(j, i\nu, \Delta^2), \tag{167}$$

and $\overline{g}^{0,0,m}$ is an SO(3,1) scalar of mass dimension m; we have encountered a special case of this statement in (152), (153). This statement itself is understood as follows. When we write down the covariant derivatives in $\overline{J}^{hh}_{z^k\lambda_1\cdots\lambda_{j-k}}$ explicitly, the SO(3,1) indices—there are $(j-k)$ of them—are one of either p_λ, Δ_λ, and $\eta_{\lambda\lambda'}$; $\eta_{\lambda\lambda'}$ can be further rewritten as $\eta_{\lambda\lambda'} - \Delta_\lambda\Delta_{\lambda'}/\Delta^2$ and $\Delta_\lambda\Delta_{\lambda'}$. Suppose that there are N_p of the SO(3,1) indices from $\{p_\lambda\}$'s, N_Δ indices from $\{\Delta_\lambda\}$'s, and $N_{\tilde{\eta}}$ from $\tilde{\eta}_{\lambda\lambda'}$'s in a given term; $N_p + N_\Delta + 2N_{\tilde{\eta}} = (j-k)$. When such an SO(3,1) tensor is contracted with $\sum_N^{[(m-k)/2]}\tilde{E}^N D^{m-k-2N}[\epsilon^{(0,0,m)}]$ in the Reggeon wave function $\overline{A}^{0,0,m}_{z^k\lambda_1\cdots\lambda_{j-k}}$, it remains nonzero only when $(m-k-2N) = N_\Delta$ and $N \geq N_{\tilde{\eta}}$ because of the relation (A37). It is not hard now to see that all of the remaining terms are proportional to the prefactor of $\overline{g}^{0,0,m}$ in (167); the mass dimension of the remaining scalar factor (the reduced matrix element) $\overline{g}^{0,0,m}$ follows from the fact that $\Gamma^{0,0,m}$ is defined to be of mass dimension j.

Finally, we note that the twist-$[2+\gamma(j)]$ contribution to the coefficient $C^{0,0,m}$ arises only from the contraction $\overline{J}^{\gamma\gamma}_{z^k\kappa_{k+1}\cdots\kappa_j}\overline{\overline{A}}^{\hat{z}^k\hat{\kappa}_{k+1}\cdots\hat{\kappa}_j}$, with $k=0$. We have already seen an example of this in the $m=0$ amplitude; the first term of (157) contributes to (163), while the second term does not because of (159), and the first term came from the $k=0$ contraction.

In order to verify the claim above, note first that both an extra ∂_z and an extra power of $1/z$ virtually change the integral of $C^{0,0,m}$ by about an extra power of $q \sim q_1 \sim q_2 \gg \Lambda, \Delta$. Explicitly writing down covariant derivatives in $\overline{J}^{\gamma\gamma}_{z^k\kappa_1\cdots\kappa_{j-k}}$ and evaluating the integrals only by the order of magnitudes, one can see that

$$(C^{0,0,m}_{V_1;+,\alpha})_k \sim \sum_M^{[\frac{j-k}{2}]}\left(\frac{\Lambda}{q}\right)^{i\nu-j}\frac{q^{k+2M}}{(q^2)^j}\left[\overbrace{(q_\kappa\cdots q_\kappa)}^{j-k-2M}(\eta_{\kappa\kappa}q^2)^M\right] \cdot\sum_N^{[\frac{s}{2}]}\frac{1}{\Delta^{s-2N}}\tilde{E}^N D^{s-2N}[\epsilon^{(0,0,m)}]. \tag{168}$$

The $M=0$ contribution above is further evaluated by using the definition of $\tilde{E}$ and D operators. Details of computation are found partially in (A82); we find that

$$(C^{0,0,m}_{V_1;+,\alpha})_{k,M=0} \sim \left(\frac{\Lambda}{q}\right)^{i\nu-j}\frac{\overbrace{(q_\kappa\cdots q_\kappa)}^{j-m}\epsilon^{(0,0,m)}}{(q^2)^j}\left(\frac{(q\cdot\Delta)}{\Delta}\right)^s q^k. \tag{169}$$

Keeping the relation $m = k+s$ and also the result (167) in mind, we obtain

$$C^{0,0,m}_{k,M=0}\cdot\Gamma^{0,0,m} \sim \left(\frac{\Lambda}{q}\right)^{i\nu-j}\frac{(q\cdot p)^{j-m}}{(q^2)^j}\left(\frac{(q\cdot\Delta)}{\Delta}\right)^s q^k\times\overline{g}^{0,0,m} \sim \left(\frac{\Lambda}{q}\right)^{i\nu-j}\left(\frac{1}{x}\right)^j\eta^{m-k}\left(\frac{(q^2)(\Delta^2)}{(q\cdot p)^2}\right)^{\frac{k}{2}}\frac{\overline{g}^{0,0,m}}{\Delta^m}. \tag{170}$$

Therefore, this is regarded as a twist-$[2+\gamma(j)+k/2]$ contribution in the generalized Bjorken scaling regime. Thus, only the $k=0$ term remains a twist-$[2+\gamma(j)]$ contribution, and the terms with $k>0$ are irrelevant to GPD.

The analysis becomes a little more complicated when $M>0$ terms are also included, but not in an essential way. Contributions with some (k,M) correspond to twist-$(2+\gamma+M+k/2)$, and only the $k=M=0$ terms contribute to GPD. This means that $C^{0,0,m}$ can be evaluated under the following approximation:

$$[A_p(z;-q_2)(-i\overleftrightarrow{\nabla})^j A_q(z;q_1)]^{\hat{m}_1\cdots\hat{m}_j}\delta^{\hat{p}\,\hat{q}}\overline{\overline{A}}_{m_1\cdots m_j} \to [A_\mu(z;-q_2)(-i\overleftrightarrow{\partial})^j A_\nu(z;q_1)]^{\hat{\kappa}_1\cdots\hat{\kappa}_j}\eta^{\mu\nu}\overline{\overline{A}}_{\kappa_1\cdots\kappa_j}. \tag{171}$$

4. Wilson coefficients, conformal OPE and hadron matrix elements

The twist-$[2+\gamma(j)]$ contribution to $C^{0,0,m}_{V_1;+,\alpha}$ can be determined completely, using the approximations above.

$$C^{0,0,m}_{V_1;+,\alpha} \simeq \left(\frac{2\Lambda}{\Delta}\right)^{i\nu}\frac{\Gamma(i\nu+1)}{(2\Lambda)^j}\int\frac{dz}{z}[(q_1z)K_1(q_1z)][(q_2z)K_1(q_2z)]z^j \times\sum_{N=0}^{[\frac{m}{2}]}[2^j(q^{\hat{\rho}_1}\cdots q^{\hat{\rho}_j})\cdot\tilde{E}^N D^{m-2N}[\epsilon^{(0,0,m)}]_{\rho_1\cdots\rho_j}]\frac{b^{(j-m)}_{m,N}}{\Delta^{m-2N}}[e^{(2-j)A}\overline{\overline{\Psi}}^{(j);m,N}_{i\nu;0,0,m}]. \tag{172}$$

The product of rank-j SO(3,1) tensors in the second line is reduced to a product of rank-$(j-m)$ tensors by the computation in (A82). The Reggeon wave function $\overline{\overline{\Psi}}$ is also rewritten by using the small $(\Delta z_\gamma) \lesssim (\Delta/q)$ approximation (158):

$$[e^{(2-j)A}\overline{\overline{\Psi}}^{(j);m,N}_{i\nu;0,0,m}] \simeq \sum_{a=0}^{N}(-1)^a {}_N C_a (\zeta^{j+1}\partial_\zeta^{m-2a}[\zeta^{-1-j+m}(\zeta/2)^{i\nu}])_{\zeta\to(\Delta z)} \frac{N_{j,m}}{\Gamma(i\nu+1)}. \tag{173}$$

The $a=0$ term in this expression has the lowest dimension in $\zeta = \Delta z_\gamma \lesssim (\Delta/q)$, and hence we only need to retain the $a=0$ term for a given N for the twist-$[2+\gamma(j)]$ contribution. Thus,

$$[e^{(2-j)A}\overline{\overline{\Psi}}^{(j);m,N}_{i\nu;0,0,m}] \simeq 2^{-i\nu}\frac{(-1)^m\Gamma(j+1-i\nu)}{\Gamma(j+1-i\nu-m)}(\Delta z_\gamma)^{i\nu}\frac{N_{j,m}}{\Gamma(i\nu+1)}. \tag{174}$$

Using this expression and (A82) in (172), we obtain

$$\begin{aligned} C^{0,0,m}_{V_1;+,\alpha} &\simeq \frac{\Lambda^{i\nu-j}}{q^{i\nu+j}}\frac{j!}{(j-m)!}\sum_{N=0}^{[m/2]}\left[\frac{(q\cdot\Delta)^2}{\Delta^2}\right]^N(-i)^m\frac{(q\cdot\Delta)^{m-2N}}{\Delta^{m-2N}}b^{(j-m)}_{m,N}[(q_{\mu_1}\cdots q_{\mu_{j-m}})\cdot\epsilon^{(0,0,m)}] \\ &\quad\times\int\frac{dz}{z}[(q_1z)K_1(q_1z)][(q_2z)K_1(q_2z)](qz)^{j+i\nu}\frac{(-1)^m\Gamma(j+1-i\nu)}{\Gamma(j+1-i\nu-m)}N_{j,m}, \qquad (175) \\ &= \left(\frac{\Lambda}{q}\right)^{i\nu-j}\frac{[(q_{\mu_1}\cdots q_{\mu_{j-m}})\cdot\epsilon^{(0,0,m)}]}{(q^2)^j}\frac{(q\cdot\Delta)^m}{\Delta^m}C_1\left(j+i\nu,\frac{\eta}{x}\right) \\ &\quad\times i^m\frac{j!}{(j-m)!}N_{j,m}\frac{\Gamma(j+1-i\nu)}{\Gamma(j+1-i\nu-m)}\left(\sum_{N=0}^{[m/2]}b^{(j-m)}_{m,N}\right), \qquad (176) \\ &= \left(\frac{\Lambda}{q}\right)^{i\nu-j}\frac{[(q_{\mu_1}\cdots q_{\mu_{j-m}})\cdot\epsilon^{(0,0,m)}]}{(q^2)^j}\frac{(q\cdot\Delta)^m}{\Delta^m}C_1\left(j+i\nu,\frac{\eta}{x}\right) \\ &\quad\times i^m\frac{\Gamma(j+1+i\nu-m)}{N_{j,m}\Gamma(j+1+i\nu)}, \qquad (177) \end{aligned}$$

where (B1), (B5) is used for the equality in the middle, while (A67) is used for the last one.

Repeating the same argument as in Sec. VI C 2, we thus arrive at

$$\begin{aligned} (V_1^{+,\alpha})_m \simeq -\int\frac{dj}{4i}\frac{1+e^{-\pi ij}}{\sin(\pi j)}\frac{t_\gamma/t_y}{\Gamma(j+1)}\frac{\lambda}{i\nu_j}C_1(j+i\nu_j)\left(\frac{\Lambda}{q}\right)^{\gamma(j)} \\ \times\left(\frac{1}{\sqrt{\lambda}x}\right)^j\eta^m\hat{d}_{j-m}([\eta])\frac{\overline{g}^{0,0,m}}{\Delta^m}\frac{i^m}{N_{j,m}} \\ \times\frac{\Gamma(j+1+i\nu-m)}{\Gamma(j+1+i\nu)}; \end{aligned} \tag{178}$$

the computation in (A77), (A79) for an even j and m was used once again. Similar to the case of the $m=0$ amplitude, this expression is in the form of the conformal OPE and inverse Mellin transformation in (20). It should be noted that the integrand can be defined as a holomorphic function of j (apart from poles and cuts), using the definition of C_1 in (B1) and that of $\hat{d}_{j-m}$ in (A79), not just for an integer-valued j; at the same time, $\eta^m\hat{d}_{j-m}([\eta])$ becomes a polynomial of η of degree j for $j\in 2\mathbb{N}$, which is one of the important properties expected for the hadron matrix element [9].

The integration contour of (178) is chosen so that it circles around the pole at $j=m$ after running just below the real positive axis in the j plane and before running just above the real positive axis. Only spin-j stringy states with $m\le j$ contribute then. It is not obvious whether the contour can be deformed so that it encircles $j=0,2,\ldots,m$ without changing $(V_1^{+,\alpha})_m$, and we leave it an open question. $\hat{d}_{j-m}$ in (178) is given by a Legendre polynomial of degree $(j-m)$ when $j-m$ is an even positive integer, but otherwise it is defined by the hypergeometric function, as in (A79), and it may or may not have a zero at negative even integer $(j-m)$ so that the pole from $\sin(\pi j)$ is canceled. Similarly, $\overline{g}^{0,0,m}(j,i\nu_j,\Delta)/N_{j,m}$ may or may not have a zero at negative integer $(j-m)$. The authors have not found a reason to believe that they have a zero, but we may be wrong.

The twist-$[2+\gamma(j)]$ contribution to the structure function $V_1^{+,\alpha}$ is obtained by summing $(V_1^{+,\alpha})_m$ from the $(n,l,m)=(0,0,m)$ modes with $m=0,2,\ldots$:

$$V_1^{+,\alpha} = \sum_{m=0,2,\ldots}^{\infty}(V_1^{+,\alpha})_m. \tag{179}$$

Combining (163), (178) with (179), a holographic version of (20) is obtained. It is not obvious, though, whether or not the integration variable j in (178) for all the different m's should be identified. If we are to define $j' \coloneqq (j-m)$ and use it as a new variable of integration, then the integration contour of (178) would be the same for all different m's; the cost of doing so, however, is this:

$$C_1(j+i\nu_j,\vartheta)\left(\frac{\Lambda}{q}\right)^{\gamma(j)}\frac{1}{x^j}\eta^m\hat{d}_{j-m} = [C_1(j'+m+i\nu_{j'+m},\vartheta)\times\vartheta^m]\left(\frac{\Lambda}{q}\right)^{\gamma(j'+m)}\frac{1}{x^{j'}}\hat{d}_{j'}. \tag{180}$$

Certainly $\hat{d}_{j'}$ still remains to be a polynomial of degree at most j', but the expression no longer fits into the form of conformal OPE. For this reason, we identify the integration variable j in (178) for all $m=0,2,\ldots$ with that (complex angular momentum) of the inverse Mellin transformation (20). This implies that the reduced hadron matrix element of the spin-j primary operator is given a holographic expression

$$\overline{A}_j^{+,\alpha}(\eta,t) \propto \sum_{m=0}^{j}\frac{(-1)^{m/2}}{\sqrt{\lambda}^j\Gamma(j+1)}\frac{\overline{g}^{0,0,m}(j,i\nu_j,\Delta^2)}{N_{j,m}\Delta^m}\times\frac{\Gamma(j+1+i\nu_j-m)}{\Gamma(j+1+i\nu_j)}\times\eta^m\hat{d}_{j-m}([\eta]). \tag{181}$$

5. The $(m=2)$-mode hadron matrix element

Most aspects of the expression (178) are dictated by basic principles of field theory, such as (conformal) OPE. Additional information from the holographic setup is found primarily in the hadron matrix element $\overline{g}^{0,0,m}(j,i\nu,\Delta)$, apart from the anomalous dimension $\gamma(j)=i\nu_j-j$ of the twist-$[2+\gamma(j)]$ operators. Now we have seen that $\overline{g}^{0,0,0}(j,i\nu_j,\Delta)$ is not the only hadron matrix element contributing to the nonperturbative information of $h+\gamma^*\to h+\gamma^{(*)}$; let us take a moment here to have a closer look at one of the new hadron matrix elements we encounter, $\overline{g}^{0,0,2}(j,i\nu,\Delta)$.

The hadron matrix element $\Gamma^{0,0,m}$ receives contributions from $\overline{J}^{hh}_{z^k\lambda_{k+1}\cdots\lambda_j}\overline{A}^{\hat{z}^k\hat{\lambda}_{k+1}\cdots\hat{\lambda}_j}$'s, with $k=0,1,\ldots,m$. The contribution from each k can be written in the form of (167), and hence $(\overline{g}^{0,0,m}(j,i\nu,\Delta))_k$ is defined ($k\le m$). We compute $(\overline{g}^{0,0,2})_k$ explicitly for $k=0,1,2$.

For this purpose, we need the following technical results:

$$(\nabla^l\Phi)_{\lambda_1\cdots\lambda_l} \equiv (\partial_{\lambda_1}\cdots\partial_{\lambda_l}\Phi) - \sum_{1\le a<b\le l}\frac{\eta_{\lambda_a\lambda_b}}{z}\left(\partial_{\lambda_1}\cdots\check{}_{\lambda_a\check{\lambda}_b}\cdots\partial_{\lambda_l}\left(\partial_z+\frac{l-a-1}{z}\right)\Phi\right) \tag{182}$$

modulo terms proportional to $\eta_{\lambda_a\lambda_b}\eta_{\lambda_c\lambda_d}$ instead of (150), and

$$\begin{aligned}(\nabla^l\Phi)_{\lambda_1\cdots z\cdots\lambda_l} &\equiv \left(\partial_z+\frac{l-1}{z}\right)\partial_{\lambda_1}\cdots\check{}_{\lambda_a}\cdots\partial_{\lambda_l}\Phi,\\ (\nabla^l\Phi)_{\lambda_1\cdots z\cdots z\cdots\lambda_l} &\equiv \left[\left(\partial_z+\frac{l-1}{z}\right)\left(\partial_z+\frac{l-2}{z}\right)+\frac{a-1}{z^2}\right]\times\partial_{\lambda_1}\cdots\check{}_{\lambda_a\check{\lambda}_b}\cdots\partial_{\lambda_l}\Phi,\end{aligned} \tag{183}$$

modulo terms proportional to $\eta_{\lambda_c\lambda_d}$.

It is now a straightforward computation to use the relations above as well as the explicit Reggeon wave functions $\overline{A}$ determined in Sec. V to derive the following:

$$\begin{aligned}\frac{\overline{g}^{0,0,2}_{k=2}}{N_{j,2}\Delta^2} &= \frac{j(j-1)}{2}\int_0^{1/\Lambda}\frac{dz}{z^3}(\Lambda z)^j\frac{\{z^2\text{“}K_{i\nu}(\Delta z)\text{”}\}}{[(\frac{\Delta}{2\Lambda})^{-i\nu}\Gamma(i\nu)]}t_h\left[2\{-\Phi(\partial_z^2\Phi)+(\partial_z\Phi)^2\}-\frac{2}{z}\Phi(\partial_z\Phi)-\frac{4(j-2)}{3z^2}\Phi^2\right],\\ \frac{\overline{g}^{0,0,2}_{k=1}}{N_{j,2}\Delta^2} &= \frac{j(j-1)}{2}\int_0^{1/\Lambda}\frac{dz}{z^3}(\Lambda z)^j\frac{\{z^{j+1}\partial_z(z^{1-j}\text{“}K_{i\nu}(\Delta z)\text{”})\}}{[(\frac{\Delta}{2\Lambda})^{-i\nu}\Gamma(i\nu)]}\left[\frac{-2t_h}{z}\Phi^2\right],\\ \frac{\overline{g}^{0,0,2}_{k=0}}{N_{j,2}\Delta^2} &= j(j-1)\int_0^{1/\Lambda}\frac{dz}{z^3}(\Lambda z)^j\left(\frac{\{[z^{j+1}\partial_z^2z^{1-j}-(z\Delta)^2]\text{“}K_{i\nu}(\Delta z)\text{”}\}}{[(\frac{\Delta}{2\Lambda})^{-i\nu}\Gamma(i\nu)]}\times\left[\frac{p^2}{(j-\frac{1}{2})\Delta^2}t_h\Phi^2\right]\right.\\ &\quad\left.+\frac{\{-z^2\text{“}K_{i\nu}(\Delta z)\text{”}\}}{[(\frac{\Delta}{2\Lambda})^{-i\nu}\Gamma(i\nu)]}\times t_h\left[\frac{1}{z}\Phi(\partial_z\Phi)+\frac{j-2}{3z^2}\Phi^2\right]\right).\end{aligned} \tag{184}$$

These results are used in the study below.

VII. A HOLOGRAPHIC MODEL OF GPD

The differential cross section of the DVCS process involves an integral of GPD; GPD needs to be parametrized first, and then the parameters are determined by fitting the data [10]. The idea of dual parametrization of GPD [15]—also known as collinear factorization approach [17,18]—is to expand the reduced hadron matrix element $\overline{A}_j^{+,\alpha}(\eta,t)$ as

$$\overline{A}_j^{+,\alpha}(\eta,t)=\sum_{m=0}^{j}\overline{\Gamma}_m^{+,\alpha}(j,t)\eta^m\times[\eta^{j-m}d_{j-m}(1/\eta)], \tag{185}$$

where $d_\ell(\cos\theta)$'s are polynomials of degree ℓ in the argument $(\cos\theta)$; Legendre polynomials, Gegenbauer polynomials, or Jacobi polynomials are used, depending on the helicity change of the target hadron h in the scattering process [9]. When the target hadron is a scalar, as in the study of this article, a Legendre polynomial is chosen for d_ℓ [15]. With no ambiguity introduced in the polynomials $d_{j-m}(x)$, $\overline{\Gamma}_m^{+,\alpha}(j,t)$'s are the fully general, yet nonredundant parametrization for the reduced hadron matrix element for GPD.

At the end of the study in the preceding sections, we arrived at a holographic model of GPD, with the reduced hadron matrix element given by (181) for the flavor-nonsinglet sector. String theory—the descendant of the dual resonance model—yields a result that fits straightforwardly with the format of the dual parametrization (185); this should not be a surprise, but rather must be something the authors of [15] have anticipated. With the string-theory implementation provided, one can now move forward; now

$$\overline{\Gamma}_m^{+,\alpha}(j,t)\sim(-1)^{m/2}\frac{\overline{g}^{0,0,m}(j,i\nu_j,\Delta)}{N_{j,m}\Delta^m} \tag{186}$$

can be computed using holographic backgrounds, independently from experimental data. Certainly the matrix elements $[\overline{g}^{0,0,m}/\Delta^m]$ will depend on holographic backgrounds to be used for computation, and predictions from individual holographic backgrounds should not be taken seriously at the quantitative level. But it is still worth looking closely into qualitative features of the holographic hadron matrix elements $\overline{g}^{0,0,m}/\Delta^m$ to learn nonperturbative aspects of $\overline{\Gamma}_m^{+,\alpha}(j,t)$.

A. $\Delta^2\to 0$ limit

As we have already remarked earlier in this article, the holographic result (181) is not precisely in the same form of parametrization as in (185); the argument of the polynomial $\hat{d}_{j-m}$ is $[\eta]$ as defined in (161), rather than η. This difference itself does not raise an issue immediately; $[\eta]$ is the same as η in the hard scattering regime, $\Delta^2\gg m_h^2$.

Let us study how the hadron matrix element behaves in the $t=-\Delta^2\to 0$ limit, however. The matrix element $\overline{g}^{0,0,0}(j,i\nu_j,\Delta)$ has already been studied in the literature and is known not to diverge or vanish in the $\Delta^2\to 0$ limit. The polynomial $\hat{d}_j([\eta])$ to be multiplied with this $\overline{g}^{0,0,0}(j,i\nu_j,\Delta)$, however, has diverging coefficients in all of the terms $\eta^2,\eta^4,\ldots$ except the η^0 term. Therefore, the $m=0$ contribution (163) alone does not have a physically reasonable behavior in the $\Delta^2\to 0$ limit. A natural expectation will be that the hadron matrix element $\overline{A}_j^{+,\alpha}(\eta,t)$ still has a reasonable behavior after summing up $m=0,2,\ldots,j$.

To get started, we focus on the η^2 term. It is generated from the $(m=0)$-mode exchange, and also from the $(m=2)$-mode exchange. There is a $(p^2)/\Delta^2$ factor both in $\overline{g}^{0,0,0}\times\hat{d}_j([\eta])|_{\eta^2}$ and $\overline{g}^{0,0,2}/\Delta^2\times\eta^2$, and hence both diverge in the $\Delta^2\to 0$ limit. When they are summed, however, the divergence may cancel, as we see in the following. Let us study the coefficient of the η^2 term

$$-\int\frac{dj}{4i}\frac{1+e^{-\pi ij}}{\sin(\pi j)}\left(\frac{\Lambda}{q}\right)^{i\nu-j}\left(\frac{1}{\sqrt{\lambda}x}\right)^j C_1\left(j+i\nu,\frac{\eta}{x}\right)\times\frac{\lambda}{i\nu_j}\frac{t_\gamma/t_y}{\Gamma(j+1)}\times\eta^2 \tag{187}$$

in the $\Delta^2\to 0$ limit, picking up a contribution to the integral $\overline{g}^{0,0,0}$ and $\overline{g}^{0,0,2}$ from the $I_{-i\nu}(\Delta z_h)$ component in $K_{i\nu}(\Delta z_h)$ first.[31] Then in that limit, the coefficient of the expression (187) becomes

$$\frac{p^2}{\Delta^2}\lim_{\Delta^2\to 0}\left[\overline{g}^{0,0,0}(j,i\nu_j,\Delta)\frac{j(j-1)}{(j-\frac{1}{2})}-\frac{\overline{g}^{0,0,2}(j,i\nu_j,\Delta)/(p^2)}{(j-1+i\nu_j)(j+i\nu_j)N_{j,2}}\right]+\mathcal{O}(\Delta^0). \tag{189}$$

The two terms in $\lim_{\Delta^2\to 0}[\cdots]$ cancel each other, as one can see by using the approximation in footnote 31. Thus, the η^2 term in $\overline{A}_j^{+,\alpha}(\eta,t)$ also has a finite limit value in the $\Delta^2\to 0$ limit.

It is quite likely, however, that the $I_{i\nu}(\Delta z)$ component in $K_{i\nu}(\Delta z)$ has just as important a contribution as the $I_{-i\nu}(\Delta z)$ component does in the $\Delta^2\to 0$ limit to the hadron matrix elements $\overline{g}^{0,0,0}$ and $\overline{g}^{0,0,2}$; the coefficient $(1-c^{(j)}_{i\nu;0,0,m})$ may behave as $(\Delta/\Lambda)^{-2i\nu}$ in the $\Delta^2\to 0$ limit. Because we have seen above that the divergence (p^2/Δ^2) cancels when only the $I_{-i\nu}(\Delta z)$ component is taken into account, the contributions from the $I_{i\nu}(\Delta z)$ should also have some cancellation mechanism. Using an approximation for the $I_{i\nu}(\Delta z)$ components in $K_{i\nu}(\Delta z)$ similar to the one in footnote 31, one finds that the (p^2/Δ^2) divergence cancels in the η^2 coefficient, if and only if

[31]The leading divergence in the $\Delta^2\to 0$ limit comes from

$$K_{i\nu}(\Delta z)\sim\left(\frac{\pi}{2}\right)\frac{I_{-i\nu}(\Delta z)}{\sin(\pi i\nu)}\simeq\left(\frac{\pi}{2}\right)\frac{(\Delta z/2)^{-i\nu}}{\sin(\pi i\nu)\Gamma(-i\nu+1)}=\frac{\Gamma(i\nu)}{2}(\Delta z/2)^{-i\nu}. \tag{188}$$

$$\lim_{\Delta^2/\Lambda^2\to 0}\left[\left(\frac{\Delta}{2\Lambda}\right)^{2i\nu}\left\{(1-c^{(j)}_{i\nu_j;0,0,0})-(1-c^{(j)}_{i\nu_j;0,0,2})\times\frac{(j-1-i\nu_j)(j-i\nu_j)}{(j-1+i\nu_j)(j+i\nu_j)}\right\}\right]=0. \tag{190}$$

The coefficients $c^{(j)}_{i\nu;0,0,m}$ are functions of Δ/Λ, rather than complex numbers. The discussion above shows that physically sensible implementations of the confining effect require one of the conditions above between the two functions $c^{(j)}_{i\nu;0,0,0}$ and $c^{(j)}_{i\nu;0,0,2}$.

The η^{2M} term with $M=2,\ldots$, instead of the η^2 term in (187), also receives divergent contributions from amplitudes of the $(m=0,2,\ldots,2M)$-mode exchange. There will be an apparent divergence of order $(p^2/\Delta^2)^M$, $(p^2/\Delta^2)^{M-1},\ldots,(p^2/\Delta^2)$. The cancellation of divergence in the $\Delta^2\to 0$ limit will set M conditions on the $\Delta^2/\Lambda^2\to 0$ limit of $(1-c^{(j)}_{i\nu_j;0,0,2M})$.

In a phenomenological approach of implementing the confining effect, that is all we can say for now. With a little more of a model building mind-set, however, we can find some solutions to the conditions above. It is not hard to verify that the combination of

$$\begin{aligned}&[\partial_z(\Psi^{(j);0,0}_{i\nu;0,0,0}(t,z))]|_{z\Lambda=1}=0,\\&[\partial_z(\Psi^{(j);2,0}_{i\nu;0,0,2}(t,z))]|_{z\Lambda=1}=0\end{aligned} \tag{191}$$

results in $c^{(j)}_{i\nu;0,0,0}$ and $c^{(j)}_{i\nu;0,0,2}$ satisfying the condition (190). It is tempting to generalize this and impose the boundary condition $\partial_z[\Psi^{(j);2M,0}_{i\nu;0,0,2M}]=0$ to determine $c^{(j)}_{i\nu;0,0,2M}$, though we do not know whether all of the m_h^2/Δ^2 divergences above are removed under this boundary condition. The top-down approach is much more authentic and well motivated than such a hand-waving and wishful approach, and we do not try to speculate beyond that; we use this implementation of the confining effect, (191), only to "get the feeling" in the numerical presentation in Sec. VII D.

B. Large Δ^2 behavior

Certainly the holographic model of GPD yields a result of the reduced hadron matrix element that fits perfectly with the dual parametrization. The holographic result, however, turns out to be a little more complicated than the models that have often been explored for the purpose of phenomenological fit of the DVCS data. An example of a model for phenomenological fit (see, e.g., [18]) was to introduce an ansatz that

$$\overline{\Gamma}^{+,\alpha}_m(j,t)=f_{j,m}\Sigma_{j-m}(t), \tag{192}$$

where only one $(t=-\Delta^2)$-dependent *function* is involved in the form of a "form factor" $\Sigma_{j-m}(t)$ for some spin $(j-m)$, and all the remaining nonperturbative information is reduced to some *numbers* $f_{j,m}\in\mathbb{R}$. The function $\Sigma_J(t)$ may also be parametrized by an ansatz like

$$\Sigma_J(t)=\frac{1}{J-\alpha_0-\alpha'_{\rm eff}t}\frac{1}{[1-\frac{t}{m^2(J)}]^p}, \tag{193}$$

in order to implement both the Regge behavior and the power-law form factor in the hard regime $1\ll -t/\Lambda^2$. To fit the data in practice, it is certainly unavoidable to reduce the unknown information into a finite set of real numbers.

A theoretical picture based on the holographic model, on the other hand, suggests that the $t=-\Delta^2$ dependence is more complicated than this. If we strictly stick to the expansion (185), then individual $\overline{\Gamma}^{+,\alpha}_m(j,t)$'s may diverge at $t=-\Delta^2=0$, as we have seen above, and are not like form factors. The $\overline{\Gamma}^{+,\alpha}_m(j,t)$ would not depend only on the difference $(j-m)$, as in (192), either; we have already seen that $\overline{\Gamma}^{+,\alpha}_{m=2}(j,t)\propto\overline{g}^{0,0,m=2}/\Delta^2$ diverges at $t=-\Delta^2\to 0$ for an arbitrary j, but there is no such divergence in $\overline{\Gamma}^{+,\alpha}_{m=0}(j,t)\propto\overline{g}^{0,0,0}$, for example. Therefore, holographic models of GPD might be used as a theoretical guide to think of parametrization (for fitting) that is different from (192).

The holographic model provided by the calculation in the previous section involves infinitely many spin-dependent form factors, $\overline{g}^{0,0,m}(j,i\nu_j,\Delta)/\Delta^m$. We can still find that they share a common behavior at large $\Delta^2=-t$. To see this, note that $K_{i\nu}(\Delta z_h)$ in the Reggeon wave function effectively cuts off the integral over the holographic radius z_h at $z_h\lesssim 1/\Delta$ in the regime

$$\Lambda^2,m_h^2\ll\Delta^2\ll|q^2|,(p\cdot q),|(q\cdot\Delta)|. \tag{194}$$

The explicit form of $\Psi^{(j);s,N}_{i\nu;0,0,m}(z;\Delta)$ in (97) is not more than a modification of $K_{i\nu}(\Delta z)$ by a function of Δz_h, and hence they still play just the role of cutting off the integral at $z_h\Delta\lesssim 1$. The "current" $\overline{J}^{hh}_{z^k\lambda_{k+1}\cdots\lambda_j}$ provides extra mth powers of either $1/z$ or ∂_z and $(j-m)$-momenta p_λ, in addition to $[\Phi]^2$, which behaves like

$$[\Phi]\sim z(\Lambda z)^{\ell_\phi-1} \tag{195}$$

in the region $z\lesssim 1/\Delta\ll 1/\Lambda$; ℓ_ϕ is the conformal dimension of an operator in a strongly coupled gauge theory dual to the holographic model, which is a property of the target hadron h. The $\tilde{E}^N D^{s-2N}[e]/\Delta^{2-2N}$ operation on the SO(3,1) tensor in (89) does not introduce any power of (Δ/Λ) or (Λz). Therefore, we find in the hard scattering regime (194) that

$$\frac{\bar{g}^{0,0,m}}{\Delta^m} \sim \left(\frac{\Delta}{\Lambda}\right)^{i\nu} \times (\Lambda/\Delta)^{j+2(\ell_\phi-1)} \times \Delta^m/\Delta^m \sim \frac{1}{(\Delta/\Lambda)^{2\ell_\phi-2-\gamma(j)}}. \quad (196)$$

Interestingly, the reduced hadron matrix elements $\bar{g}^{0,0,m}/\Delta^m$ for (j,m) have the large Δ^2 power-law behavior that is independent of m; $2\Delta_\phi$ reflects a property of the target hadron h, and $-(2+\gamma(j)) = -\tau_n$ is j dependent, but the power does not depend on m.[32] Holographic models suggest this j-dependent $p = \text{const} - \gamma(j)/2$ scaling behavior as an alternative to the fixed-power $p = \text{const.}$ scaling of (193).

We have chosen a factorization into the Wilson coefficient and the matrix element that corresponds to renormalization at $\mu = \Lambda$; this choice was made implicitly when we chose a factor $[\Delta^{i\nu}/\Lambda^{i\nu-j}]^{\pm 1}$ at the time the amplitude was factorized into $C^{0,0,m}$ and $\Gamma^{0,0,m}$ in (149). When we keep the renormalization scale μ arbitrary (e.g., taking μ higher than Δ when $\Delta \gg \Lambda$), the Wilson coefficient contains a factor $(\mu/q)^{\gamma(j)}$ instead of $(\Lambda/q)^{\gamma(j)}$, and the reduced matrix element also has the following large Δ^2 behavior,

$$\frac{\bar{g}^{0,0,m}}{\Delta^m} \sim \frac{1}{(\Delta/\Lambda)^{2\ell_\phi-2}} \times \frac{1}{(\mu/\Delta)^{\gamma(j)}}. \quad (197)$$

C. Pomeron and superstring

We have so far talked about Reggeon and the flavor-nonsinglet sector in Secs. VI and VII, instead of Pomeron. Since the flavor-singlet sector ($\approx$ gluon) dominates in small-x physics, that was not a desired choice.

This is due to technical limitations in string theory at this moment. In order to deal with the propagation of string states on a curved spacetime, vertex operators and L_0 (the Virasoro generator) need to be defined properly as composite operators; the nonlinear σ model for $\text{AdS}_5 \times W_5$ on the world sheet becomes conformal and the renormalization of the composite operators well defined, however, only after the Ramond-Ramond background is also implemented (e.g., [35]). Presumably an option in the future will be to implement the Klebanov-Strassler model and its variations in the Green-Schwarz formalism. One then computes the spectrum of stringy excited states, and further works out the world-sheet OPE, in the form of

$$V^{(q_1)}(z)V^{(-q_2)}(-z) \sim \sum_I C_I(z)\mathcal{O}_I(0), \quad (198)$$

using operators $\mathcal{O}_I(0)$ at the middle point, where $V^{(q_1)}$ and $V^{(-q_2)}$ are the vertex operators corresponding to the incoming and outgoing photons (32). In this way, we would not have to use string field theory.

It may also be possible to use bosonic string field theory for closed string theory, instead of the bosonic open string field theory we used in Sec. IV of this article. Bosonic closed string field theory is also well understood already [36]. Certainly the bosonic closed string field theory is not for type IIB superstring theory, but it will still allow us to get the feeling of how much open string (flavor-nonsinglet sector) and closed string (flavor-singlet sector) theories are different, from theoretical perspectives, as well as in phenomenological consequences. At least it is known that the Virasoro-Shapiro amplitude is generated, not just by the one string exchange in the t channel, the s channel, and the u channel, but also a four-point contact interaction vertex in string field theory [37]. The Virasoro-Shapiro amplitude does not have a simple s-t duality of the Veneziano amplitude, either. Certainly it is possible to write it down in the form of "t-channel" expansion only (cf. [3] and [7]), but we also need to be aware that the discussion in these two references did not use the OPE at the middle point as in (198), but instead used an OPE of the form $V(z)V(0) \sim \sum_I C_I(z)\mathcal{O}_I(0)$. To get the skewness dependence right, this difference really matters. Thus, an analogue of the prescription (52) needs to be worked out separately for the closed string amplitude.

Orthodox approaches such as those above are way beyond the scope of this article. One can hardly overestimate the importance of such a solid approach, but at the same time, very few would find the following guess terribly wrong. For practical purposes, therefore, one can live with that for the time being. First of all, the on-shell relation for the bosonic open string in (164) will be replaced by

$$\frac{j}{2} - 1 + \frac{4 + j + \nu^2 + c_j}{4\sqrt{\lambda}} = 0, \quad (199)$$

with the constraint $c_{j=1} = -4$ for the bosonic open string replaced by $c_{j=2} = -2$. Interaction vertices should also be different; looking at the difference between the Veneziano amplitude and the Virasoro-Shapiro amplitude, one finds that the following replacements should be made:

$$\frac{t_\gamma/t_y}{\Gamma(j+1)} \to \frac{t_\gamma/t_y}{[\Gamma(j/2)]^2}, \qquad \left(\frac{1}{\sqrt{\lambda}x}\right)^j \to \left(\frac{1}{4\sqrt{\lambda}x}\right)^j. \quad (200)$$

The overall normalization t_γ/t_y is like $N_c/N_c^{-2} \sim N_c^{-1}$ now, when the Pomeron (closed string) contribution is used in the t channel, and the source field for the "QED current" is implemented in the form of the D7-brane gauge field; the $1/N_c$ scaling (see footnotes 14 and 27) is also the natural expectation in the large N_c argument.

[32] This scaling was known already for $\bar{g}^{0,0,0}$ [7].

D. Numerical results

At the end of this article, we leave a few plots of numerical evaluation of various results that have been obtained. We do not intend to provide a quantitative (precise) prediction from holography, as we have repeatedly emphasized our perspective on this issue in this article; the holographic approach to GPD will provide at best a qualitatively new way to think of how to parametrize the matrix elements for GPD. Having said that, it is still desirable to grasp various expressions in a more intuitive form and bring them down to more practical situations. This section serves this purpose.

There are a couple of parameters that need to be specified in order to obtain numerical outputs in a few summary plots. We used the on-shell relation (164), which means that we should understand the numerical results to be that of the Reggeon contribution. We adopted $c_j + 4 = 0$ for all j, although there is no rationale to specify the j dependence in this way (see [12,38] and the literature therein for how to work out the j dependence of c_j). The confining effect was implemented in the form of the boundary condition (191) for the Reggeon wave function. As for the target hadron, we set the mass term of the scalar field to be $5/R^2$ (i.e., $c_y = 5$), just like the lowest nontrivial spherical harmonics on $W_5 = S^5$ for the type IIB dilaton field [39]. The operator dimension in the dual CFT becomes $\ell_\phi = 2 + \sqrt{4 + R^2 M_{\rm eff}^2} = 2 + \sqrt{4 + c_y} = 5$.

Figure 6 shows the reduced matrix element $\overline{g}^{0,0,0}(j, i\nu_j, \Delta)$ for the $(m = 0)$-mode exchange; the results for different values of spin $j = 1$, 1.5, 2, 2.5 are shown in the figure. Lattice computation can be used to determine matrix elements at integer-valued spins, but the analytic expression (153) allows us to determine the matrix element even for noninteger spin, so that the inverse Mellin transformation is possible, and we can also talk of the matrix elements evaluated at the saddle point value of spin $j = j^*$. Panel (b) in Fig. 6 is essentially the same as that of Fig. 5 in [7], while panel (a) shows $\overline{g}^{0,0,0}$ without normalizing the matrix element by its value at $t = -\Delta^2 = 0$. Since they are not the matrix element of a "conserved current" for $j \neq 1$, the matrix element does not necessarily approach 1 in the $\Delta^2 \to 0$ limit. Panel (b) has a property such that $\overline{g}^{0,0,0}$ is soft ($\overline{g}^{0,0,0}$ gets smaller slowly in Δ^2) for a larger j; this is consistent with the observation in (196) because $\partial\gamma(j)/\partial j > 0$.

A numerical result for the η^2 term in $\overline{A}_j^{+,\alpha}$, which is proportional to

$$\overline{g}^{0,0,0}(j, i\nu_j, \Delta) \times \left[\frac{p^2}{\Delta^2}\frac{j(j-1)}{j-\frac{1}{2}}\right] + \frac{\overline{g}^{0,0,2}(j, i\nu_j, \Delta)}{N_{j,2}\Delta^2} \times \frac{-1}{(j + i\nu_j)(j - 1 + i\nu_j)}, \tag{201}$$

is shown in Fig. 7, using $j = 2$. The first and second terms of (201) both diverge at the $\Delta^2 \to 0$ limit, as we saw in Sec. VII A, but their sum has a finite value at $\Delta^2 = 0$, as one can see in the figure. It is worth mentioning that this finite limit value ≈ -700 is much larger than that of $\overline{g}^{0,0,0}$. This is likely due, at least partially, to the hadron mass m_h value in this case; for the value of parameters we chose, $m_h = j_{\ell_\phi - 2,1}\Lambda$, $j_{3,1} \simeq 6.4$, and $m_h^2/\Lambda^2 \approx 40$. An extra derivative ∂_z in the matrix elements $\overline{g}_k^{0,0,2}$ is more like m_h than Λ, and hence the second term can be larger than the first term by about $(m_h/\Lambda)^2$. The factor $(m_h/\Lambda)^2 \approx 40$ does not explain all of the moderately large value -700, however. The $t = -\Lambda^2$ dependence of the η^0 term [i.e., $\overline{g}^{0,0,0}(j, i\nu_j, \Delta)$] is quite different from that of the coefficient of the η^2, at least at small Δ^2.

In the DGLAP phase, a crude approximation of the GPD is given by

$$\overline{H}^{+,\alpha}(x, \eta, t; q^2) \approx \left(\frac{1}{x}\right)^{j_*}\left(\frac{\Lambda}{q}\right)^{\gamma(j_*)}\overline{A}_{j*}^{+,\alpha}(\eta, t), \tag{202}$$

where j^* is the saddle point value of j depending primarily on $\ln(1/x)$, $\ln(q/\Lambda)$, and $t = -\Lambda^2$. Apart from applications

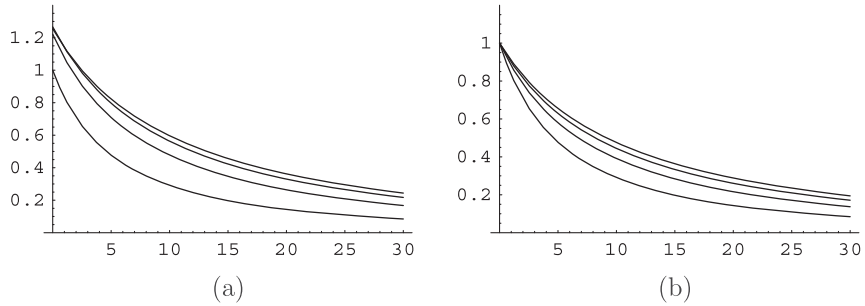

FIG. 6. Panel (a) shows $\bar{g}^{0,0,0}(j, i\nu_j, \Delta)$ as a function of Δ^2/Λ^2. The curve at the bottom is for $j = 1$, while the one at the top is for $j = 2.5$; the two in the middle correspond to $j = 1.5$ and $j = 2$. Panel (b) shows $\bar{g}^{0,0,0}(\Delta)/\bar{g}^{0,0,0}(\Delta = 0)$, i.e., $\bar{g}^{0,0,0}(j, i\nu_j, \Delta)$ normalized at the value of $\Delta^2 = 0$. The curve at the bottom is for $j = 1$, and the curve goes up for $j = 1.5$, 2, and 2.5; this softer behavior for larger j is consistent with (196).

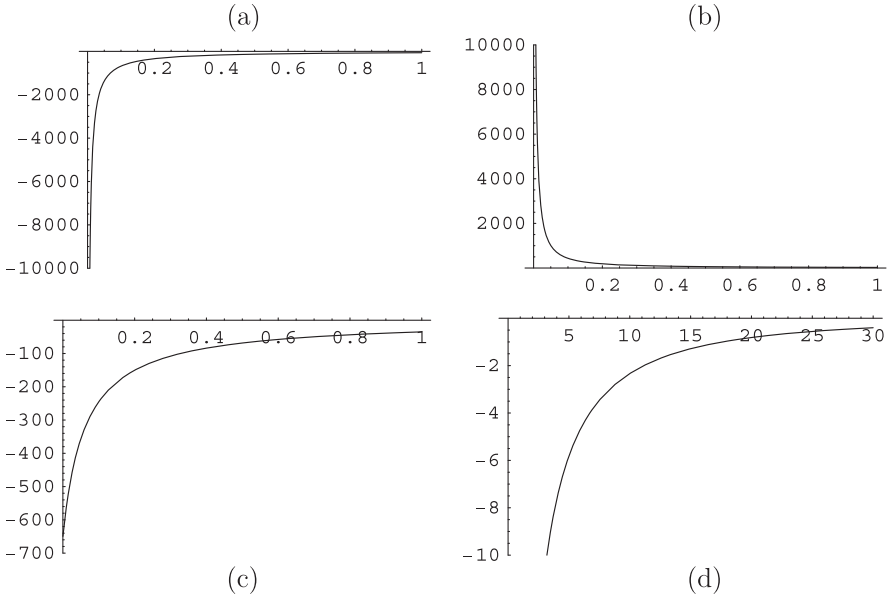

FIG. 7. The first and second term of (201) are plotted in (a) and (b), respectively, as functions of Δ^2/Λ^2; parameters are set to the values described in the text, and we used $j = 2$ in these figures. Although both (a) and (b) diverge at $\Delta^2 \to 0$, they add up to be (c), where the $\Delta \to 0$ limit is finite. The large Δ^2 behavior is seen better in panel (d).

to the timelike Compton scattering with very large (positive) lepton invariant mass square, the relevant range of $|\eta|$ is not much more than x in such processes as TCS, DVCS, and VMP. Suppose, in the power series expansion of $\overline{A}^{+,\alpha}_{j*}$ in η, that all of the terms with a different power of η have a (t-dependent) coefficient at most of $\mathcal{O}(1)$. Then the GPD [or $\overline{A}^{+,\alpha}_{j*}(\eta, t)$] in the small-$x$ regime would not have skewness dependence very much in the range of interest, $|\eta| \lesssim x$, because η^2 and higher-order terms are small relative to the η^0 term. The coefficient of the η^2 term, however, turns out to be of $\mathcal{O}(-700)$ for $\Delta^2 \approx 0$, which at least contains a factor m_n^2/Λ^2. Thus, for the range of moderately small x's, such as $x \sim 10^{-1}$ and $|\eta| \lesssim x$, the η^2 term in $\overline{A}^{+,\alpha}_{j*}(\eta, t)$ can be just as important as the η^0 term for small Δ^2. Consequently the prediction/fit of the slope parameter

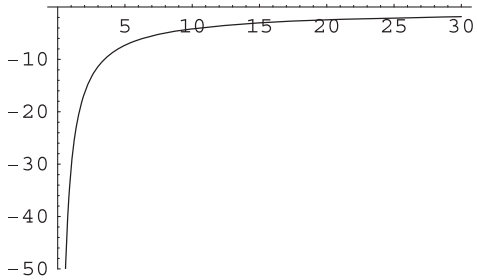

FIG. 8. The ratio of the coefficient of the η^2 term of $\bar{A}^{+,\alpha}_{j}(\eta, t)$ to that of the η^0 term, as a function of $-t/\Lambda^2 = \Delta^2/\Lambda^2$. We used $j = 2$ and other parameters described in the text. This is the ratio of Fig. 7(d) to Fig. 6(a).

(the t dependence) may also be affected since the η^2 term with a steeper t dependence is involved. Toward higher Δ^2, however, the ratio of the coefficient of the η^2 term to that of the η^0 term changes as in a numerical computation shown in Fig. 8. Since the η^2-term coefficient becomes not more than 10 times the η^0 term for $5\Lambda^2 \lesssim (\Delta^2 = -t)$ at $j = 2$ in this numerical computation, the η^0 term alone will become a good enough approximation in this range of t, even for the moderately small $|\eta| \lesssim x \approx \mathcal{O}(10^{-1})$; for an even smaller x, the η^2 term can be negligible for a broader range of $t = -\Lambda^2$. We have nothing more to say about the η^4 term and higher at this moment, or whether this moderately large value ≈ 700 is an artifact of a specific implementation of confining effects we adopted for the numerical presentation in this section. If this relatively large coefficient of the η^2 term (and also higher-order terms) turns out to be a robust consequence of holographic models, that may be regarded as an unexpected lesson from holography to phenomenology.

ACKNOWLEDGMENTS

We thank Wen Yin, with whom we worked at an earlier stage of this project, for the discussion and Simeon Hellerman and Teruhiko Kawano for their useful comments. This work is supported in part by the JSPS Research Fellowships for Young Scientists (R. N.), the WPI Initiative, and a Grant-in-Aid for Scientific Research on Innovative Areas 2303 from MEXT, Japan (R. N. and T. W.).

APPENDIX A: MORE ON THE MODE DECOMPOSITION ON AdS_5

For convenience, let us copy here the eigenmode equation (65) for a totally symmetric rank-j tensor field on AdS_5; the equation consists of the following equations labeled by $k = 0, \ldots, j$:

$$\begin{aligned}&((R^2\Delta_j) - [(2k+1)j - 2k^2 + 3k])A_{z^k\mu_1\cdots\mu_{j-k}} \\ &\quad + 2zk\partial^{\hat\rho}A_{z^{k-1}\rho\mu_1\cdots\mu_{j-k}} + k(k-1)A^{\hat\rho}_{z^{k-2}\rho\mu_1\cdots\mu_{j-k}} \\ &\quad - 2z(D[A_{z^{k+1}\ldots}])_{\mu_1\cdots\mu_{j-k}} + (E[A_{z^{k+2}\ldots}])_{\mu_1\cdots\mu_{j-k}} \\ &= -\mathcal{E}A_{z^k\mu_1\cdots\mu_{j-k}}. \end{aligned} \tag{A1}$$

1. Eigenvalues and eigenmodes for $\Delta^\mu = 0$

a. Block diagonal decomposition

In the main text, we considered a decomposition of the rank-j totally symmetric tensor field with $(-i\partial_\mu) = \Delta_\mu = 0$ in the form of

$$A_{z^k\mu_1\cdots\mu_{j-k}}(z;\Delta^\mu = 0) = \sum_{N=0}^{[(j-k)/2]} (E^N[a^{(k,N)}])_{\mu_1\cdots\mu_{j-k}},$$

where $a^{(k,N)}$'s are z-dependent rank-$(j-k-2N)$ totally symmetric tensor fields of SO(3, 1), satisfying the 4D-traceless condition (76). This is indeed a decomposition, in that all of the degrees of freedom in $A_{z^k\mu_1\cdots\mu_{j-k}}(z;\Delta^\mu = 0)$ are described by $a^{(k,N)}(z)_{\mu_1\cdots\mu_{j-k-2N}}$, with $0 \le N \le [(j-k)/2]$ without redundancy. To see this, one needs only to note that there is a relation[33] that, for a totally symmetric 4D-traceless rank-r SO(3, 1) tensor a,

$$\eta^{\hat\rho\hat\sigma}E^N[a]_{\rho\sigma\mu_1\cdots\mu_{r+2N-2}} = 4N(r+N+1)E^{N-1}[a]_{\mu_1\cdots\mu_{r+2N-2}}. \tag{A2}$$

Using this relation, $a^{(k,N)}_{\mu_1\cdots\mu_{j-k-2N}}$ can be retrieved from $A_{z^k\mu_1\cdots\mu_{j-k}}$, progressing from ones with a larger N to ones with a smaller N.

Let us now see that the eigenmode equation (65), (69), (A1) can be made block diagonal by using this decomposition. The eigenmode equation (A1) with the label k for $\Delta^\mu = 0$ can be rewritten by using this relation (A2) as follows:

$$\begin{aligned}&\sum_N [(R^2\Delta_j - [(2k+1)j - 2k^2 + 3k] + \mathcal{E})E^N[a^{(k,N)}] \\ &\quad + k(k-1)[4(N+1)(j-k-N+2)]E^N[a^{(k-2,N+1)}] \\ &\quad + E^N[a^{(k+2,N-1)}]] = 0. \end{aligned}$$

[33]This relation can be verified recursively in N.

Although this equation has to hold only after the summation in N, it actually has to be satisfied separately for different N's. To see this, let us first multiply $\eta^{\hat\rho\hat\sigma}$ for $[(j-k)/2]$ times and contract indices just like in (A2); we obtain an equation that involves only $a^{(k,[(j-k)/2])}$, $a^{(k-2,[(j-k)/2]+1)}$, and $a^{(k+2,[(j-k)/2]-1)}$. Next, multiply $\eta^{\hat\rho\hat\sigma}$ for $[(j-k)/2]-1$ times to obtain another equation involving $a^{(k,[(j-k)/2]-1)}$, $a^{(k-2,[(j-k)/2])}$, and $a^{(k+2,[(j-k)/2]-2)}$. In this way, we obtain

$$\begin{aligned}&(R^2\Delta_j - [(2k+1)j - 2k^2 + 3k] + \mathcal{E})a^{(k,N)} \\ &\quad + k(k-1)[4(N+1)(j-k-N+2)]a^{(k-2,N+1)} \\ &\quad + a^{(k+2,N-1)} = 0 \quad (\text{for } {}^\forall k, N). \end{aligned} \tag{A3}$$

Fields $a^{(k,N)}$'s with the same $k+2N = n$ form a system of coupled equations, but those with different $n = k+2N$ do not mix. Thus, the eigenmode equation for $\Delta^\mu = 0$ is decomposed into sectors labeled by n. The nth sector consists of z-dependent fields that are all in the $(j-n) = (j-k-2N)$ totally symmetric tensor of SO(3, 1).

b. Classification of eigenmodes for $\Delta^\mu = 0$

Let us now study the eigenmode equations in more detail for the separate diagonal blocks we have seen. Simultaneous treatment is possible for all of the nth sectors with an even n and for all of the sectors with an odd n.

Let us first look at the nth sector of the eigenmode problem for an $n = 2\bar n \le j$. In the eigenmode equation of $\Delta^\mu = 0$, we can assume[34] the same z dependence for all of the fields in this diagonal block:

$$a^{(k,N)}(z)_{\mu_1\cdots\mu_{j-n}} = \bar a^{(k,N)}_{\mu_1\cdots\mu_{j-n}} z^{2-j-i\nu}, \qquad k+2N = n, \tag{A4}$$

where $\bar a^{(k,N)}$'s are (x,z)-independent 4D-traceless rank-$(j-n)$ tensors of SO(3, 1). The eigenmode equations with the label $(k,N) = (2\bar k, \bar n - \bar k)$, with $\bar k = 0, \ldots, \bar n$, are relevant to the $n = 2\bar n$ sector and are now written in a matrix form:

$$\sum_{\bar k'=0}^{\bar n} \mathcal{D}_{2\bar k,2\bar k'}\bar a^{(2\bar k',\bar n-\bar k')} = ((4+\nu^2) - \mathcal{E})\bar a^{(2\bar k,\bar n-\bar k)}, \tag{A5}$$

where

(i) diagonal $(k,k') = (2\bar k, 2\bar k)$ entry: $\mathcal{D}_{2\bar k,2\bar k} = -[(2k+1)j - 2k^2 + 3k]$,
(ii) diagonal$^+$; $(k,k') = (2\bar k, 2\bar k+2)$ entry: $\mathcal{D}_{2\bar k,2\bar k+2} = 1$,
(iii) diagonal$^-$; $(k,k') = (2\bar k, 2\bar k - 2)$ entry: $\mathcal{D}_{2\bar k,2\bar k-2} = k(k-1) \times 4(\bar n - \bar k + 1)(j - \bar n - \bar k + 2)$.

[34]This is because, in the absence of $z^2\partial^2$ term, the operator Δ_j becomes a constant multiplication when it acts on a simple power of z. Upon $z^{2-j-i\nu}$, for example, $R^2\Delta_j$ returns $-(4+\nu^2)$.

There must be $(\overline{n}+1)$ independent eigenmodes in this $(\overline{n}+1)\times(\overline{n}+1)$ matrix equation. Let $\mathcal{E}_{n,l}$ denote the collection of eigenvalues in this $n=2\overline{n}$th diagonal block, and $l=0,\ldots,\overline{n}=n/2$ label distinct eigenmodes. The corresponding eigenmode wave function for the $(n=2\overline{n},l)$ mode is in the form of

$$a^{(k,N)}(z;\Delta^\mu=0)=a^{(2\overline{k},\overline{n}-\overline{k})}=c_{2\overline{k},l,n}\epsilon^{(n,l)}z^{2-j-i\nu}, \tag{A6}$$

where $\epsilon^{(n,l)}$ is an (x,z)-independent 4D-traceless totally symmetric rank-$(j-n)=(j-2\overline{n})$ tensor of SO(3, 1), and $c_{2\overline{k},l,n}$ are (x,z)-independent constants determined as the eigenvector corresponding to the eigenvalue $\mathcal{E}_{n,l}$.

Similarly, in the $n=2\overline{n}+1\le j$th sector of the eigenmode problem, with an odd n, we can assume a simple power law for all of the component fields involved in this sector;

$$a^{(k,N)}(z)_{\mu_1\cdots\mu_{j-n}}=\overline{a}^{(k,N)}_{\mu_1\cdots\mu_{j-n}}z^{2-j-i\nu},\qquad k+2N=n, \tag{A7}$$

where $\overline{a}^{(k,N)}$ are (x,z)-independent 4D-traceless totally symmetric tensors of SO(3, 1). The eigenmode equation with the label $(k,N)=(2\overline{k}+1,\overline{n}-\overline{k})$, with $\overline{k}=0,\ldots,\overline{n}$, are relevant to this sector, and in the matrix form, the eigenmode equation now looks like

$$\sum_{\overline{k}'=0}^{\overline{n}}\mathcal{D}_{2\overline{k}+1,2\overline{k}'+1}\overline{a}^{(2\overline{k}'+1,\overline{n}-\overline{k})}=((4+\nu^2)-\mathcal{E})\overline{a}^{(2\overline{k}+1,\overline{n}-\overline{k})}, \tag{A8}$$

where

(i) diagonal $(k,k')=(2\overline{k}+1,2\overline{k}+1)$ entry: $\mathcal{D}_{2\overline{k}+1,2\overline{k}+1}=-[(2k+1)j+(-2k^2+3k)]$,
(ii) diagonal$^+$ $(k,k')=(2\overline{k}+1,2\overline{k}+3)$ entry: $\mathcal{D}_{2\overline{k}+1,2\overline{k}+3}=1$,
(iii) diagonal$^-$ $(k,k')=(2\overline{k}+1,2\overline{k}-1)$ entry: $\mathcal{D}_{2\overline{k}+1,2\overline{k}-1}=k(k-1)\times4(\overline{n}-\overline{k}+1)(j-\overline{n}-\overline{k}+1)$.

From here, $\overline{n}+1$ independent modes arise; their eigenvalues are denoted by $\mathcal{E}_{n,l}$, and $l=\{0,\ldots,\overline{n}\}$ is the label distinguishing different modes. The eigenmode labeled by $(n=2\overline{n}+1,l)$ has a wave function

$$a^{(k,N)}(z;\Delta^\mu=0)=a^{(2\overline{k}+1,\overline{n}-\overline{k})}=c_{2\overline{k}+1,l,n}\epsilon^{(n,l)}z^{2-j-i\nu}, \tag{A9}$$

where $\epsilon^{(n,l)}$ is an (x,z)-independent 4D-traceless rank-$(j-n)$ totally symmetric tensor of SO(3, 1), and $c_{2\overline{k}+1,l,n}$ is the eigenvector for the (n,l) eigenmode determined in the matrix equation above.

c. Explicit examples

Let us take a moment to see how the general theory above works in practice.

The easiest of all is the $n=0$ sector, which contains only one rank-j 4D-traceless field, $a^{(0,0)}$. The eigenmode equation is

$$\left[\Delta_j-\frac{[(2k+1)j-2k^2+3k]_{k=0}}{R^2}\right]a^{(0,0)}=\left[\Delta_j-\frac{j}{R^2}\right]a^{(0,0)}=-\frac{\mathcal{E}_{0,0}}{R^2}a^{(0,0)}. \tag{A10}$$

The eigenmode wave function has the form

$$a^{(0,0)}(z)_{\mu_1\cdots\mu_j}=\epsilon^{(0,0)}_{\mu_1\cdots\mu_j}z^{2-j-i\nu}, \tag{A11}$$

and the eigenvalue $\mathcal{E}_{n,l}$ is

$$\mathcal{E}_{0,0}=(j+4+\nu^2). \tag{A12}$$

Also to the $n=1$ sector, only one rank-$(j-1)$ 4D-traceless tensor field contributes. That is $a^{(1,0)}$. The eigenmode equation becomes

$$[R^2\Delta_j-[(2k+1)j-2k^2+3k]|_{k=1}]a^{(1,0)}=[R^2\Delta_j-(3j+1)]a^{(1,0)}=-\mathcal{E}_{1,0}a^{(1,0)}. \tag{A13}$$

The solution is

$$a^{(1,0)}(z)_{\mu_1\cdots\mu_{j-1}}=\epsilon^{(1,0)}_{\mu_1\cdots\mu_{j-1}}z^{2-j-i\nu},\qquad \mathcal{E}_{1,0}=(3j+5+\nu^2). \tag{A14}$$

In the $n=2$ sector, two rank-$(j-2)$ 4D-traceless fields are involved. They are $a^{(0,1)}$ and $a^{(2,0)}$. After introducing the z dependence $\propto z^{2-j-i\nu}$, the eigenmode equation (A5) in the $n=2$ sector becomes

$$\begin{bmatrix}-j & 1\\ 8j & -(5j-2)\end{bmatrix}\begin{pmatrix}\overline{a}^{(0,1)}\\ \overline{a}^{(2,0)}\end{pmatrix}=((4+\nu^2)-\mathcal{E})\begin{pmatrix}\overline{a}^{(0,1)}\\ \overline{a}^{(2,0)}\end{pmatrix}. \tag{A15}$$

One of the two eigenmodes is

$$\mathcal{E}_{2,0}=(4+5j+\nu^2),\ \begin{pmatrix}a^{(0,1)}(z)_{\mu_1\cdots\mu_{j-2}}\\ a^{(2,0)}(z)_{\mu_1\cdots\mu_{j-2}}\end{pmatrix}=\begin{pmatrix}1\\ -4j\end{pmatrix}\epsilon^{(2,0)}_{\mu_1\cdots\mu_{j-2}}z^{2-j-i\nu}, \tag{A16}$$

and the other is

$$\mathcal{E}_{2,1} = (2 + j + \nu^2), \begin{pmatrix} a^{(0,1)}(z)_{\mu_1\cdots\mu_{j-2}} \\ a^{(2,0)}(z)_{\mu_1\cdots\mu_{j-2}} \end{pmatrix} = \begin{pmatrix} 1 \\ 2 \end{pmatrix} \epsilon^{(2,1)}_{\mu_1\cdots\mu_{j-2}} z^{2-j-i\nu}. \quad \text{(A17)}$$

In the $n = 3$ sector, two rank-$(j-3)$ 4D-traceless tensor fields are involved: $a^{(1,1)}$ and $a^{(3,0)}$. The eigenmode equations (A8) become

$$\begin{bmatrix} -(3j+1) & 1 \\ 24(j-1) & -(7j-9) \end{bmatrix} \begin{pmatrix} \overline{a}^{(1,1)} \\ \overline{a}^{(3,0)} \end{pmatrix} = ((4+\nu^2) - \mathcal{E}) \begin{pmatrix} \overline{a}^{(1,1)} \\ \overline{a}^{(3,0)} \end{pmatrix}. \quad \text{(A18)}$$

So, one of the two eigenmodes is

$$\mathcal{E}_{3,0} = (7j + 1 + \nu^2), \begin{pmatrix} a^{(1,1)}(z)_{\mu_1\cdots\mu_{j-3}} \\ a^{(3,0)}(z)_{\mu_1\cdots\mu_{j-3}} \end{pmatrix} = \begin{pmatrix} 1 \\ -4(j-1) \end{pmatrix} \epsilon^{(3,0)}_{\mu_1\cdots\mu_{j-3}} z^{2-j-i\nu}, \quad \text{(A19)}$$

and the other one is

$$\mathcal{E}_{3,1} = (3j - 1 + \nu^2), \begin{pmatrix} a^{(1,1)}(z)_{\mu_1\cdots\mu_{j-3}} \\ a^{(3,0)}(z)_{\mu_1\cdots\mu_{j-3}} \end{pmatrix} = \begin{pmatrix} 1 \\ 6 \end{pmatrix} \epsilon^{(3,1)}_{\mu_1\cdots\mu_{j-3}} z^{2-j-i\nu}. \quad \text{(A20)}$$

Finally, in the $n = 4$ sector, the eigenmode equation (A5) is given by

$$\begin{bmatrix} -j & 1 & 0 \\ 16(j-1) & -(5j-2) & 1 \\ 0 & 48(j-2) & -(9j-20) \end{bmatrix} \begin{pmatrix} \overline{a}^{(0,2)} \\ \overline{a}^{(2,1)} \\ \overline{a}^{(4,0)} \end{pmatrix} = ((4+\nu^2) - \mathcal{E}) \begin{pmatrix} \overline{a}^{(0,2)} \\ \overline{a}^{(2,1)} \\ \overline{a}^{(4,0)} \end{pmatrix}. \quad \text{(A21)}$$

There are three solutions. First,

$$\mathcal{E}_{4,0} = (9j - 4 + \nu^2), \quad \text{(A22)}$$

$$(a^{(0,2)}, a^{(2,1)}, a^{(4,0)}) = (1, -8(j-1), 32(j-1)(j-2))\epsilon^{(4,0)} z^{2-j-i\nu}, \quad \text{(A23)}$$

second,

$$\mathcal{E}_{4,1} = (5j - 6 + \nu^2), \quad \text{(A24)}$$

$$(a^{(0,2)}, a^{(2,1)}, a^{(4,0)}) = (1, -(4j-10), -48(j-2))\epsilon^{(4,1)} z^{2-j-i\nu}, \quad \text{(A25)}$$

and, finally,

$$\mathcal{E}_{4,2} = (j + \nu^2), \quad \text{(A26)}$$

$$(a^{(0,2)}, a^{(2,1)}, a^{(4,0)}) = (1, 4, 24)\epsilon^{(4,2)} z^{2-j-i\nu}. \quad \text{(A27)}$$

An empirical relation is observed in the j dependence of the eigenvalues we have worked out so far. The eigenvalues in the nth sector are in the form of $\mathcal{E}_{n,l} = \nu^2 + (2n + 1 - 4l)j + \mathcal{O}(1)$ for $0 \le l \le [n/2]$.

d. 5D-traceless modes: the $l = 0$ modes

Although the precise expressions for the eigenvalues $\mathcal{E}_{n,l}$ and the eigenvectors $c_{k,l,n}$ are not given for all of the eigenmodes, there is a class of eigenmodes whose eigenvalues and eigenvectors (wave functions) are fully understood.

As we discussed in Sec. V B 3, it is possible to require both that a field is an eigenmode and that it satisfies the 5D-traceless condition (95) at the same time. In the $n = (k + 2N)$th sector, the 5D-traceless condition becomes

$$\begin{aligned} 0 &= (E^N[a^{(k,N)}])^{\hat{\rho}}_{\rho\mu_3\cdots\mu_{j-n}} + (E^{N-1}[a^{(k+2,N-1)}])_{\mu_3\cdots\mu_{j-n}}, \\ &= E^{N-1}[4N(j-n+N+1)a^{(k,N)} + a^{(k+2,N-1)}] \\ &\quad \times \begin{cases} k = 0, 2, \ldots, 2(\overline{n}-1) & (\text{even } n), \\ k = 1, 3, \ldots, 2\overline{n}-1 & (\text{odd } n). \end{cases} \end{aligned} \quad \text{(A28)}$$

Thus, the 5D-traceless condition uniquely determines one eigenmode in each one of the nth sectors.

$$\mathcal{E}_{n,0} = (2n+1)j + 2n - n^2 + 4 + \nu^2 \quad \text{(A29)}$$

and

$$c_{2\overline{k},0,2\overline{n}} = (-)^{\overline{k}} 4^{\overline{k}} \frac{\overline{n}!}{(\overline{n}-\overline{k})!} \frac{(j-\overline{n}+1)!}{(j-\overline{n}-\overline{k}+1)!}, \quad c_{2\overline{k}+1,0,2\overline{n}+1} = (-)^{\overline{k}} 4^{\overline{k}} \frac{\overline{n}!}{(\overline{n}-\overline{k})!} \frac{(j-\overline{n})!}{(j-\overline{n}-\overline{k})!}. \quad \text{(A30)}$$

2. MODE DECOMPOSITION FOR NONZERO Δ_μ

a. Diagonal block decomposition for the $\Delta^\mu \neq 0$ case

Let us now turn our attention to the eigenmode equations (65), (69) with $\Delta^\mu \neq 0$. Because of the second and fourth terms in (69), the eigenmode problem becomes much more complicated. We begin by finding a diagonal block decomposition suitable for the case with $\Delta^\mu \neq 0$.

In the main text, we introduced a decomposition of a totally symmetric rank-j tensor field $A_{m_1\cdots m_j}$ of SO(4, 1) into a collection of totally symmetric 4D-traceless 4D-transverse tensor fields of SO(3, 1). Instead of (75), a new decomposition is given by (85), (A31):

$$A_{z^k\mu_1\cdots\mu_{j-k}}(z;\Delta^\mu)=\sum_{s=0}^{j-k}\sum_{N=0}^{[s/2]}(\tilde{E}^N D^{s-2N}[a^{(k,s,N)}])_{\mu_1\cdots\mu_{j-k}}, \tag{A31}$$

where $a^{(k,s,N)}$ are totally symmetric 4D-traceless 4D-transverse rank-$(j-k-s)$ tensor fields of SO(3, 1). An operation $a\mapsto\tilde{E}[a]$ on a totally symmetric SO(3, 1) tensor a is given by (86).

In order to see that the parametrization of $A_{z^k\mu_1\cdots\mu_{j-k}}$ by $(a^{(k,s,N)})_{\mu_1\cdots\mu_{j-k-s}}$'s above is indeed a decomposition, one needs to see that $a^{(k,s,N)}$'s can be retrieved from $A_{z^k\mu_1\cdots\mu_{j-k}}$ so that the degrees of freedom $a^{(k,s,N)}$ are independent. For this purpose, it is convenient to derive some relations analogous to (A2). First of all, note that $E[D[a]]=D[E[a]]$ and[35] $\tilde{E}[D[a]]=D[\tilde{E}[a]]$ for a totally symmetric SO(3, 1) tensor a. If the rank-r tensor a is also 4D transverse and 4D traceless, one can then derive the following relations:

$$\partial^{\hat\rho}(E^tD^{s-2t}[a])_{\rho\mu_2\cdots\mu_{r+s}}=-\Delta^2(s-2t)E^tD^{s-2t-1}[a]+(2t)E^{t-1}D^{s-2t+1}[a], \tag{A33}$$

$$\eta^{\hat\rho\hat\sigma}(E^tD^{s-2t}[a])_{\rho\sigma\mu_3\cdots\mu_{r+s}}=-\Delta^2(s-2t)(s-2t-1)E^tD^{s-2t-2}[a]+4t(r+s-t+1)E^{t-1}D^{s-2t}[a], \tag{A34}$$

$$\partial^{\hat\rho}(\tilde{E}^ND^{s-2N}[a])_{\rho\mu_2\cdots\mu_{r+s}}=-(s-2N)\Delta^2\tilde{E}^ND^{s-2N-1}[a], \tag{A35}$$

$$\left(\eta^{\hat\rho\hat\sigma}-\frac{\partial^{\hat\rho}\partial^{\hat\sigma}}{\partial^2}\right)(\tilde{E}^ND^{s-2N}[a])_{\rho\sigma\mu_3\cdots\mu_{r+s}}=4N(r+N+1/2)\tilde{E}^{N-1}D^{s-2N}[a]. \tag{A36}$$

With the relations above, it is now possible to compute

$$\left(\eta^{\hat\mu_1\hat\mu_2}-\frac{\partial^{\hat\mu_1}\partial^{\hat\mu_2}}{\partial^2}\right)\cdots\left(\eta^{\hat\mu_{2p-1}\hat\mu_{2p}}-\frac{\partial^{\hat\mu_{2p-1}}\partial^{\hat\mu_{2p}}}{\partial^2}\right)\frac{\partial^{\hat\mu_{2p+1}}}{\partial^2}\cdots\frac{\partial^{\hat\mu_{2p+q}}}{\partial^2}(\tilde{E}^ND^{s-2N}[a])_{\mu_1\cdots\mu_{r+s}}=\begin{cases}\frac{b^{(r)}_{s-2p-q,N-p}}{b^{(r)}_{s,N}}(\tilde{E}^{N-p}D^{s-2N-q}[a])_{\mu_{2p+q+1}\cdots\mu_{r+s}} & \text{if } p\le N \text{ and } q\le s-2N,\\ 0 & \text{otherwise,}\end{cases} \tag{A37}$$

where we assume that a is a totally symmetric 4D-traceless 4D-transverse rank-r tensor of SO(3, 1). In the last line,

$$b^{(r)}_{s,N}:=\frac{1}{4^N N!(s-2N)!}\frac{\Gamma(r+3/2)}{\Gamma(r+N+3/2)}. \tag{A38}$$

It is now clear how to retrieve $a^{(k,s,N)}$ from the $A_{z^k\mu_1\cdots\mu_{j-k}}$ given by (85), (A31). First, one has to multiply $\eta^{\hat\rho\hat\sigma}-\partial^{\hat\rho}\partial^{\hat\sigma}/\partial^2$ and $\partial^{\hat\sigma}/\partial^2$ by $A_{z^k\mu_1\cdots\mu_{j-k}}$ as many times as possible in order to obtain $a^{(k,s,N)}$ with a larger N and $(s-2N)$. Then $a^{(k,s,N)}$'s with smaller N or $(s-2N)$ can be determined by multiplying $\eta^{\hat\rho\hat\sigma}-\partial^{\hat\rho}\partial^{\hat\sigma}/\partial^2$ and $\partial^{\hat\sigma}/\partial^2$ fewer times.

Let us now return to the eigenmode equation for the cases with $\Delta^\mu\neq 0$. Following precisely the same argument as in Sec. A. 1, one can see that the eigenmode equation can be separated into the following independent equations labeled by k, s, and N:

$$\begin{aligned}&[R^2\Delta_j-[(2k+1)j-2k^2+3k]+\mathcal{E}]a^{(k,s,N)}+2zk(s+1-2N)(\partial^2)a^{(k-1,s+1,N)}\\&+k(k-1)(s+2-2N)(s+1-2N)(\partial^2)a^{(k-2,s+2,N)}+4k(k-1)(N+1)(j-m+N+3/2)a^{(k-2,s+2,N+1)}\\&-2za^{(k+1,s-1,N)}+a^{(k+2,s-2,N-1)}+(\partial^2)^{-1}a^{(k+2,s-2,N)}=0\quad\text{for }{}^\forall k,s,N.\end{aligned} \tag{A39}$$

The relations (A33), (A34) were used to evaluate the second–fourth terms of (A1). One can see that $a^{(k,s,N)}$'s with a common value of $m:=k+s$ form coupled eigenmode equations, but those with different m's do not. Thus, $a^{(k,s,N)}(z;\Delta^\mu)$'s with $k+s=m$ form the mth subspace of $A_{m_1\cdots m_j}(z;\Delta^\mu)$, and the eigenmode equation becomes block diagonal in the decomposition into the subspaces labeled by $m=0,\ldots,j$.

[35]
$$E^tD^{s-2t}[a]=\sum\eta_{\mu_{p_1}\mu_{p_2}}\cdots\eta_{\mu_{p_{2t-1}}\mu_{p_{2t}}}\partial_{\mu_{p_{2t+1}}}\cdots\partial_{\mu_{p_s}}[a]_{\mu_1\ldots\hat{\cdot}\ldots\mu_{r+s}}, \tag{A32}$$

where the sum is taken over all possible ordered choices of $p_1,p_2,\ldots,p_s\in\{1,\ldots,j\}$ such that $p_i\neq p_j$ for $i\neq j$.

The eigenmode equation on the mth subspace is given by the equation above, with $0 \le k = (m-s) \le m$ and $0 \le N \le [s/2]$. Thus, the total number of equations is

$$\sum_{s=0}^{m} ([s/2]+1), \tag{A40}$$

and the same number of eigenvalues should be obtained from the mth sector.

b. Examples

The sector $m = 0$.—There is only one field $a^{(0,0,0)}$ in this sector, and the eigenmode equation is

$$\left[\Delta_j - \frac{j}{R^2}\right] a^{(0,0,0)}(z;\Delta^\mu) = -\frac{\mathcal{E}}{R^2} a^{(0,0,0)}(z;\Delta^\mu). \tag{A41}$$

Assuming a power series expansion for the solution to this equation, beginning with some power $z^{2-j-i\nu}$, the eigenvalue is determined as a function of $(i\nu)$:

$$\mathcal{E}_{0,0} = (j+4+\nu^2),$$

and the wave function can be chosen as

$$a^{(0,0,0)}(z;\Delta^\mu)_{\mu_1\cdots\mu_j} = \epsilon^{(0,0,0)}_{\mu_1\cdots\mu_j} \Psi^{(j)}_{i\nu}(-\Delta^2, z), \tag{A42}$$

$$\Psi^{(j)}_{i\nu}(\Delta^2, z) := \frac{2}{\pi}\sqrt{\frac{\nu \sinh(\pi\nu)}{2R}} e^{(j-2)A} K_{i\nu}(\Delta z). \tag{A43}$$

The sector $m = 1$.—The eigenmode equation in this sector becomes

$$\begin{bmatrix} R^2\Delta_j - j & -2z \\ -2z\Delta^2 & R^2\Delta_j - (3j+1) \end{bmatrix} \begin{pmatrix} a^{(0,1,0)} \\ a^{(1,0,0)} \end{pmatrix} = -\mathcal{E} \begin{pmatrix} a^{(0,1,0)} \\ a^{(1,0,0)} \end{pmatrix}. \tag{A44}$$

Assuming the power series expansion in z, beginning with $z^{2-j-i\nu}$ terms, we obtain two eigenvalues depending on $i\nu$. They are given by evaluating $R^2\Delta_j - j$ and $R^2\Delta_j - (3j+1)$ on $z^{2-j-i\nu}$:

$$\mathcal{E}_{0,0} = (j+4+\nu^2) \quad \text{and} \quad \mathcal{E}_{1,0} = (3j+5+\nu^2). \tag{A45}$$

The sector $m = 2$.—The eigenmode equation becomes

$$\left((R^2\Delta_j + \mathcal{E})\mathbf{1}_{4\times 4} + \begin{bmatrix} -j & & -2z & 1/\partial^2 \\ & -j & & 1 \\ 4z\partial^2 & & -(3j+1) & -2z \\ 4\partial^2 & 8j-4 & 4z\partial^2 & -(5j-2) \end{bmatrix} \right) \begin{pmatrix} a^{(0,2,0)} \\ a^{(0,2,1)} \\ a^{(1,1,0)} \\ a^{(2,0,0)} \end{pmatrix} = 0. \tag{A46}$$

The indicial equation relating the exponent $(2-j-i\nu)$ at $z=0$ and the eigenvalues split into two parts; three eigenvalues of this matrix,

$$\begin{pmatrix} -j & & 1 \\ & -j & 1 \\ 4 & (8j-4) & -(5j-2) \end{pmatrix}, \tag{A47}$$

determine $-\mathcal{E} - (4+\nu^2)$ for the three eigenmodes, and $-(\mathcal{E} - (4+\nu^2)) = -(3j+1)$ for the last eigenmode. Therefore, the four eigenvalues in the $m=2$ sector are

$$\mathcal{E}_{0,0} = (j+4+\nu^2), \qquad \mathcal{E}_{1,0} = (3j+5+\nu^2),$$
$$\mathcal{E}_{2,0} = (5j+4+\nu^2), \qquad \mathcal{E}_{2,1} = (j+2+\nu^2). \tag{A48}$$

In all of the examples above, the mth sector consists of eigenmodes with eigenvalues $\mathcal{E}_{n,l}$ for $0 \le n \le m$, $0 \le l \le [n/2]$. The number of eigenmodes is, of course, the same as in (A40).

3. Wave functions of 5D-traceless 5D-transverse modes

As we discussed toward the end of Sec. V B, it is possible to require for a rank-j totally symmetric tensor field configuration $A_{m_1\cdots m_j}(z;\Delta^\mu)$ to be an eigenmode and to be 5D traceless and 5D transverse (95), (96) at the same time. We will see in the following that these two extra conditions (95), (96) leave precisely one eigenmode in each one of the block diagonal sectors labeled by $m = 0, \ldots, j$. We will further determine the wave function profile of such eigenmodes.

Let us first rewrite the 5D-traceless condition (95) in a more convenient form:

$$\eta^{\hat\rho\hat\sigma} A_{z^{k-2}\rho\sigma\mu_1\cdots\mu_{j-k}} + A_{z^k\mu_1\cdots\mu_{j-k}} = 0, \tag{A49}$$

which, in the mth sector, means

$$a^{(k,s,N)} = (s+2-2N)(s+1-2N)\Delta^2 a^{(k-2,s+2,N)} + 4(N+1)(j-m+N+3/2) a^{(k-2,s+2,N+1)} \tag{A50}$$

for $N = 0, \ldots, [s/2]$; $k + s = m$ is understood. Under the 5D-traceless condition, the 5D-transverse condition

$$(k-1)\eta^{\hat{\rho}\hat{\sigma}} A_{z^{k-2}\rho\sigma\mu_1\cdots\mu_{j-k}} + z\partial^{\hat{\rho}} A_{z^{k-1}\rho\mu_1\cdots\mu_{j-k}} + (z\partial_z + (k-4)) A_{z^k\mu_1\cdots\mu_{j-k}} = 0 \tag{A51}$$

becomes

$$z\partial^{\hat{\rho}} A_{z^{k-1}\rho\mu_1\cdots\mu_{j-k}} + (z\partial_z - 3) A_{z^k\mu_1\cdots\mu_{j-k}} = 0. \tag{A52}$$

In the mth sector ($k + s = m$), therefore,

$$(s + 1 - 2N)\Delta^2 a^{(k-1,s+1,N)} = z^3\partial_z z^{-3} a^{(k,s,N)} \tag{A53}$$

for $N = 0, \ldots, [s/2]$. Hereafter, we use a simplified notation $\mathcal{D} \coloneqq z^3\partial_z z^{-3}$. One can see that all of the $a^{(k,s,N)}$'s with $k + s = m$ and $N \le [s/2]$ can be determined from $a^{(m,0,0)}$ by using the relations (A50), (A53). This observation already implies that there can be at most one eigenmode in a given mth sector that satisfies both the 5D-traceless and the 5D-transverse conditions.

For now, let us assume that there is one, and proceed to determine the wave function. The wave function—z dependence—of $a^{(m.0.0)}(z;\Delta^\mu)$ can be determined from the eigenmode equation (A39), with $k = m$, $s = N = 0$. Using (A50) and (A53), we can rewrite the equation as

$$[R^2\Delta_j - \{(2m+1)j - m^2 + 2m\} - 2m(z\partial_z - 3) + \mathcal{E}] \times a^{(m,0,0)}(z;\Delta) = 0. \tag{A54}$$

For this equation,

$$(a^{(m,0,0)}(z;\Delta))_{\mu_1\cdots\mu_{j-m}} = \epsilon_{\mu_1\cdots\mu_{j-m}} \left(\frac{z}{R}\right)^{2-j} (\Delta z)^m K_{i\nu}(\Delta z), \qquad \mathcal{E} = (j + 4 + \nu^2), \tag{A55}$$

is a solution, where $\epsilon_{\mu_1\cdots\mu_{j-m}}$ is a z-independent 4D-traceless 4D-transverse totally symmetric rank-$(j-m)$ tensor of SO(3, 1). From the value of the eigenvalue, it turns out that the 5D-traceless 5D-transverse mode in the mth sector corresponds to the $(n, l, m) = (0, 0, m)$ mode. The z dependence we determined above implies that

$$\Psi^{(j);0,0}_{i\nu;0,0,m}(-\Delta^2, z) \propto (\Delta z)^m \Psi^{(j);0,0}_{i\nu;0,0,0}(-\Delta^2, z). \tag{A56}$$

This result corresponds to the $(s, N) = (0, 0)$ case of (97). The normalization constant $N_{j,m}$ is determined later in this section.

Let us now proceed to determine other $\Psi^{(j);s,N}_{i\nu;0,0,m}$, not just for $(s, N) = (0, 0)$. Using the 5D-transverse condition, (A53), $a^{(m-1,1,0)}(z;\Delta)$ can be determined from $a^{(m,0,0)}(z;\Delta)$.

$$a^{(m-1,1,0)} = \frac{\mathcal{D}}{\Delta^2} a^{(m,0,0)}, \qquad \Psi^{(j);1,0}_{i\nu;0,0,m} = \frac{\mathcal{D}}{\Delta} \Psi^{(j);0,0}_{i\nu;0,0,m}. \tag{A57}$$

In order to determine the $s = 2$ components $a^{(m-2,2,N)}$ ($N = 0, 1$) of the $(n, l) = (0, 0)$ mode in the mth sector, one has to use both the 5D-transverse condition and the 5D-traceless condition:

$$2\Delta^2 a^{(m-2,2,0)} = \mathcal{D} a^{(m-1,1,0)}, \tag{A58}$$

$$2\Delta^2 a^{(m-2,2,0)} - 4(j - m + 3/2) a^{(m-2,2,1)} = a^{(m,0,0)}. \tag{A59}$$

Therefore,

$$a^{(m-2,2,0)} = \frac{1}{2\Delta^2}\left(\frac{\mathcal{D}}{\Delta}\right)^2 a^{(m,0,0)}, \qquad a^{(m-2,2,1)} = \frac{1}{4(j-m+3/2)}\left\{\left(\frac{\mathcal{D}}{\Delta}\right)^2 - 1\right\} a^{(m,0,0)}. \tag{A60}$$

After factoring out the normalization factor $(b^{(j-m)}_{s,N}/\Delta^{s-2N})$ and the common 4D-tensor $\epsilon^{(0,0,m)}$, we obtain

$$\Psi^{(j);2,0}_{i\nu;0,0,m} = \left(\frac{\mathcal{D}}{\Delta}\right)^2 \Psi^{(j);0,0}_{i\nu;0,0,m}, \qquad \Psi^{(j);2,1}_{i\nu;0,0,m} = \left\{\left(\frac{\mathcal{D}}{\Delta}\right)^2 - 1\right\} \Psi^{(j);0,0}_{i\nu;0,0,m}. \tag{A61}$$

The 5D-transverse conditions (A53) determine the $s = 3$ components $a^{(m-3,3,N)}(z;\Delta)$ ($N = 0, 1$) from the $s = 2$ components:

$$a^{(m-3,3,0)} = \frac{1}{6\Delta^3}\left(\frac{\mathcal{D}}{\Delta}\right)^3 a^{(m,0,0)}, \qquad a^{(m-3,3,1)} = \frac{1}{4(j-m+3/2)\Delta}\left\{\left(\frac{\mathcal{D}}{\Delta}\right)^3 - \left(\frac{\mathcal{D}}{\Delta}\right)\right\} a^{(m,0,0)}, \tag{A62}$$

and after factoring out the normalization factor $(b^{(j-m)}_{s,N}/\Delta^{s-2N})$ and $\epsilon^{(0,0,m)}$ as before, we obtain

$$\Psi^{(j);3,0}_{i\nu;0,0,m} = \left(\frac{\mathcal{D}}{\Delta}\right)^3 \Psi^{(j);0,0}_{i\nu;0,0,m}, \qquad \Psi^{(j);3,1}_{i\nu;0,0,m} = \left\{\left(\frac{\mathcal{D}}{\Delta}\right)^3 - \left(\frac{\mathcal{D}}{\Delta}\right)\right\} \Psi^{(j);0,0}_{i\nu;0,0,m}. \tag{A63}$$

The $s = 3$ components determined purely by the conditions (A53) satisfy the 5D-traceless condition (A50) with the $s = 1$ component:

$$6\Delta^2 a^{(m-3,3,0)} - 4(j-m+3/2) a^{(m-3,3,1)} = \frac{\mathcal{D}}{\Delta^2} a^{(m,0,0)} = a^{(m-1,1,0)}. \tag{A64}$$

In this way, the wave functions $\Psi^{(j);s,N}_{i\nu;0,0,m}(-\Delta^2,z)$ for all (s,N) are determined, and the result is

$$\Psi^{(j);s,N}_{i\nu;0,0,m}(-\Delta^2,z) = \sum_{a=0}^{N}(-)^a{}_N C_a \left(\frac{\mathcal{D}}{\Delta}\right)^{s-2a}[(z\Delta)^m \Psi^{(j);0,0}_{i\nu;0,0,0}(-\Delta^2,z)] \times N_{j,m}. \tag{A65}$$

The only remaining concern was that there are more conditions from (A50), (A53) than number of components $a^{(k,s,N)}$ in the mth sector; there can be at most one eigenmode satisfying these 5D-traceless 5D-transverse conditions, as we stated earlier, but there may be no eigenmode left if the conditions are overdetermining. We have confirmed, however, that the wave functions (97), (A65) satisfy all of the relations given by (A50), (A53).

a. Normalization

We have yet to determine the normalization factor $N_{j,m}$; as in the main text, we choose (99) to be the normalization condition. Orthogonal nature among the eigenmodes is guaranteed because of the Hermitian nature of the operator $\alpha'(\nabla^2 - M^2)$. It is thus sufficient to focus only on the divergent part of the integral in the normalization condition in order to determine $N_{j,m}$.

The divergent part of the integral in (99) comes only from terms with $s = m$, $k = 0$, $(0 \le N \le [m/2])$, and $a = 0$. For a given m,

$$\begin{aligned}[\epsilon\cdot\epsilon']\delta(\nu-\nu') \sim N_{j,m}^2 \int_0 dz\sqrt{-g(z)}e^{-2jA} &\times \left(\sum_{N=0}^{[m/2]} \tilde{E}^N D^{m-2N}[\epsilon^{(0,0,m)}]\frac{b^{(j-m)}_{m,N}}{\Delta^{m-2N}}\frac{z^3\partial_z^m z^{-3}}{\Delta^m}(z\Delta)^m\Psi^{(j);0,0}_{i\nu;0,0,m}(-\Delta^2,z)\right)_{\mu_1\cdots\mu_j} \\ &\times \left(\sum_{M=0}^{[m/2]} \tilde{E}^M D^{m-2M}[\epsilon^{(0,0,m)}]\frac{b^{(j-m)}_{m,M}}{\Delta^{m-2M}}\frac{z^3\partial_z^m z^{-3}}{\Delta^m}(z\Delta)^m\Psi^{(j);0,0}_{i\nu;0,0,m}(-\Delta^2,z)\right)^{\hat{\mu}_1\cdots\hat{\mu}_j}.\end{aligned} \tag{A66}$$

The divergent part of the integral in this expression comes from

$$\begin{aligned}&\left(\frac{2}{\pi}\right)^2\frac{\nu\sinh(\pi\nu)}{2}\int dx x^{2j-5}[x^3\partial_x^m x^{-1-j+m}K_{i\nu}(x)][x^3\partial_x^m x^{-1-j+m}K_{i\nu'}(x)] \\ &\simeq \prod_{p=1}^{m}[(j-p+1)^2+\nu^2]\delta(\nu-\nu') = \frac{\Gamma(j+1-i\nu)\Gamma(j+1+i\nu)}{\Gamma(j+1-m-i\nu)\Gamma(j+1-m+i\nu)}\delta(\nu-\nu').\end{aligned}$$

Noting that

$$\begin{aligned}&\left(\sum_{N=0}^{[m/2]}\tilde{E}^N D^{m-2N}[\epsilon^{(0,0,m)}]\frac{b^{(j-m)}_{m,N}}{\Delta^{m-2N}}\right)\left(\sum_{M=0}^{[m/2]}\tilde{E}^M D^{m-2M}[\epsilon'^{(0,0,m)}]\frac{b^{(j-m)}_{m,M}}{\Delta^{m-2M}}\right), \\ &= \frac{j!}{(j-m)!}\left(\sum_{N=0}^{[m/2]} b^{(j-m)}_{m,N}\right)\epsilon^{(0,0,m)}_{\mu_1\cdots\mu_{j-m}}\cdot\epsilon'^{(0,0,m)\hat{\mu}_1\cdots\hat{\mu}_{j-m}},\end{aligned}$$

we find that (A66) implies

$$\begin{aligned}N_{j,m}^{-2} &= \frac{\Gamma(j+1-i\nu)\Gamma(j+1+i\nu)}{\Gamma(j+1-m-i\nu)\Gamma(j+1-m+i\nu)}\frac{j!}{(j-m)!}\left(\sum_{N=0}^{[m/2]} b^{(j-m)}_{m,N}\right), \\ &= \frac{\Gamma(j+1-i\nu)}{\Gamma(j+1-m-i\nu)}\frac{\Gamma(j+1+i\nu)}{\Gamma(j+1-m+i\nu)}{}_jC_m\frac{\Gamma(3/2+j-m)}{2^m\Gamma(3/2+j)}\frac{\Gamma(2+2j)}{\Gamma(2+2j-m)}.\end{aligned} \tag{A67}$$

4. A note on the wave function of the massless vector field

For a rank-1 tensor (vector) field on AdS_5, we can determine the wave function of the $(n,l,m) = (1,0,1)$ eigenmode, not just for the $(n,l,m) = (0,0,m)$ modes with $m = 0,1$. With the eigenvalue $\mathcal{E}_{1,0} = (3j+5+\nu^2)|_{j=1}$,

$$a^{(0,1,0)} = \epsilon^{(1,0,1)} z^2 K_{i\nu}(\Delta z),$$
$$a^{(1,0,0)} = \epsilon^{(1,0,1)} \partial_z (z^2 K_{i\nu}(\Delta z)) \tag{A68}$$

is the eigenvector solution to (A44).

The $(n,l,m) = (0,0,1)$ mode and the $(n,l,m) = (1,0,1)$ mode are independent, even after the mass-shell condition (66) for generic vector fields in bosonic string theory. However, for the massless vector field A_m obtained by the simple dimensional reduction of the massless vector field $A_M^{(Y)}$ with $Y = \{1,0,0\}$, these two modes become degenerate. To see this, note that $c_y = -4$ for this mode, so that the mass-shell condition (66) implies,

$$(j + 4 + \nu^2 + c_y)|_{j=1} = 0 \ (0,0,1) \text{ mode},$$
$$(3j + 5 + \nu^2 + c_y)|_{j=1} = 0 \ (1,0,1) \text{ mode}, \tag{A69}$$

or, equivalently, $i\nu = 1$ and $i\nu = 2$, respectively, for these two modes. It is now obvious that the terms proportional to $(\epsilon \cdot q)$ in (35) are in the form of this $(n,l,m) = (1,0,1)$ mode. With the relations $x^3 \partial_x [x^{-3+2} K_1(x)] = -x^3 [x^{-1} K_2(x)]$ and $\partial_x [x^2 K_2(x)] = -x^2 K_1(x)$, one can also see that the wave function for the $(n,l,m) = (0,0,1)$ mode is also proportional to the form given in (35) when the on-shell condition is imposed.

5. Projection operator of SO(3, 1) tensors

Note first that

$$a = \sum_{s=0}^{r} \sum_{N=0}^{[s/2]} \tilde{E}^N D_\Delta^{s-2N} [a^{(s,N)}] \tag{A70}$$

is an *orthogonal* decomposition of a totally symmetric SO(3, 1) tensor a of rank r into totally symmetric 4D-traceless 4D-transverse SO(3, 1) tensors $a^{(s,N)}$ of rank $(r-s)$. Here, the metric is given by

$$[b_{(-\Delta)}] \cdot [a_{(\Delta)}] := [b_{(-\Delta)}]_{\rho_1 \cdots \rho_r} [a_{(+\Delta)}]_{\sigma_1 \cdots \sigma_r} \eta^{\hat{\rho}_1 \hat{\sigma}_1} \cdots \eta^{\hat{\rho}_r \hat{\sigma}_r}, \tag{A71}$$

as in the main text. To see that the decomposition is orthogonal under this metric, one needs to use only (A37) to verify that

$$[\tilde{E}^M D_{-\Delta}^{t-2M} [b^{(t,M)}]] \cdot [\tilde{E}^N D_\Delta^{s-2N} [a^{(s,N)}]]$$
$$= \delta_{M,N} \delta_{t-2M,s-2N} \frac{\Delta^{2(s-2N)}}{b_{s,N}^{(r-s)}} [b^{(t,M)}] \cdot [a^{(s,N)}]. \tag{A72}$$

Using the fact that (A70) is an orthogonal decomposition, let us construct projection operators $\overline{P}^{(r;s,N)}$ that extract various components $a^{(s,N)}$ from a totally symmetric SO(3, 1) tensor a of rank r. We introduced an operator $P^{(r)}$ in (102) which acts on rank-r SO(3, 1) tensors. From what we have seen above, it can be used to extract the $a^{(s,N)=(0,0)}$ component from a rank-r tensor a. That is, $\overline{P}^{(r;0,0)} = P^{(r)}$. It is straightforward to see that the projection operator for other components $a^{(s,N)}$ with general (s,N) is given by

$$\overline{P}^{(r;s,N)} := \sum_a \frac{b_{s,N}^{(r-s)}}{\Delta^{2(s-2N)}} \frac{1}{D_a} (\tilde{E}^N D_\Delta^{s-2N} [\epsilon_a])_{\rho_1 \cdots \rho_r}$$
$$\times (\tilde{E}^N D_{-\Delta}^{s-2N} [\epsilon_a])_{\sigma_1 \cdots \sigma_r}, \tag{A73}$$

where ϵ_a's are an orthogonal basis of totally symmetric 4D-traceless 4D-transverse SO(3, 1) tensors of rank $(r-s)$.

It is also useful to have a concrete form of the projection operator $P^{(r)}$, not just its abstract definition in (102). We find that it is given by

$$P^{(r)} \cdot a = \sum_{M=0}^{[\frac{r}{2}]} \frac{(-1)^M \Gamma(r + \frac{1}{2} - M)}{4^M M! \Gamma(r + \frac{1}{2})}$$
$$\times \sum_{k=0}^{r-2M} \frac{(-1)^k}{k!} [\tilde{E}^M D^k O P_{(p,q)=(M,k)}] \cdot a, \tag{A74}$$

where $OP_{(p,q)}$ is the operator given in (A37). A totally symmetric rank-r tensor a is converted once into rank-$(r-2M-k)$ tensors, and then they are converted back to a rank-r tensor under the operator $P^{(r)}$. To see that all of the $\tilde{E}^N D^{s-2N} [a^{(s,N)}]$ components are projected out by $P^{(r)}$, one needs to use only the following formula [40]:

$$\sum_{M=0}^{N} (-1)^M {}_N C_M \frac{\Gamma(r - N + \frac{3}{2})}{\Gamma(r - N + \frac{3}{2} - M)} \frac{\Gamma(r + \frac{1}{2} - M)}{\Gamma(r + \frac{1}{2})}$$
$$= \frac{\Gamma(\frac{1}{2} - r)}{\Gamma(\frac{1}{2} - r + N) \Gamma(1 - N)}, \tag{A75}$$

which vanishes for an integer $N \geq 0$.

6. Some tensor computations

Let us derive a more concrete expression for the product $(q^{\mu_1} \ldots q^{\mu_r}) \cdot [P^{(r)}]^{\nu_1 \ldots \nu_r}_{\mu_1 \ldots \mu_r} \cdot (p_{\nu_1} \ldots p_{\nu_r})$ by using the explicit expression for the projection operator $P^{(r)}$ to the SO(3, 1)-transverse SO(3, 1)-traceless rank-r tensor:

$$(q^{\mu_1} \ldots q^{\mu_r}) \cdot [P^{(r)}]^{\nu_1 \ldots \nu_r}_{\mu_1 \ldots \mu_r} \cdot (p_{\nu_1} \ldots p_{\nu_r})$$
$$= \sum_{M=0}^{[r/2]} \frac{(-1)^M \Gamma(j + \frac{1}{2} - M)}{4^M M! \Gamma(j + \frac{1}{2})} \frac{r!}{(r-2M)!}$$
$$\times \left[q^2 - \frac{(q \cdot \Delta)^2}{\Delta^2} \right]^M (p^2)^M (q \cdot p)^{r-2M}, \tag{A76}$$

where we made $p \cdot \Delta = 0$. Within the regime of $q^2, (p \cdot q), (q \cdot \Delta) \gg \Lambda^2, \Delta^2, p^2$ that we have been interested in this article, $(q \cdot \Delta)^2 / \Delta^2 \gg q^2$. Thus, after ignoring q^2,

$$(q^{\mu_1}\cdots q^{\mu_r})\cdot[P^{(r)}]^{\nu_1\cdots\nu_r}_{\mu_1\cdots\mu_r}\cdot(p_{\nu_1}\cdots p_{\nu_r})$$
$$\approx (p\cdot q)^r\sum_{M=0}^{[r/2]}\frac{\Gamma(r+\frac{1}{2}-M)}{4^M M!\Gamma(r+\frac{1}{2})}\frac{r!}{(r-2M)!}\left[\left(\frac{q\cdot\Delta}{q\cdot p}\right)^2\frac{p^2}{\Delta^2}\right]^M$$
$$=: (p\cdot q)^r\times\hat{d}_r(\eta,\Delta^2). \tag{A77}$$

This introduces $\hat{d}_r$, which is a polynomial of skewness $(q\cdot\Delta)/(p\cdot q)=-2\eta$ of degree $2[r/2]$.

When r is even, this polynomial of η can also be rewritten by using a Legendre polynomial, $P_\ell(x)$, which is defined by ([41], page 82)

$$P_\ell(x)={}_2F_1\left(-\ell,\ell+1,1;\frac{1-x}{2}\right)$$
$$=\frac{(2\ell-1)!!}{\ell!}x^\ell\,{}_2F_1\left(-\frac{\ell}{2},\frac{1-\ell}{2},\frac{1}{2}-\ell;\frac{1}{x^2}\right). \tag{A78}$$

For an even r,

$$\hat{d}_r(\eta,\Delta^2)=\sum_{M=0}^{r/2}\frac{(-\frac{r}{2})_M(\frac{1-r}{2})_M}{M!(\frac{1}{2}-r)_M}\left(-\frac{4p^2}{\Delta^2}\eta^2\right)^M={}_2F_1\left(-\frac{r}{2},\frac{1-r}{2},\frac{1}{2}-r;\frac{(4m_h^2+\Delta^2)\eta^2}{\Delta^2}\right)$$
$$=\frac{r!}{(2r-1)!!}\left[\sqrt{\frac{4m_h^2+\Delta^2}{\Delta^2}}\eta\right]^r P_r\left(\sqrt{\frac{\Delta^2}{4m_h^2+\Delta^2}}\frac{1}{\eta}\right)=:\hat{d}_r([\eta]), \tag{A79}$$

where we used the kinematical relation $4p^2=-(4m_h^2+\Delta^2)$.

Similarly, it is also necessary to compute the following expression in order to study the $m=0$ exchange amplitude in Sec. VI C 2:

$$\left[\sum_{a\neq b}\epsilon^{2*}_{\rho_a}\epsilon^1_{\rho_b}q_{\rho_1}\cdots\check{}_{\rho_a}\check{}_{\rho_b}\cdots q_{\rho_j}\right]\cdot[P^{(j)}]^{\hat{\rho}_1\cdots\hat{\rho}_j}_{\sigma_1\cdots\sigma_j}\cdot[p^{\hat{\sigma}_1}\cdots p^{\hat{\sigma}_j}], \tag{A80}$$

which is also evaluated as above. The term proportional to $\eta^{\hat{\mu}\hat{\nu}}\epsilon^{2*}_\nu\epsilon^1_\mu$ (the contribution to the structure function V_1) is

$$2^2\sum_{M=1}^{[j/2]}\frac{(-1)^M\Gamma(j+\frac{1}{2}-M)}{4^M M!\Gamma(j+\frac{1}{2})}\frac{j!}{(j-2M)!2!}\left[q^2-\frac{(q\cdot\Delta)^2}{\Delta^2}\right]^{M-1}(p^2)^M(q\cdot p)^{j-2M}$$
$$\approx -2\frac{\Delta^2}{(q\cdot\Delta)^2}\times(q\cdot p)^j\sum_{M=1}^{[j/2]}\frac{\Gamma(j+\frac{1}{2}-M)}{4^M M!\Gamma(j+\frac{1}{2})}\frac{j!}{(j-2M)!}\left[\left(\frac{q\cdot\Delta}{q\cdot p}\right)^2\frac{p^2}{\Delta^2}\right]^M. \tag{A81}$$

This expression is once again a polynomial of η of degree $2[j/2]-2$ and is roughly of order $\Delta^2/(q\cdot p)^2$ times the expression (A77).

We will also need the following computation in Secs. VI C 3 and VI C 4:

$$(q_{\mu_1}\cdots q_{\mu_{j-k}})\cdot(\tilde{E}^N D^{s-2N}_{-\Delta}[\epsilon^{(0,0,m)}])^{\hat{\mu}_1\cdots\hat{\mu}_{j-k}}=\frac{(j-k)!}{(j-m)!}\left[q^2-\frac{(q\cdot\Delta)^2}{\Delta^2}\right]^N(-iq\cdot\Delta)^{s-2N}[(q_{\mu_1}\cdots q_{\mu_{j-m}})\cdot\epsilon^{(0,0,m)}]. \tag{A82}$$

APPENDIX B: CONFORMAL OPE COEFFICIENTS FROM AdS INTEGRALS

Let us introduce an integral,

$$C_1(\delta,\vartheta):=(1-\vartheta^2)^{1/2}\int_0^\infty dy y^{1+\delta}K_1(y\sqrt{1+\vartheta})K_1(y\sqrt{1-\vartheta}), \tag{B1}$$

which we encounter as the photon-photon– Pomeron/Reggeon vertex on AdS_5. $\vartheta=\eta/x$ and $\delta=j+i\nu$ in that context.

It is known ([42], page 101), if $\mathrm{Re}(\alpha+\beta)>0$ and $\mathrm{Re}(1\pm\nu\pm\mu-\rho)>0$, that

$$\begin{aligned}\int_0^\infty dt t^{-\rho}K_\mu(\alpha t)K_\nu(\beta t) &= 2^{-\rho-2}\alpha^{\rho-\nu-1}\beta^\nu[\Gamma(1-\rho)]^{-1}\\ &\times\Gamma\left(\frac{1+\nu+\mu-\rho}{2}\right)\Gamma\left(\frac{1+\nu-\mu-\rho}{2}\right)\Gamma\left(\frac{1-\nu+\mu-\rho}{2}\right)\Gamma\left(\frac{1-\nu-\mu-\rho}{2}\right)\\ &\times {}_2F_1\left(\frac{1+\nu+\mu-\rho}{2},\frac{1+\nu-\mu-\rho}{2};1-\rho;1-\frac{\beta^2}{\alpha^2}\right).\end{aligned} \tag{B2}$$

Substituting in $\rho=-1-\delta$, $\mu=1$, $\nu=-1$, $\alpha=\sqrt{1-\vartheta}$, and $\beta=\sqrt{1+\vartheta}$, we obtain

$$C_1(\delta,\vartheta)=\frac{\Gamma(\frac{\delta}{2})(\Gamma(\frac{\delta}{2}+1))^2\Gamma(\frac{\delta}{2}+2)}{\Gamma(\delta+2)}2^{\delta-1}(1-\vartheta)^{-\frac{\delta}{2}}{}_2F_1\left(\frac{\delta}{2},\frac{\delta+2}{2};\delta+2;\frac{2\vartheta}{\vartheta-1}\right). \tag{B3}$$

An equivalent, but slightly different expression is also obtained by using the following relation ([41], page 60):

$${}_2F_1(\alpha,\beta,2\beta;2z)=(1-z)^{-\alpha}{}_2F_1\left(\frac{\alpha}{2},\frac{\alpha+1}{2},\beta+\frac{1}{2};\left(\frac{z}{1-z}\right)^2\right); \tag{B4}$$

namely,

$$C_1(\delta,\vartheta)=2^{\delta-1}\frac{\delta+2}{\delta}\frac{(\Gamma(\frac{\delta}{2}+1))^4}{\Gamma(\delta+2)}{}_2F_1\left(\frac{\delta}{4},\frac{\delta}{4}+\frac{1}{2};\frac{\delta}{2}+\frac{3}{2};\vartheta^2\right). \tag{B5}$$

As a function of $\vartheta=\eta/x$, (B3) and (B5) are precisely of the form (25) and (26), respectively, required in the conformal OPE coefficients.

Abstract: Supersymmetric flux compactification of F-theory in the geometric phase yields numerous vacua, and provides an ensemble of low-energy effective theories with a variety of symmetry, matter multiplicity and Lagrangian parameters. Theoretical tools have already been developed so that we can study how the statistics of those flux vacua depend on the choice of symmetry and some of the Lagrangian parameters. In this article, we estimate the fraction of i) vacua that have a U(1) symmetry for spontaneous R-parity violation, and ii) those that realise ideas which achieve hierarchical eigenvalues of the Yukawa matrices. We also learn a lesson that the number of flux vacua is reduced very much when the unbroken $U(1)_Y$ symmetry is obtained from a non-trivial Mordell-Weil group, while it is not, when $U(1)_Y$ is in SU(5) unification. It also turns out to be likely that vacua with an approximate U(1) symmetry form a locus of accumulation points of the flux vacua distribution.

1 Introduction

Flux compactification of F-theory/Type IIB string theory generates a discretum of vacua in the complex structure parameter space, making it possible to *count* vacua and argue statistics of some of observables in the low-energy effective theories [1, 2]. It is virtually impossible to work out the vacuum for each one of individual flux configurations in practice, but this difficulty can be overcome in an approximate treatment of this problem introduced by Ashok-Denef-Douglas [3, 4]. Their treatment becomes a very powerful tool, when used for F-theory compactifications [2, 5], since one can estimate the number of flux vacua that lead to low-energy effective theories with a given set of 7-brane gauge groups and the number of generations of matter fields. It turns out [6, 7] that the number of flux vacua is reduced in the order of $10^{-O(100)}$ generically as we require the rank of 7-brane gauge group to be higher by one. Focusing on an ensemble of flux vacua with a given 7-brane gauge group, one further finds that the number of flux vacua follows the Gaussian distribution on the number of generations $N_{\rm gen}$, with the variance $\langle N_{\rm gen}^2 \rangle$ not more than O(1).

Obviously the analysis method above can be applied also to more refined and practical problems. It often happens in model building that more than one theoretically and phenomenologically consistent idea (model) has been proposed for a given phenomenon, and one cannot say which is better within the framework of low-energy effective field theory. By counting the number of flux vacua that realise various ideas and comparing the numbers, however, one can introduce a measure of naturalness on those consistent ideas. Such attempts have been made often in Type IIB compactifications so far; we are returning to this program by using F-theory compactifications so that we can address questions involving non-Abelian/Abelian gauge groups in the low-energy effective theories.

There are two kinds of naturalness/statistics questions. Note first that a low-energy effective theory is specified by providing a set of model data; a set of data consists of algebraic data (e.g. symmetry), topological data (e.g., matter multiplicity) and moduli data (i.e. coupling constants, symmetry breaking scale, etc.). Since a choice of algebraic and topological data is discrete in nature, we ask such questions as how much fraction of flux vacua survives when a certain symmetry is imposed. Section 3 is devoted to this category of problems. Moduli data, on the other hand, show up as continuous parameters in effective theories, and the flux vacua statistics need to be presented as a continuous distribution on the parameter space. This second category of questions is addressed by using F-theory compactifications in section 4.

Sections 3.1 and 3.2 deal with

- dimension-4 proton decay: spontaneous R-parity violation (v.s. $\mathbb{Z}_2$ symmetry),
- SU(5) unification v.s. $\mathrm{SU}(3) \times \mathrm{SU}(2) \times \mathrm{U}(1)$ without unification,

respectively. We do not get our hands on discrete symmetries in this article; we just estimate statistical cost of introducing an extra U(1) symmetry, which is relevant to both of the physics questions above. Section 4 begins with a recap of [53, 55]; observations made in these articles — originally in Type IIB context — hold readily in F-theory compactifications. We then discuss

- distribution of symmetry breaking scale of an approximate U(1) symmetry,
- two solutions to the hierarchical structure problem of Yukawa matrices,

in sections 4.1 and 4.2, respectively. The first and last of the four subjects above are found in the list of "possible applications" in [6, 7], and we just carry out the analysis in this article. Discussions in sections 3.2 and 4.1, on the other hand, are more like thought provoking ideas than solid analysis. The appendix A is a brief review note on two constructions of fourfold geometry for F-theory compactifications with a U(1) symmetry; the appendix B provides a little more details about SU(6) unification models with up-type Yukawa coupling in F-theory than in the literature. Monodromy of four-cycles in a fourfold is studied in the appendix C.2, as we need the result in section 4.1.

JHEP11(2015)065

2 A quick review of the formulation

Suppose that one is interested in estimating the number of flux vacua which have a given set of algebraic and topological properties in the effective theory below the Kaluza-Klein scale. Once we specify topology of the base threefold B_3 and of the divisor class $S \subset B_3$ supporting unification gauge group (7-brane),[1] we can think of a family of non-singular Calabi-Yau fourfolds $\hat{Y}_4$ with elliptic fibration over B_3 consistent with the set of algebraic properties one is interested in. Let $\mathcal{M}_*$ be the space of complex structure parameters for this family.[2] Statistics of flux vacua should turn out as a scatter plot on this parameter space $\mathcal{M}_*$. When the ensemble of topological flux configurations is replaced by its continuous approximation [3, 4], the scatter plot of vacua turns into a vacuum distribution function (an (m,m)-form on $\mathcal{M}_*$; $m := \dim_{\mathbb{C}}\mathcal{M}_*$). Ashok-Douglas [3] introduced vacuum index density $d\mu_I$, to which individual flux vacua contribute by ± 1 (rather than by $+1$). It is also an (m,m)-form on $\mathcal{M}_*$ under the continuous approximation, and is much easier to compute [3, 4]. For this practical reason, we also use the vacuum index density $d\mu_I$ in this article, instead of the vacuum density.

The vacuum index density turns out to have the following expression [2–5]:[3]

$$d\mu_I \sim \left\{ \begin{array}{ll} \dfrac{(2\pi L_*)^{K/2}}{(K/2)!} & \text{if } K \ll L_* \\ \dfrac{K^{L_*}}{L_*!} & \text{if } L_* \ll K \end{array} \right\} \times \rho_I, \qquad \rho_I = \det{}_{m\times m}\left(-\frac{R}{2\pi i} + \frac{\omega}{2\pi}\mathbf{1}_{m\times m}\right). \quad (2.1)$$

Here, R is the curvature two-form of $T\mathcal{M}_*$ and ω the Kähler form on $\mathcal{M}_*$. K is the dimension of an Affine subspace

$$\{G_{\text{fix}} + \Delta G \mid \Delta G \in H_{\text{scan}}\} \subset H^4(\hat{Y}_4;\mathbb{R}) \quad (2.2)$$

in which the four-form flux is scanned freely; H_{scan} is a vector subspace of $H^4(\hat{Y}_4;\mathbb{R})$, and $K := \dim_{\mathbb{R}} H_{\text{scan}}$. L_* is the upper bound on the 3-brane charge that the scanning component of the four-form flux ΔG contributes to. See [6, 7] for more detailed explanations. For the ensemble of fluxes above to correspond to an inclusive enough ensemble of effective theories with a given set of algebraic and topological data, H_{scan} needs to contain the primary horizontal component

$$\left[H^{4,0}(\hat{Y}_4;\mathbb{C}) + \text{h.c.}\right] \oplus \left[H^{3,1}(\hat{Y}_4;\mathbb{C}) + \text{h.c.}\right] \oplus H^{2,2}_H(\hat{Y}_4;\mathbb{R}). \quad (2.3)$$

[1] In this article, except in section 3.2, we use the two expressions *unification group* and *non-Abelian 7-brane gauge group* interchangeably, because gauge coupling unification is guaranteed when a flux on S breaks the non-Abelian gauge group symmetry on S to its subgroup $G_1 \times G_2 \times \cdots$.

[2] We avoid using the term "moduli space" for this meaning for the most part in this article. The space $\mathcal{M}_*$ is introduced and used in the present context just as a mathematical construct on which the result (vacuum index density $d\mu_I$) is presented, not as the non-linear sigma model target space in some approximation scheme of low-energy effective theory; once flux is introduced, these two notions are not the same. We hope to make this distinction clear by avoiding the word "moduli space" for the former, although it is perfectly correct to refer to the former as a moduli space in math context.

[3] The prefactor for $L_* \ll K$ was discussed in [3], but was corrected in [2, 6, 7].

JHEP11(2015)065

This condition on the minimum inclusiveness of flux ensemble is also known to be a necessary and sufficient condition for the formula of ρ_I in (2.1) to hold in F-theory compactifications [2, 5]. This means that

$$K \geq K_0 := 2(1 + h^{3,1}) + h^{2,2}_H. \tag{2.4}$$

Specific physics questions of one's interest determine how inclusive an ensemble of effective theories one wants to pay attention to, and how large a subspace of $H^{2,2}_V(\hat{Y}_4;\mathbb{R}) \oplus H^{2,2}_{RM}(\hat{Y}_4;\mathbb{R})$ should be included in $H_{\rm scan}$; the choice of $K - K_0$ is discussed in an application to the spontaneous R-parity violation scenario in section 3.1; see also [5–7].

As the integral $\int \rho_I$ over a fundamental domain of $\mathcal{M}_*$ usually turns out to have a value of order unity, we can just use the prefactor in (2.1) as an estimate of the number of flux vacua that have a set of algebraic and topological data specified at the beginning; we just use this prefactor for the study in section 3. The distribution ρ_I can be used to study statistical distribution of coupling constants / Lagrangian parameters within a class of low-energy effective theories with a given set of algebraic and topological properties; this ρ_I is used for the study in section 4.

One needs to keep in mind that the distribution as well as the estimate of the number of flux vacua here does not require that the vacuum expectation value (vev) of superpotential is much smaller than the Planck-scale-cubed; a large fraction of vacua has AdS supersymmetry. Stabilisation of Kähler moduli is not studied either. For these reasons and for other reasons stated elsewhere in this article, the formula (2.1) should be regarded only as partial information of statistical distribution of observables in string landscapes.

3 Fraction of flux vacua with enhanced symmetries

3.1 Statistical cost of spontaneous R-parity violation

Dimension-4 proton decay problem in supersymmetric Standard Models can be avoided, for example, by either imposing a $\mathbb{Z}_2$-symmetry (matter/R-parity) or assuming spontaneous breakdown of a U(1) symmetry triggered by a non-zero Fayet-Iliopoulos parameter (spontaneous R-parity violation).[4] When we assume that the $\mathbb{Z}_2$ symmetry originates from a $\mathbb{Z}_2$ symmetry of a geometry for compactification, complex structure parameters of the geometry need to be in a special sub-locus for enhancement of the $\mathbb{Z}_2$ symmetry [8, 9], and the flux vacua that end up in such a sub-locus will constitute small fraction of all the flux vacua [10, 11] (see also a remark at the end of this section 3.1). The spontaneous R-parity violation scenario (see [12–14] for its string implementation) also requires tuning, because we need a U(1) symmetry. This tuning should be translated into restriction on flux configuration. In this section 3.1, we estimate the fraction of flux configurations that have an extra U(1) symmetry. Comparing the fraction of flux vacua for the spontaneous R-parity

[4] For right-handed neutrinos to be able to have large Majorana masses, it is better that the U(1) symmetry is broken at high energy. Despite the spontaneous breaking, the SUSY-zero mechanism [15] remain at work in getting rid of dangerous proton decay operators at least for some UV constructions (see [13] for discussion).

JHEP11(2015)065

violation and that for matter/R-parity, one could argue which solution to the dimension-4 proton decay problem is more "natural" in terms of flux vacua statistics.

There are two different ways to implement an extra U(1) symmetry in F-theory compactifications. One is to assume a 7-brane locus $S \times \mathbb{R}^{3,1}$ with an SU(6) or SO(10) gauge group, and introduce a U(1) flux on the complex surface S, so that the symmetry is broken[5] from SU(6) or SO(10) to $\mathrm{SU}(3)_C \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y \times \mathrm{U}(1)$ [12, 14].[6] The other [20–23] is to get an extra U(1) symmetry by assuming a Calabi-Yau fourfold with a non-trivial Mordell-Weil group [24]. In the latter implementation, more variety is available in the choice of U(1) charge assignment than those that follow from Heterotic string geometric (supergravity) compactification [25–28].

To get started, let us first take a moment to consider how one should choose H_{scan} for this problem. We address this question by working on a few concrete examples. First of all, the base threefold is set to be $B_3 = \mathbb{P}^1 \times \mathbb{P}^2$, and we require SU(5) 7-branes along a divisor $S = H_{\mathbb{P}^1} = \mathrm{pt} \times \mathbb{P}^2$ in B_3. There is a wide variety in constructing families of Calabi-Yau fourfolds with a non-trivial Mordell-Weil group[7] [27, 28], but we just pick up only two of them to work on; in both of the two constructions, a Calabi-Yau fourfold Y_4 is obtained as a hypersurface of an ambient space that has a toric surface fibration over the base manifold B_3; the fibre surface is a blow-up of $WP^2_{[1:2:3]}$ in one of the two, and it is $F_1 = dP_1$ in the other. The appendix A provides a brief summary note on the facts about the two constructions.

In the first construction (see the appendix A.1), where $\mathrm{Bl}_{[1:0:0]}WP^2_{[1:2:3]}$ is the fibre of the ambient space, the vertical component of $H^{2,2}$, namely, $H^{2,2}_V(\hat{Y}_4; \mathbb{Q})$, is of 11 dimensions. Four among them are generated by

$$\sigma_0 \cdot H_{\mathbb{P}^1}, \qquad \sigma_0 \cdot H_{\mathbb{P}^2}, \qquad H_{\mathbb{P}^1} \cdot H_{\mathbb{P}^2}, \qquad H_{\mathbb{P}^2} \cdot H_{\mathbb{P}^2}, \tag{3.1}$$

where σ_0 is a zero section of $\pi : \hat{Y}_4 \longrightarrow B_3$ and $H_{\mathbb{P}^2}$ the hyperplane divisor of $\mathbb{P}^2$. Four other generators are the vanishing two-cycles of rank-4 SU(5) symmetry fibred over $H_{\mathbb{P}^2}|_S$:

$$E_a \cdot H_{\mathbb{P}^2} \qquad (a = 1, 2, 3, 4), \tag{3.2}$$

where E_a's are the Cartan divisors of SU(5). All the three remaining generators are vanishing cycles associated with charged matter fields; two are for the $\bar{\mathbf{5}}_{-2}$ and $\bar{\mathbf{5}}_{+3}$ representations of the $\mathrm{SU}(5) \times \mathrm{U}(1)$ symmetry, and the last one for the $\mathbf{1}_5$ representation. The dimension

[5] The F-theory implementation of spontaneous R-parity violation scenario is always an example of "T-brane" [16]. The D-term condition $\sum_i q_i |\phi_i|^2 - \xi = 0$ in the 4D effective theory corresponds [17, 18] to a (D-term) BPS condition $[\varphi, \overline{\varphi}] + \omega \wedge F = 0$ in the effective field theory on $S \times \mathbb{R}^{3,1}$ (Katz-Vafa type field theory [19]). The off-diagonal components of the Higgs field vev $\langle\varphi\rangle$ is therefore essential in the spontaneous R-parity violation scenario [12, 14].

[6] We maintain the discussion simple here, by assuming SU(5) unification. Once the "tempting argument" in page 8 is verified, however, it will be obvious what to conclude about the statistical cost of various implementations of the spontaneous R-parity violation scenario even in the absence of SU(5) unification.

[7] We do not work on the H_{scan}-determination problem for the SU(6) or SO(10) realisation of the spontaneous R-parity violation in this article. That will be a doable problem. As we see later, however, precise determination of H_{scan} is not much of importance when $h^{3,1} \gg h^{1,1}$.

JHEP11(2015)065

of the remaining (i.e., non-horizontal non-vertical) component is determined by using the formula of [6, 7]; it turns out that $h^{2,2}_{RM} = 0$.

How should we choose $H_{\rm scan}$, then? First of all, the four-form ΔG needs to stay away from the 8 four-cycles listed in (3.1), (3.2) in order not to break the SO(3,1) and SU(5) unification symmetry.[8] Secondly, the net chirality "$N_{\rm gen}$" of $\bar{\mathbf{5}}_{-2}$ and $\bar{\mathbf{5}}_{+3}$ need to be fixed, which means that the integral of a four-form over these two cycles need to have values designated by a phenomenology (low-energy) model of interest. Therefore, there should not be scanning of ΔG in the 8+2 dimensions of $H^{2,2}_{RM}(\hat{Y};\mathbb{R}) \oplus H^{2,2}_{V}(\hat{Y}_4;\mathbb{R})$. The net chirality of the $\mathbf{1}_5$ field, however, may be chosen arbitrarily, as they do not appear in the low-energy spectrum in the spontaneous R-parity violation scenario.[9] Thus, this means that the four-form flux quanta can be scanned also in a one dimensional subspace of $H^{2,2}_{RM}(\hat{Y};\mathbb{R}) \oplus H^{2,2}_{V}(\hat{Y}_4;\mathbb{R})$ for the question we are facing. This brings us to

$$K = K_0 + 1. \tag{3.3}$$

Let us also work on one more construction of a Calabi-Yau fourfold with a non-trivial Mordell-Weil group, where the ambient space of $\hat{Y}_4$ has F_1 fibre (see a review in the appendix A.2). The construction comes with a topological choice of two divisors κ^1 and κ^2 on B_3; we stick to the same choice of $(B_3, [S])$ as before for now. The choice of the divisor classes κ^1, κ^2 changes the topological class of various matter curves, but the U(1) charge assignment is not affected. When the two divisors are parameterised by

$$\kappa^1 = a_1 H_{\mathbb{P}^1} + a_2 H_{\mathbb{P}^2}, \qquad \kappa^2 = b_1 H_{\mathbb{P}^1} + b_2 H_{\mathbb{P}^2}, \tag{3.4}$$

we focus our attention to the choices satisfying the conditions

$$b_1 = 0, \quad a_1 = 1, 2, \quad 0 \le a_2, b_2, \quad 0 \le 6 + a_2 - 2b_2, \quad 0 \le 6 - 2a_2 + b_2, \tag{3.5}$$

since some of the coefficients $A_{0,1}$, $A_{1,0}$, $B_{-1,1}$, $B_{0,0}$, $b_{1,-1|2}$, $C_{-2,1}$, $c_{-1,0|1}$, $c_{0,1|3}$ and $c_{1,-2|5}$ in the defining equation of $\hat{Y}_4$ (A.7), (A.8), (A.15) would vanish identically otherwise.[10] We further focus on cases with $a_2 = 0$, when the non-singular fourfold $\hat{Y}_4$ remains a flat fibration over B_3, and the low-energy spectrum is guaranteed to be free from tensionless string (cf [29–31]). This means that $0 \le b_2 \le 3$.

We studied geometry associated with $H^{2,2}(\hat{Y}_4)$ carefully for $a_1 = 1$ and $0 < b_2 < 3$. The non-vertical and non-horizontal component $H^{2,2}_{RM}(\hat{Y}_4)$ turns out to be trivial, which follows from the formula in [6, 7]. The vertical component $H^{2,2}_{V}(\hat{Y}_4;\mathbb{R})$ has 13 independent generators. The five independent generators other than those in (3.1), (3.2) all correspond to the vanishing cycles associated with charged matter fields. Three correspond to $\bar{\mathbf{5}}_0$, $\bar{\mathbf{5}}_1$

[8] We ignore SU(5) symmetry breaking to the Standard Model gauge group in this article, in order not to be distracted by unessential details.

[9] This argument is a little simplified too much for phenomenology, but we keep the story simple in this article (see [13] for more). After all, small changes in the argument in these paragraphs do not severely affect the qualitative conclusion we draw later in this section.

[10] This constraint is not from physical reasons; when one of those conditions is not satisfied, it often happens that analysis of geometry is done better by using an ambient space that has a fibre other than $F_1 = dP_1$.

JHEP11(2015)065

and $\bar{\mathbf{5}}_{-1}$, and two others to $\mathbf{1}_1$ and $\mathbf{1}_2$. Repeating the same argument as in the case of the first construction, we find that $H_{\rm scan}$ has a dimension

$$K = K_0 + 2. \tag{3.6}$$

Spontaneous R-parity violation, or the SUSY-zero mechanism more generally, is a little special in that the U(1) symmetry exerts some controlling power on types of interactions in the low-energy effective theory even after it is broken spontaneously at high-energy (primarily for dimension-4 operators, not necessarily on non-renormalisable operators; see [13] for discussion). Chirality is not well-defined any more, however, for SU(5)-neutral U(1)-charged matter fields after the spontaneous breaking of the U(1). Without the chirality protection, they do not survive in the low-energy spectrum.[11] For this reason, when we count the number of flux vacua that realise the spontaneous R-parity violation scenario, it is appropriate that the flux quanta changing the net chirality of SU(5)-neutral U(1)-charged fields should be scanned, as we have discussed above in detail. Some part of the vertical component of $H^{2,2}(\hat{Y}_4)$ therefore contributes to the dimension K of the scanning space of flux $H_{\rm scan}$, and $K > K_0$.

Let us now study the statistical cost of an extra U(1) symmetry. An easiest way to do that is to compute L_* and K for some concrete choices of $(B_3, [S])$, and work out the prefactor of (2.1). Comparing the prefactor for the case with an SU(5)×U(1) symmetry with the one for the case with just SU(5) unification, we can estimate the tuning cost of the spontaneous R-parity violation scenario. We will take this experimental approach first, by using $B_3 = \mathbb{P}^1 \times \mathbb{P}^2$ and $S = H_{\mathbb{P}^1}$ as before, and then discuss later how the tuning cost depends on the choice of $(B_3, [S])$.

It takes extra efforts to compute the dimension of the horizontal component $h^{2,2}_H$ (by using the formula in [6, 7]) and $\chi(\hat{Y}_4)$ (which are used for L_* in (2.1)), but there is a short-cut for such choices as $B_3 = \mathbb{P}^1 \times \mathbb{P}^2$. So long as $h^{3,1}(\hat{Y}_4) \gg h^{1,1}(\hat{Y}_4)$, which is the case for the topology of $(B_3, [S])$ we chose above, $H^{2,2}(\hat{Y}_4)$ is dominated by the horizontal component, i.e.,

$$h^{2,2}(\hat{Y}_4) \sim h^{2,2}_H(\hat{Y}_4) \gg h^{2,2}_V(\hat{Y}_4), \quad h^{2,2}_{RM}(\hat{Y}_4), \tag{3.7}$$

as experience in [6, 7] shows. This is enough to see that [2, 6, 7]

$$L_* \sim \frac{\chi(\hat{Y}_4)}{24} \sim \frac{b_4}{24} \sim \frac{K}{24}, \qquad \frac{K^{L_*}}{(L_*)!} \sim \exp\left[\frac{b_4(\hat{Y}_4)}{24}\ln(24)\right]. \tag{3.8}$$

Furthermore, if one is interested only in the ratio of two prefactors $K^{L*}/(L_*)!$ (relative tuning cost) in geometries with $h^{3,1} \gg h^{1,1}$, a relation [32–34]

$$h^{2,2} = 4(h^{3,1} + h^{1,1}) + 44 - 2h^{2,1} \tag{3.9}$$

[11] By "low-energy" and "high-energy", we mean $\mathcal{O}(1\text{–}1000)$ TeV and $\mathcal{O}(10^{13-16})$ GeV in this paragraph, whereas we also use the term low-energy (effective theory) in the sense that an intended energy scale is below the Kaluza-Klein scale. It will not be difficult to figure out from the context in which meaning "low-energy" is used at each place in this article.

JHEP11(2015)065

implies that $\Delta h^{2,2} \sim 4\Delta h^{3,1}$, and $\Delta b_4 \sim 6\Delta h^{3,1}$. All these combined allows us to estimate the relative tuning cost by [6, 7]

$$\exp\left[\frac{\ln(24)}{4} \times (\Delta h^{3,1})\right]. \tag{3.10}$$

Numerically,[12] $[\ln(24)]/4 \simeq 0.8$. The fraction of flux vacua with an enhanced symmetry is determined in this expression by the number of complex structure parameters to be tuned.

Now we only need to compute $h^{3,1}$'s and compare.

$$WP_{[1:2:3]}\text{-fibred, no gauge group} \qquad h^{3,1} = 3277, \tag{3.11}$$

$$WP_{[1:2:3]}\text{-fibred, SU(5) gauge group} \qquad h^{3,1} = 2148, \tag{3.12}$$

which are the reference values of $h^{3,1}$ for $(B_3, [S])$ we have chosen. In the spontaneous R-parity violation scenario realised in a rank-5 unification,

$$WP_{[1:2:3]}\text{-fibred, SO(10) gauge group} \qquad h^{3,1} = 2138, \tag{3.13}$$

$$WP_{[1:2:3]}\text{ fibred, SU(6) gauge group} \qquad h^{3,1} \sim 1900. \tag{3.14}$$

The values of $h^{3,1}$ are taken from [6, 7] for SU(5) and SO(10), and the value for SU(6) is computed in the appendix B. Among the Mordell-Weil implementations of the extra U(1), we have also computed $h^{3,1}$ for the two constructions referred to earlier (and reviewed in the appendix A); Batyrev's formula for toric hypersurface Calabi-Yau's is used for these results:

$$\mathrm{Bl}_{[1:0:0]}WP^2_{[1:2:3]}\text{-fibred} \qquad h^{3,1} = 932, \tag{3.15}$$

$$F_1\text{-fibred, no.2} \qquad h^{3,1} = 7(b_2)^2 - 12b_2 + 372, \quad (a_1 = 1, \quad 0 < b_2 < 3). \tag{3.16}$$

It turns out, for $(B_3, [S])$ we chose, that the cost of the Mordell-Weil implementations of the spontaneous R-parity violation comes at the order of e^{-1000}, relatively to generic SU(5) unification; the number of flux vacua is reduced that much by requiring an extra U(1) symmetry through the existence of a non-trivial section. In the other group of implementations, namely rank-5 unifications with U(1) flux, the cost comes out as something like e^{-10} for SO(10) and e^{-200} for SU(6). All these cost estimates have been read out by comparing $h^{3,1}$ in (3.13)–(3.16) with that in (3.12).

It is tempting to argue, based on the numerical experiment for a single choice of $(B_3, [S])$ though, that the Mordell-Weil implementations of an extra U(1) tend to be much more costly than those through unification with one rank higher.[13] Plausible explanation

[12] This numerical value should not be taken at face value. The underlying cohomology lattice of the flux scanning space H_{scan} is not necessarily unimodular, whereas the derivation of the prefactor $K^{L_*}/L_*!$ is stated in [2, 6, 7] in its simplest form, where the underlying lattice is unimodular. The relative tuning cost in (3.10) should be read only as $\exp[\mathcal{O}(1) \times (\Delta h^{3,1})]$.

[13] It is naive just to compare the tuning cost of those different implementations. The SO(10) and SU(6) implementations predict SO(10)-like and SU(6)-like flavour structure automatically, and the tuning cost for appropriate flavour structure in SU(5) unification is not the same as those in SU(6) or SO(10) unification. This tuning cost for flavour is significant in SO(10) unification, because both quark doublets and lepton doublets live on the same matter curve. The tuning cost for flavour in SU(6) unification will vary for its particle identifications; see discussion in the appendix B.

JHEP11(2015)065

will be that the Mordell-Weil implementations require more parameters to be tuned, because existence of an extra section restrains geometry over the entire base manifold B_3; the implementations through rank-5 unification, on the other hand, require higher order of vanishing of some sections along a divisor in B_3, which is a condition only on semi-local geometry. It is desirable, however, that this argument is either confirmed (or refuted instead) by $h^{3,1}$ computation for other constructions of Calabi-Yau's with a non-trivial Mordell-Weil group, and for other choices of $(B_3, [S])$.

Studies show [35–37] that Calabi-Yau fourfolds eligible for supersymmetric compactification of F-theory are distributed almost evenly in the $h^{3,1} \gg h^{1,1}$ corner and $h^{3,1} \ll h^{1,1}$ corner of the $h^{3,1}$–$h^{1,1}$ plane; this fits very well with an observation that a morphism of elliptic fibration to some threefold is allowed for large fraction of Calabi-Yau fourfolds with various topology [38, 39]. Such a choice as $B_3 = \mathbb{P}^1 \times \mathbb{P}^2$, which we used for the numerical experiment above, ends up in the corner of $h^{3,1} \gg h^{1,1}$, and hence the estimates of the fraction of flux vacua with an extra U(1) symmetry is hardly typical values for all the possible topological choices of $(B_3, [S])$.

It is not hard to find out how things go in the $h^{3,1}$–$h^{1,1}$ plane for various choices of $(B_3, [S])$, if we maintain K close to K_0. Along an $h^{3,1} + h^{1,1} = \text{const}$ line in the $h^{3,1}$–$h^{1,1}$ plane, the Euler number $\chi \sim 2(h^{3,1} + h^{1,1}) + h^{2,2} \sim 6(h^{3,1} + h^{1,1})$ and the value of $L_* \sim \chi/24$ do not change much, but the value of $K_0 \sim 2[1 + h^{3,1}] + h_H^{2,2}$ increases toward the $h^{3,1} \gg h^{1,1}$ corner. The prefactor in (2.1) is an increasing function of K for a given L_*, regardless of whether $L_* \ll K$ or $L_* \gg K$. The more Fano-like B_3 is, the *ampler* sections are available to $(-K_B)^{\otimes \text{positive}}$, the larger $h^{3,1}$ is, and the larger the number of flux vacua is, after all. When a stack of SU(5) 7-branes is required along $S \subset B_3$, more sections (and hence $h^{3,1}$, and the flux vacua) are lost when B_3 is more Fano like; the loss is severer, if $c_1(N_{S|B_3})$ is "positive". The relative tuning cost is higher for Fano-like B_3, with positive $c_1(N_{S|B_3})$. Experience in [6, 7] also shows, however, that the number of remaining flux vacua (i.e., those with an SU(5) symmetry) tends to be larger in Fano-like B_3 and positive $c_1(N_{S|B_3})$, despite the severer tuning cost for the SU(5) 7-branes. The same story will hold, even when SU(5) × U(1) symmetry is required instead.

Let us note that the qualitative argument above is naive in various respects. First, we set $K = K_0$ above for simplicity, but there is a large room for $K - K_0$, when B_3 is far from being Fano, and $c_1(N_{S|B_3})$ far from being "positive". Such a set-up is possible in F-theory compactifications [35–37, 40, 41], and it is known in such cases that there can be many other 7-branes with non-Abelian gauge groups, and $h^{1,1} \gg h^{3,1}$ for the fourfolds. It is then expected from experience in [6, 7] that $h_V^{2,2} \gg h_H^{2,2}$. One then needs to ask how much four-form flux can be introduced in the vertical component $H_V^{2,2}(\hat{Y}_4; \mathbb{Q})$ without breaking SO(3,1) symmetry and supersymmetry (if one wishes); based on an answer to this technical question, one can then wonder how inclusive an ensemble of low-energy effective theory one is interested in, and how large $(K - K_0)$ is. Secondly, particle physics with SU(5) unification is not all we need in this universe. Some source of supersymmetry breaking needs to be present. While anti-D3 branes may be able to play some role, dynamical supersymmetry breaking in a non-Abelian gauge theory (e.g. the 3-2 model in [42]) might also be at work. The tuning-cost-free non-Abelian gauge group in the non-Higgsable cluster

JHEP11(2015)065

may have something to do with dynamical supersymmetry breaking. Thirdly, the Kähler moduli need to be stabilised without a tachyon. U(1) fluxes change the effective number of Kähler moduli to be stabilised non-perturbatively, through the Fayet-Iliopoulos D-term potential (primitiveness condition of the flux). Finally, inflation or cosmological evolution in general may introduce some preference in the choice of $(B_3, [S])$. All these issues are beyond the scope of this article.

This article does not try to estimate the fraction of flux vacua with an unbroken matter/R-parity symmetry. If one is to argue which one of R-parity and spontaneous R-parity violation is more natural solution to the dimension-4 proton decay problem in terms of flux vacua statistics, we also need an estimate for the R-parity scenario. Although there are earlier works on this issue in the context of Type IIB orientifold compactifications (e.g. [10, 11]), further study in F-theory is desirable. It is worth reminding ourselves that the fact that $L_* \ll K$ in cases of $h^{3,1} \gg h^{1,1}$ may have an important implication to this issue. Continuous approximation to the space of fluxes in [3, 4] is fairly good when $K \ll L_*$; intuitively, as in [43], that is when the radius-square (L_*) of a K-dimensional "sphere"[14] is much larger than the number of dimensions K. In the case with $L_* \ll K$ (which is the case at least when $h^{1,1} \ll h^{3,1}$), however, much larger fraction of flux configurations may end up with special points in the complex structure parameter space (sometimes with an accidental discrete symmetry) than expected in the continuous approximation [4, 44].

3.2 GUT's and SU(3) × SU(2) × U(1)

Pursuit of supersymmetric SU(5) unification is a primary motivation to study F-theory compactification. The doublet-triplet splitting problem motivates compactification in the geometric phase (supergravity regime), rather than stringy regime, because it is solved in a simple way by topology (hypercharge line bundle or Wilson line) on an internal space [45, 46]; the up-type Yukawa coupling of the form $\mathbf{10}^{ij}\mathbf{10}^{kl}\mathbf{5}^{m}\epsilon_{ijklm}$ hints at algebra of the exceptional Lie groups $E_{6,7,8}$ [12]. There is no direct experimental evidence (such as proton decay) so far for unification, however; certainly renormalisation group of the minimal supersymmetric Standard Model (MSSM) is consistent with gauge coupling unification, but we do not know for sure what the particle spectrum is like at energy scale higher than TeV. If one does not take SU(5) unification seriously, then string vacua based on CFT's with a non-geometric target space are perfectly qualified for the description of the real world; we do not have to require that $E_{6,7,8}$ algebra be relevant for "compactification" either.

With this perspective in mind, it makes sense to ask a question which is more popular in the ensemble of supersymmetric vacua of F-theory compactification in the geometric phase, SU(5) unification or MSSM without unification. If there are more MSSM vacua without unification than vacua with SU(5) unification within the landscape of F-theory, the MSSM vacua will surely outnumber vacua with unification in the entire string landscape, which includes string vacua based on non-geometric CFT's, and those without a dual

[14] In reality, the lattice $H^4(\hat{Y};\mathbb{Z})$ is not positive definite. It still seems, however, that this "intuition" holds at least to some extent, because the Bousso-Polchinski like prefactor of (2.1) was obtained in [3, 4] without assuming that the lattice is positive definite.

JHEP11(2015)065

description in F-theory. Democracy, or simple majority rule, may not be the ultimate vacuum selection principle of string theory, but this question will still be of interest for those who are concerned about particle physics.

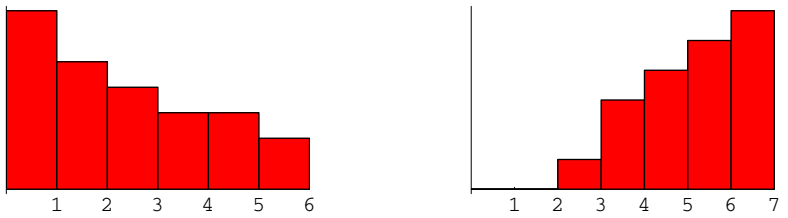
It is necessary, before answering the question above, to think what *unification* means. The motivation of unified theories at the very beginning [47] was to explain quantisation of hypercharges. This charge quantisation is achieved in any realisation of the Standard Model in F-theory/Type IIB string theory, however. Even when the U(1) hypercharge is not embedded into a larger non-Abelian group, charges of (p, q) strings (or M2-branes) are determined by algebraic topology, and the charges turn out to be quantised. Charge quantisation is therefore not a distinction criterion of, or motivation for, unification from the perspective of string theory.

Let us list up a couple of criteria for unified theories:

- $\mathrm{SU}(3)_C \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ originates from a single stack of branes,
- all of $\mathrm{SU}(3)_C$, $\mathrm{SU}(2)_L$ and $\mathrm{U}(1)_Y$ are understood in a semi-simple brane configuration
- gauge coupling unification is explained automatically,
- matter fields in some of the five irreducible representations of the Standard Model, $(\mathbf{3}, \mathbf{2})_{1/6}$, $(\bar{\mathbf{3}}, \mathbf{1})_{-2/3}$, $(\bar{\mathbf{3}}, \mathbf{1})_{+1/3}$, $(\mathbf{1}, \mathbf{2})_{-1/2}$ and $(\mathbf{1}, \mathbf{1})_{+1}$, are localised in the same locus in the internal space.

SU(5) GUT models discussed in section 3.1 satisfy all of those criteria. On the other hand, none of those criteria is satisfied, if $\mathrm{SU}(3)_C$ and $\mathrm{SU}(2)_L$ come from 7-branes on topologically different divisors S_3 and S_2, respectively, and $\mathrm{U}(1)_Y$ from a non-trivial section in the Mordell-Weil group. There will be constructions that satisfy some of the criteria, but not all, but we will foucus on the two extreme cases in this article, to keep the story simple.

Let us use $B_3 = \mathbb{P}^1 \times \mathbb{P}^2$, as before, and quantify the number of flux vacua of those different implementations of the Standard Model, so that we can compare. Here, we do not pay attention to the dimension-4 proton decay problem or any other phenomenological requirements. For SU(5) unification, we already have a result,



$$h^{3,1} = 3277 \longrightarrow h^{3,1} = 2148, \qquad \Delta h^{3,1} = -1129 \qquad \text{for SU(5)} \quad \text{on} \quad S = H_{\mathbb{P}^1}. \tag{3.17}$$

If we deform this Calabi-Yau fourfold further so that only $\mathrm{SU}(3) \times \mathrm{SU}(2)$ remains unbroken, the two gauge group factors are localised on divisors S_3 and S_2 both of which belong to the same divisor class as $S = H_{\mathbb{P}^2}$.

$$h^{3,1} = 3277 \longrightarrow h^{3,1} = 2149, \qquad \Delta h^{3,1} = -1128 \qquad S_3 \sim S_2 \sim H_{\mathbb{P}^1}. \tag{3.18}$$

We can go back to the family of fourfolds for SU(5) unification by suppressing one deformation parameter corresponding to $H^0(S; N_{S|B_3}) = H^0(\mathbb{P}^2; \mathcal{O})$ in this case. Therefore, the tuning cost for the unbroken U(1) hypercharge symmetry is obtained by $-\Delta h^{3,1} = 1$ in (3.10) in the case of SU(5) unification.

JHEP11(2015)065

(a) $c_1(N_{S|B}) > 0$ (A_n, D_n) (b) $c_1(N_{S|B}) < 0$ (A_n, D_n)

Figure 1. Extra tuning cost $-(\Delta L_*)/(\Delta\text{rank})$ decreases or increases for higher rank, depending on whether $c_1(N_{S|B_3})$ is positive or negative, as one goes down the A_n or D_n chain. $c_1(N_{S|B})$ is replaced by K_S in the case of E_n series.

In case we require SU(3) and SU(2) 7-branes on two divisors, S_3 and S_2, respectively, in different divisor classes in B_3, back of the envelope calculation[15] reveals that

$$h^{3,1} = 3277 \longrightarrow h^{3,1} = 2130,\ \Delta h^{3,1} = -1147, \qquad S_3 = H_{\mathbb{P}^1},\quad S_2 = H_{\mathbb{P}^2}; \tag{3.21}$$

$$h^{3,1} = 3277 \longrightarrow h^{3,1} = 2087,\ \Delta h^{3,1} = -1190, \qquad S_3 = H_{\mathbb{P}^2},\quad S_2 = H_{\mathbb{P}^1}. \tag{3.22}$$

Comparing these $\Delta h^{3,1}$'s with that in (3.18), we see that the topological configuration of $\mathrm{SU}(3)\times\mathrm{SU}(2)$ 7-branes does not make much difference in the fraction of flux vacua. If the hypercharge symmetry is obtained as a Mordell-Weil U(1) in addition to such $\mathrm{SU}(3)\times\mathrm{SU}(2)$ 7-brane configurations (cf [48]), $h^{3,1}$ will be reduced further by 1000 or so, as we have experienced in section 3.1. The number of flux vacua does not depend very much on topological configuration of 7-branes for $\mathrm{SU}(3)_C \times \mathrm{SU}(2)_L$, but it does very much on how we obtain $\mathrm{U}(1)_Y$.

The original motivation for unification — explaining quantisation of hypercharge — is no longer persuasive in string construction of particle physics, because it is explained without relying on unification. Unification may still have advantage in F-theory compactification in the geometric phase, in that the tuning cost for having an unbroken U(1) hypercharge in addition to $\mathrm{SU}(3)_C \times \mathrm{SU}(2)_L$ is small, in terms of flux vacua counting.

We should leave a cautionary remark on the B_3-dependence of this argument, however. Extra tuning cost for one extra rank of 7-brane gauge group has a behaviour shown in figure 1, where the behaviour is qualitatively different for cases with "positive" $c_1(N_{S|B_3})$ and "negative" $c_1(N_{S|B_3})$, when one goes down the chain of $A_n = \mathrm{SU}(n+1)$ series and $D_n = \mathrm{SO}(2n)$ series [6, 7]. When a divisor $c_1(N_{S|B_3})$ on S is negative, in particular, it may happen sometimes that $\Delta L_*/\Delta\text{rank} = 0$ for a choice of 7-brane gauge group with a

[15] Reasoning behind the values of $h^{3,1}$'s are

$$[2 + 3N_{3,2} + 4N_{5,2} + 6N_{8,2} + 7N_{11,2} + 10N_{16,2}] - [1 + 4 + 2N_{2,2} + 4N_{5,2} + 5N_{8,2}] - 6 = 2130, \tag{3.19}$$

$$[2 + 3N_{3,2} + 4N_{5,2} + 6N_{8,2} + 8N_{10,2} + 11N_{15,2}] - [1 + 4 + 2N_{2,2} + 4N_{5,2} + 6N_{7,2}] - 6 = 2087, \tag{3.20}$$

where $N_{h,2} = (h+1)(h+2)/2$ is the number of lattice points on a 2-dimensional pyramid of height h. We do not think that these values of $h^{3,1}$ are necessarily correct, but will not be off so much as to lose credibility in the estimate $\Delta h^{3,1} \approx -1000$. Because discusion in the main text is not affected by 10% change in the estimate of $\Delta h^{3,1}$, we do not need to compute $\Delta h^{3,1}$ at a precision better than that.

JHEP11(2015)065

small rank; the rank of 7-brane gauge group can be large to some extent without losing the number of flux vacua. This is the phenomenon called non-Higgsable cluster [24, 40, 41]. When either $SU(3)_C$ or $SU(2)_L$ or both are identified with 7-brane gauge groups in a non-Higgsable cluster [49], the tuning cost argument above is affected inevitably. In a family of fourfolds where the Mordell-Weil group is non-trivial everywhere on its complex structure parameter space [50–52], we cannot talk of relative statistical cost of requiring an extra U(1) symmetry; in such a case, we need to discuss relative tuning cost of U(1) through some transitions connecting such a family to another where the fourfolds have different topology, or to use the prefactor in (2.1) directly to estimate the number of flux vacua.

4 Distribution of Lagrangian parameters

While the prefactor in the formula (2.1) can be used to estimate the number of flux vacua with a given set of algebraic and topological properties (i.e., symmetry, matter multiplicity etc.), the (m, m)-form ρ_I in (2.1) can be used to "derive" distribution of Lagrangian parameters in such an ensemble of vacua. This is a source of rich information, as is evident already in its applications to Type IIB compactifications [53, 54]. In this section, we will discuss its F-theory applications in the context of particle physics.

It should be remembered, though, that the expression for ρ_I was derived by assuming that the continuous approximation of the K-dimensional flux space is good, while the approximation is not good in the case of $K \gg L_*$. It may be that the distribution ρ_I remains to have reasonable level of predictability, while the problem of bad approximation is mitigated, when the complex structure parameter space $\mathcal{M}_*$ is binned very coarsely, and ρ_I is used only by being integrated over such a large bin. Justification is not given even to this hope, however. When one is interested in the choice of $(B_3, [S])$ where $K \gg L_*$, one should keep this remark in mind.

4.1 Symmetry breaking scale of an approximate U(1) symmetry

We discuss applications of the distribution ρ_I in both sections 4.1 and 4.2. The set-up for the application in section 4.1 is chosen so that it suits best for exploring creative ways to use the distribution ρ_I; the physics problems discussed in section 4.1 should be interesting on their own, but we are focused more in finding out creative ways to use ρ_I, rather than in carrying out solid analysis of the physics problems being discussed. Section 4.2, on the other hand, is devoted to a more problem-oriented application.

While it is not theoretically impossible to compute period integrals and evaluate ρ_I, it is not practical to do so, when there are O(1000) complex structure parameters. Fortunately, it is possible to learn essential features of the distribution ρ_I without carrying out such computations, as experience in Type IIB applications indicates [53, 55]. First, the parameter space of complex structure $\mathcal{M}_*$ has a natural set of coordinates; in a case a Calabi-Yau n-fold is given by a toric hypersurface, for example, we can use, for the coordinates of $\mathcal{M}_*$, various products of monomial coefficients that are invariant under rescaling [56]. The distribution ρ_I will show more or less uninteresting behaviour on these coordinates in $\mathcal{M}_*$, except at special loci in $\mathcal{M}_*$. ρ_I exhibits singular behaviour in these

JHEP11(2015)065

coordinates, when the period integrals involve logarithm of those coordinates; only derivatives of logarithm introduce poles. Logarithm of such coordinates indicates that there is a non-trivial monodromy of cycles [55]. All the arguments above hold true for applications to Calabi-Yau fourfolds.[16]

Consider a family of Calabi-Yau fourfolds $Y_{n=4}$ obtained as a hypersurface of an ambient space given by $WP_{[1:2:3]}$-fibration over some B_3;

$$X^3 + Y^2 + XYZA_1 + X^2Z^2A_2 + YZ^3A_3 + XZ^4A_4 + Z^6A_6 = 0, \tag{4.1}$$

with $A_k \in \Gamma(B_{n-1=3}; \mathcal{O}_B(-kK_B))$. Let $\mathcal{M}_*$ be its parameter space of complex structure. Sitting within this family is a family of Calabi-Yau fourfolds with the ambient space replaced by $\mathrm{Bl}_{[1:0:0]}W\mathbb{P}_{[1:2:3]}$-fibration over B_3; the last term Z^6A_6 is simply dropped (followed by small resolution) to get to the sub-family given by (A.2), where there is a non-trivial section in Y_4, and hence a U(1) symmetry in the low-energy effective theory. Let $\mathcal{M}_*^{\mathrm{U}(1)} \subset \mathcal{M}_*$ be the locus of this sub-family. We study the behaviour of ρ_I on $\mathcal{M}_*$ near the locus of this sub-family.

In the $A_6 \longrightarrow 0$ limit, Y_4 has a curve of codimension-three conifold singularity, $X = Y = A_3 = A_4 = 0$ [23]; this curve in B_3 is denoted by Σ. The conifold transition in such a limit was studied extensively in [57]. The genus of this curve is determined by

$$2g(\Sigma) - 2 = (-3K_B) \cdot (-4K_B) \cdot (-6K_B) = 72(c_1(TB_3))^3. \tag{4.2}$$

Incidentally, the parameter space $\mathcal{M}_*^{\mathrm{U}(1)}$ for this $A_6 \longrightarrow 0$ limit is of complex codimension-$(-\Delta h^{3,1})$ in $\mathcal{M}_*$, where

$$(-\Delta h^{3,1}) = h^0(B_3; \mathcal{O}_B(-6K_B)) - h^0(B_3; \mathcal{O}_B(-3K_B)) - h^0(B_3; \mathcal{O}_B(-2K_B)); \tag{4.3}$$

the first term is obviously the degree of freedom in A_6. The last two terms are there because only the ϵ_1-term in the automorphism of the form

$$\delta Y = XZ\epsilon_1 + Z^3\epsilon_3, \qquad \delta X = Z^2\epsilon_2, \qquad \epsilon_k \in \Gamma(B_3; \mathcal{O}_B(-kK_B)) \tag{4.4}$$

survives for Y_4 in the sub-family over $\mathcal{M}_*^{\mathrm{U}(1)}$. One can see that $(-\Delta h^{3,1}) = g$, at least when B_3 is a Fano variety. Indeed, because the divisor $(-K_B)$ is ample, Kodaira's vanishing theorem implies that

$$h^q(B_3; \mathcal{O}_B(-nK_B)) = 0 \qquad \text{for } q > 0, \quad n \geq 0. \tag{4.5}$$

Combining this theorem and the expression for $(-\Delta h^{3,1})$, we find that

$$(-\Delta h^{3,1}) = 36(c_1(TB_3))^3 + 1 = g. \tag{4.6}$$

[16] Certainly there is small difference between threefolds and fourfolds; the number of cycles $b_3 \sim 2h^{2,1}$ for period integrals is not much different from $2h^{2,1}$ period integrals forming special coordinates for Calabi-Yau threefolds, there are much larger number of four-cycles $b_4 \sim 2h^{3,1} + h^{2,2} \sim 6h^{3,1} + \text{const}$ than the number of independent period integrals for fourfolds. We do not see this difference as a serious obstacle in recycling the Type IIB lesson in the main text for the application to F-theory.

JHEP11(2015)065

This agreement always holds at local level, but $(-\Delta h^{3,1}) = g - \tilde{h}^{2,1} \leq g$ at global level [57]; the argument above shows that $\tilde{h}^{2,1} = 0$ at least when B_3 is a Fano variety.

$6g-3$ topological four-cycles are identified in the local geometry of Y_4 [57], and all of them are lifted to topological cycles in the global geometry of Y_4 at least when B_3 is a Fano variety. Period integrals on these $6g-3$ four-cycles vanish when all the g transverse coordinates of $\mathcal{M}_*^{\mathrm{U}(1)} \hookrightarrow \mathcal{M}_*$ are set to zero; see [57] and the appendix C. We found, in the appendix C.2, that there are at least g independent generators of unipotent monodromy[17] acting on these topological four-cycles, and the period integrals are of the form,

$$\Pi_{\widetilde{A}_k} \sim z_k, \qquad \Pi_{\widetilde{C}^k} \sim c^{kl} z_l \ln(z's); \tag{4.7}$$

the $A_6 \longrightarrow 0$ limit corresponds to $z_1 = z_2 = \cdots z_g = 0$. It is then quite likely, as in [53, 55], that the (m,m)-form distribution ρ_I on $\mathcal{M}_*$ has an asymptotic behaviour

$$\rho_I \approx \rho_I^{\mathrm{U}(1)} \wedge \rho_I^{\perp}, \qquad \rho_I^{\perp} := \prod_{k=1}^{g} \frac{dz_k \wedge d\bar{z}_k}{|z_k|^2 (\ln(|z|^2))^2} \sim \prod_{k=1}^{g} d[\arg(z_k)] \wedge \frac{d\ln(1/|z_k|^2)}{[\ln(1/|z_k|^2)]^2} \tag{4.8}$$

near $\mathcal{M}_*^{\mathrm{U}(1)}$. While derivation of the asymptotic form above is not as rigorous as it is desired to be, let us explore what this behaviour implies, assuming that it is correct.

The most important consequence is that the fraction of flux vacua with hierarchically small value of $\mathrm{U}(1)$ symmetry breaking parameter $|z_k|$ is not hierarchically small, but is only suppressed by some power of the logarithm of the hierarchy, $\ln(1/|z_k|^2)$. That makes it much more *natural* to think of approximate $\mathrm{U}(1)$ symmetry in bottom-up model building. Secondly, though, it is likely that the $\mathrm{U}(1)$ symmetry is preserved approximately only if all the $|z_k|$'s are hierarchically small; that is, what really matters will be a fraction of flux vacua satisfying, say, $|z_k|^2 < \delta$ for $^\forall k = 1, \cdots, g$ for some small δ. This then implies that only the fraction

$$\int_{\mathcal{M}_*^{\mathrm{local}};\leq\delta} \rho_I^{\perp} = \prod_k \left[\int_{\ln(1/\delta)}^{+\infty} \frac{d\ln(1/|z_k|^2)}{[\ln(1/|z_k|^2)} \right] = \frac{1}{[\ln(1/\delta)]^g} \tag{4.9}$$

of flux vacua in $\mathcal{M}_*$ has such an approximate $\mathrm{U}(1)$ symmetry in the effective theory Lagrangian, with the symmetry breaking not more than δ. The value of $g(\Sigma)$ is often quite large; when $B_3 = \mathbb{P}^3$, for example, $g = 36 \times 4^3 + 1$. Thus, the fraction of flux vacua decreases very quickly, when we require the approximate $\mathrm{U}(1)$ symmetry to be preserved for very hierarchically small δ.

Let us take one more step and ask the following question. Although ρ_I or (2.1) is presented in the form of a continuous distribution, it is originally a scatter plot on $\mathcal{M}_*$ of isolated flux vacua. What is the smallest value δ_{min} of the approximately preserved $\mathrm{U}(1)$ symmetry in $\mathcal{M}_* \setminus \mathcal{M}_*^{\mathrm{U}(1)}$? This is a prototype of such questions as what the minimum symmetry breaking scale is for supersymmetry and flavour symmetry in string landscape.

A wild speculation will be to think as follows. When we set δ small enough, the fraction of flux vacua (4.9) becomes so small that it reaches the fraction of flux vacua on $\mathcal{M}_*^{\mathrm{U}(1)}$

[17] Unipotent monodromy means, here, that a monodromy matrix is a sum of a nilpotent matrix and the identity matrix.

JHEP11(2015)065

among those on $\mathcal{M}_*$. The integral of $\rho_I^\perp$ over the normal coordinates of $\mathcal{M}_*^{\mathrm{U}(1)} \hookrightarrow \mathcal{M}_*$ in such a small region as $|z_k|^2 < \delta$ may correspond to flux vacua that sit right on top of the $\mathcal{M}_*^{\mathrm{U}(1)}$ locus. This thought leads to a relation

$$\left[\frac{1}{\ln(1/\delta_{\min})}\right]^g = \exp\left[\frac{\ln(24)}{4}(\Delta h^{3,1})\right], \tag{4.10}$$

where (3.10) — valid for cases with $h^{3,1} \gg h^{1,1}$ — was used in the right hand side. Geometry dependence through $g = -\Delta h^{3,1}$ drops out from this relation then, and we find that

$$\delta_{\min} \sim \exp\left[-e^{\frac{\ln(24)}{4}}\right]. \tag{4.11}$$

This "prediction", however, is not as powerful as it looks. We have to keep in mind the limited reliability in the value of "ln(24)/4", as remarked in footnote 12. It will not be still too bad to conclude that $\delta_{\min}$ will not be much smaller than

$$\exp[-e^{(\text{a few})}] \approx \exp[-10] \approx 10^{-(3\text{-}4)}, \tag{4.12}$$

provided all the speculative arguments leading to this conclusion are not wrong.[18]

4.2 Statistical cost of Yukawa hierarchical structure problem

In section 4.2, we discuss the fraction of flux vacua that realise solutions to the hierarchical structure problem of Yukawa matrices. Each one of codimension-three singularity (matter-curve intersection) points in F-theory compactifications for SU(5) unification gives rise to an approximately rank-1 Yukawa matrix, provided complex structure is generic [58–61], but the up-type [resp. down-type and charged lepton] Yukawa matrix in the low-energy effective theory below the Kaluza-Klein scale receives contributions from all the "E_6"-type points [resp. D_6 type] on $S \subset B_3$. The number of "E_6"-type and D_6-type points are determined by topological intersection numbers, and are generically not equal to one [61, 62]. The approximately rank-1 nature of the Yukawa matrices at short distance in F-theory is therefore lost at energy scale below the Kaluza-Klein scale, at least in a

[18] Here is a recap of the major caveats. First, as remaked already just before section 4.1, very little is known about the validity of the continuous approximation in the flux scanning space for cases with $K \gg L_*$; there is a related discussion in [4, 44], but we need to go beyond. The relevant question here is whether ρ_I can still be used after coarse binning. Secondly, monodromy analysis leading to (4.7) neither study all the generators of the monodromy group nor period integrals of all the $(6g-3)$ topological four-cycles; the asymptotic behaviour of ρ in (4.8) is derived by looking at partial contributions, while ignoring other terms; thus it is worth doing reanalysis of (4.7), (4.8) for those who prefer solid and rigorous analysis. Thirdly, we assumed that the U(1) symmetry breaking parameter δ in the low-energy effective theory will be tied with $\max(|z_k|^2\text{'s})$, rather than with $\min(|z_k|^2\text{'s})$ or anything else. This assumption, however, relies only on intuition of the author, without any justification. Finally, the "wild guess" leading to (4.10) is nothing more than a guess at this moment. As remarked at the beginning, the primary purpose of the discussion of this section 4.1 is in illustrating possible scope of particle physics applications of ρ_I, rather than in having a final word on the physics problems in question. A lot more work needs to be done, as we have discussed in this footnote, in order to establish the various claims and guesses made in this section 4.1, and those tasks are beyond the scope of this article.

JHEP11(2015)065

generic flux vacuum. There have been proposed a few ideas,[19] however, how to exploit the approximate rank-1 nature at short distance. We pick up two among them[20] for the study in this section 4.2.

One of the two ideas is to tune parameters so that only a single "E_6"-type point contributes to the up-type Yukawa matrix in the effective theory below the Kaluza-Klein scale (and just one D_6-type point to the down-type Yukawa matrix); this idea was proposed originally in [59, 65] and the Yukawa matrices in this scenario have been studied carefully in [60, 66–71]. In order to make sure that the low-energy Yukawa matrix receives contribution only from just one "E_6"-type point, it is safe to consider that splitting of matter curves is controlled by a U(1) symmetry [14, 22, 23].

It is true that, for the CKM mixing angles to be small, the single "E_6"-type point and the single D_6-type point should be at the same point in S, or at least be close enough [72]; this property does not follow from a U(1) symmetry (and the matter curve factorisation). If one is happy to ignore this aspect in the mixing angle and to focus on the hierarchical structure of the Yukawa eigenvalues for now,[21] then the study in section 3.1 as well as section 4.1 can be used to study statistical aspects of this idea of tuning. We will be brief in section 4.2.1 for this reason.

The other idea whose tuning we discuss in section 4.2.2 is a string-theory implementation of the idea of [76, 77]. Sections of a line bundle on a torus T^2 (a term "magnetised torus" is sometimes used for this) are given by Theta functions, which become approximately Gaussian for large complex structure of T^2; the exponentially small tail of the Gaussian wavefunctions is used to create hierarchical structure among three copies of $(Q, \bar{U}, \bar{E}) = \mathbf{10}$, which leads to realistic mixing angles and hierarchy in Yukawa eigenvalues [73–75, 78–80]. See [61, 81] for more detailed account of the string implementation of this idea. In this idea, therefore, one assumes that the matter curve for SU(5)-**10** representation has a large complex structure parameter.[22] We estimate how much fraction of flux vacua we lose by requiring this tuning in the complex structure parameter of the matter curve, by exploiting the "distribution" ρ_I.

[19] In Heterotic string compactification with SU(5) unification, at least some neighbourhoods of orbifold limits of the parameter space must be included as a part of the semi-realistic corners of string landscape [63]. Also, when a Calabi-Yau threefold for Heterotic string compactification has an elliptic fibration, one can translate the solutions in F-theory to Heterotic language. The whole picture of the landscape of Heterotic string parameter space remains to be far from clear, however. When it comes to G_2-holonomy compactification of M-theory, the author is unaware of any idea in the literature to get around the difficulty in the up-type Yukawa matrix when SU(5) unification is assumed [12] (Reference [64] arrived at the same observation independently).

[20] In this article, we do not study the statistics of the idea of alignment among Yukawa matrices due to a discrete symmetry [61].

[21] It is understood in phenomenology community, by now, that mixing angles will carry more fundamental information than the hierarchical Yukawa eigenvalues (see, e.g., [73–75]). This is because the CKM mixing angles reflect properties only of three quark doublets $(\mathbf{3}, \mathbf{2})_{+1/6} \subset \mathbf{10}$, and the lepton mixing angles those of just the three lepton doublets $(\mathbf{1}, \mathbf{2})_{-1/2} \subset \bar{\mathbf{5}}$, whereas the down-type/charged lepton Yukawa eigenvalues reflect the properties of both $(\bar{D}, L) = \bar{\mathbf{5}}$ and $(Q, \bar{E}) \subset \mathbf{10}$.

[22] Before making this assumption on the complex structure parameter, we make another assumption (a discrete choice in topology) that this matter curve has $g = 1$. Generalisation of this idea to higher genus cases has not been studied very much, apart from partial attempt in [61].

JHEP11(2015)065

4.2.1 Split matter curve under a U(1) symmetry

Suppose that the matter curves $\Sigma_{(\mathbf{10})}$ and $\Sigma_{(\bar{\mathbf{5}})}$ for the **10** and $\bar{\mathbf{5}}$ representations of Georgi-Glashow SU(5) unification are split into irreducible pieces, due to an extra unbroken U(1) symmetry originating from a non-trivial section. Let $\Sigma_{(\mathbf{10})} = \cup_a \Sigma_{(\mathbf{10});a}$ and $\Sigma_{(\bar{\mathbf{5}})} = \cup_b \Sigma_{(\bar{\mathbf{5}});b}$ be the irreducible decomposition protected by the U(1) symmetry. The idea of [59, 65] assumes, among other things, that there is a pair $\Sigma_{(\mathbf{10});a0}$ and $\Sigma_{(\bar{\mathbf{5}});b0}$ such that they intersect transversely (i.e., "E_6"-type) just once in the SU(5) 7-brane locus S; the matter $\mathbf{10} = (Q, \bar{U}, \bar{E})$ are localised in $\Sigma_{(\mathbf{10});a0}$ and H_u in $\Sigma_{(\bar{\mathbf{5}});b0}$, respectively, so that the single transverse intersection point gives rise to the approximately rank-1 up-type Yukawa matrix at low-energy. It is an interesting question whether there are such Calabi-Yau fourfold geometries. The two constructions of fourfolds with a non-trivial Mordell-Weil group which we reviewed in the appendix A do not have enough freedom to accommodate such configuration of matter curves, but this is far from being a no-go. Given the variety of constructions for fourfolds with a non-trivial Mordell-Weil group [27, 28], it may not be too bad to assume that there are constructions satisfying the assumption above. The rest of this section 4.2.1 is based on that assumption.

We have already estimated in section 3.1 the fraction of flux vacua that have an unbroken U(1) symmetry from a non-trivial Mordell-Weil group; factorisation of matter curves just follows as a consequence of the U(1) symmetry. Given the fact that the faction of such vacua depends on the choice of a construction of fourfolds with a non-trivial Mordell-Weil group, as well as on the choice of topology of $(B_3, [S])$, we do not find it meaningful to estimate the cost at precision higher than in section 3.1. By using the results there, we conclude right away that the cost of an extra U(1) symmetry to split the matter curves is something like

$$e^{-1000} \sim 10^{-\mathcal{O}(100)} \qquad \text{for } (B_3, [S]) = (\mathbb{P}^1 \times \mathbb{P}^2, H_{\mathbb{P}^1}). \tag{4.13}$$

The tuning cost estimated above should be compared against the naive estimate of the non-triviality of flavour structure of the Standard Model, first of all. Suppose that individual Yukawa eigenvalues are tuned to be small enough, one by one, by tuning the complex structure parameters by hand, and that these tunings for individual eigenvalues can be carried out independently from each other. Then the total tuning cost of the hierarchical eigenvalues of the Standard Model by this naive individual tuning is estimated by[23]

$$\left(\frac{\lambda_c}{\lambda_t}\frac{\lambda_u}{\lambda_t}\right)\left(\frac{\lambda_e}{\lambda_\tau}\frac{\lambda_\mu}{\lambda_\tau}\right) \approx \left(10^{-2}\cdot 10^{-4.5}\right) \times \left(10^{-1}\cdot 10^{-3.5}\right) = 10^{-11}. \tag{4.14}$$

[23] As we assume SU(5) unification, the hierarchical eigenvalues either in the down-type quark sector or charged lepton sector should be taken into account in this naive estimate of the tuning, not both. Also, only the ratio of the eigenvalues is used in this estimate, because the value of $(\tan\beta)$ is not known yet. On top of the naive estimate in the main text, one should multiply the tuning for the small mixing angles in the quark sector, $\theta_{us}\cdot\theta_{ub}\cdot\theta_{cb} \sim 10^{-4.5}$, in principle. We did not include this, however, because the idea of matter-curve splitting under a U(1) symmetry does not attempt to reproduce the small CKM mixing angles.

JHEP11(2015)065

It is much easier,[24] therefore, to obtain the semi-realistic hierarchical structure of Yukawa eigenvalues by just an accidental tuning, by chance of 10^{-11}, than by matter-curve splitting under a Mordell-Weil U(1) symmetry, at least for choices of $(B_3, [S])$ with $h^{3,1} \gg h^{1,1}$.

In fact, we may not have to require that the U(1) symmetry for matter-curve splitting is exact. Higher precision is required for a U(1) symmetry in the application to the dimension-4 proton decay problem, but that is not the case in the application to the flavour structure; the level of precision required for flavour physics is not more than $m_e/(174\ \mathrm{GeV}) \sim 10^{-5.6}$. This motivates us to pay attention also to flux vacua with an approximate U(1) symmetry, where the matter curves $\Sigma_{(\mathbf{10})}$ and $\Sigma_{(\bar{\mathbf{5}})}$ are near the factorisation limit. Qualitative aspects of flux vacua distribution with an approximate U(1) symmetry in section 4.1 will remain the same, even after requiring an extra SU(5) symmetry on $S \subset B_3$, because the geometry of U(1) symmetry breaking (i.e., conifold transition) in SU(5) models remains qualitatively the same as in the case without SU(5) unification, at least away from the GUT divisor $S \subset B_3$; the $A_4 = A_3 = 0$ curve in B_3 — Σ — in the SU(5) models has a component given by $a_2 = a_3 = 0$, where $A_4 = s^3 a_2$ and $A_3 = s^2 a_3$. An approximate U(1) symmetry is realised in much larger number of flux vacua than an exact U(1) symmetry is, and therefore the tuning problem for the hierarchical structure may be alleviated in this way.

It remains to be seen, however, to what extent the idea of [59, 65] works successfully even in the presence of a small symmetry breaking in the approximate U(1) symmetry. The question we asked at the end of section 4.1 — the minimum symmetry breaking scale $\delta_{\min}$ — may also become relevant in this context.

4.2.2 Gaussian wavefunction due to large complex structure

The second solution to the hierarchical structure problem of low-energy Yukawa matrices also requires tuning in one of the complex structure parameters. We use the distribution ρ_I in (2.1) in order to estimate the fraction of flux vacua for this solution.

As we have reminded ourselves at the beginning of section 4.1, the two important things in using ρ_I are i) to identify the natural coordinates of the parameter space $\mathcal{M}_*$, and ii) to find out the locus of $\mathcal{M}_*$ where there is a unipotent monodromy on the four-cycles of $\hat{Y}_4$. Although we also need dictionary between the coordinates on $\mathcal{M}_*$ and parameters of the low-energy Lagrangian (Yukawa couplings in particular), this part has already been worked out in the literature at the level we need in the present context [17, 18, 58, 61].[25]

The dictionary we use is the following. Let us use the base $B_3 = \mathbb{P}^1 \times \mathbb{P}^2$, and the SU(5) 7-brane locus $S = \mathrm{pt} \times \mathbb{P}^2 \subset B_3$ for concreteness. With a generic choice of complex structure of a fourfold $\hat{Y}_4$ for SU(5) unification, the matter curve $\Sigma_{(\mathbf{10})}$ is an irreducible curve[26] of genus 1, so that we can use the second solution. Let τ be the complex structure parameter of the genus one curve $\Sigma_{(\mathbf{10})}$. The j-invariant of an elliptic curve has an expansion

$$j \simeq e^{-2\pi i \tau} + 744 + \mathcal{O}(e^{2\pi i \tau}) \tag{4.15}$$

[24] There is no proof, however, that such an accidental tuning for individual Yukawa eigenvalues are possible, or impossible, in string theory moduli space.

[25] Except one caveat: see footnote 27.

[26] When the base manifold is $B_3 = \mathbb{P}[\mathcal{O}_{\mathbb{P}^2} \oplus \mathcal{O}_{\mathbb{P}^2}(nH_{\mathbb{P}^2})]$, the genus of this matter curve is determined by $2g(\Sigma_{(\mathbf{10})}) - 2 = (3-n)(-n)$. We chose $n = 0$ in this article so that $2g - 2 = 0$.

JHEP11(2015)065

which is convenient for large $\mathrm{Im}(\tau)$. Hierarchical Yukawa eigenvalues as well as small mixing angles in the CKM matrix follow, if $\mathrm{Im}(\tau)$ is parametrically large, or equivalently, the value of $|j(\Sigma_{(\mathbf{10})})|$ is exponentially large. This j-invariant of the genus one curve should be some modular function over the $m = h^{3,1} = 2148$-dimensional space $\mathcal{M}_*$ of complex structure of this compactification for SU(5) unification.

The first task in this section 4.2.2 is to identify the natural coordinates on $\mathcal{M}_*$ and to find out how $j(\Sigma_{(\mathbf{10})})$ depends on these coordinates. The Calabi-Yau fourfold $\hat{Y}_4$ in question — for the choice of $(B_3, [S])$ — is given as a hypersurface of a toric variety:

$$\begin{aligned} y^2 + x^3 + &(a_{5|0} + s a_{5|1} + s^2 a_{5|2}) xy + (s a_{4|1} + s^2 a_{4|2} + \cdots) x^2 \\ &+ (s^2 a_{3|2} + s^3 a_{3|3} + \cdots) y + (s^3 a_{2|3} + \cdots) x + (s^5 a_{0|5} + \cdots) = 0, \end{aligned} \tag{4.16}$$

where s is the inhomogeneous coordinate of $\mathbb{P}^1$, and is regarded as the normal coordinate of $S \subset B_3$. We understand here that all the terms corresponding to interior lattice points of facets of the dual polytope are set to zero in this defining equation; the automorphism group action on the monomial coefficients is now gauge-fixed for the most part, and only the coordinate rescaling $(\mathbb{C}^\times)^4$ acts on the coefficients. As a part of standard story in the toric hypersurface construction of Calabi-Yau manifolds, the complex structure parameter space $\mathcal{M}_*$ is given a natural set of coordinates; each one of them is in the form of

$$z_a := \prod_{\tilde{\nu}_\alpha} (a_\alpha)^{\tilde{\ell}^a_\alpha}, \tag{4.17}$$

where α runs over the monomials in the defining equation, and a labels linear relations $\sum_\alpha \tilde{\ell}^a_\alpha \tilde{\nu}_\alpha = 0$ in the dual lattice M of the toric data (e.g. [56]). In the case of $\hat{Y}_4$ we consider, there are 2148 such independent coordinates.

The matter curve $\Sigma_{(\mathbf{10})}$ is given by $a_{5|0} = 0$, and $a_{5|0}$ is a cubic homogeneous function on $S \cong \mathbb{P}^2$:

$$a_{5|0} = a^{5|0}_{300} T^3 + a^{5|0}_{210} T^2 U + a^{5|0}_{201} T^2 V + \cdots + a^{5|0}_{003} V^3, \tag{4.18}$$

where $[T : U : V]$ are the homogeneous coordinates of $\mathbb{P}^2 \cong S$. None of the ten terms in this cubic form corresponds to an interior point of a facet of the dual polytope, and hence we should retain all of them. Using the ten coefficients $a^{5|0}_{300}, \cdots, a^{5|0}_{003}$, seven independent rescaling invariants (i.e., the coordinates of the form (4.17)) can be constructed. The j-invariant of $\Sigma_{(\mathbf{10})}$ should depend on the seven coordinates out of[27] the 2148 coordinates of $\mathcal{M}_*$.

Before talking of how the j-invariant of a generic cubic curve of $\mathbb{P}^2$ depends on its monomial coefficients, let us have a look at the result for easier ones. When an elliptic

[27] An idea that large $\mathrm{Im}(\tau)$ of the matter curve $\Sigma_{(\mathbf{10})}$ results in Gaussian profile of wavefunctions along $\Sigma_{(\mathbf{10})}$ and consequently to hierarchical Yukawa eigenvalues is spelled out [61] in the language of Katz-Vafa type field theory (field theory local model) on $S \times \mathbb{R}^{3,1}$. Very little discussion is found in the literature, however, over to what extent we can rely on this field theory picture for generic choice of complex structure parameters. Put differently, is it really true that only the coefficients $a^{5|0}_{***}$'s are relevant to the hierarchical structure?

JHEP11(2015)065

curve is given in the Weierstrass form or Hesse form, the j-invariant is given in this way:

$$y^2 = x^3 + fx + g : \qquad j = 4^4 \times 27 \frac{f^3}{4f^3 + 27g^2}, \tag{4.19}$$

$$a_1 X^3 + a_2 Y^3 + a_3 Z^3 + a_0 XYZ = 0 : \qquad j = -\frac{z(z-216)^3}{27(z+27)}, \quad z := \left(\frac{a_0^3}{a_1 a_2 a_3}\right). \tag{4.20}$$

The condition $\mathrm{Im}(\tau) \gg 1$ corresponds to the vanishing locus of the denominator, $4f^3 + 27g^2 \simeq 0$ or $z + 27 \simeq 0$, or the discriminant locus, to put differently. When the defining equation is in the Jacobi form,

$$w^2 = c_0 u^4 - c_1 u^3 + c_2 u^2 - c_3 u + c_4, \tag{4.21}$$

the discriminant locus is given by

$$\begin{aligned} &6912 c_0^3 c_4^3 - 3456 c_0^2 c_2^2 c_4^2 + 432 c_0 c_2^4 c_4 - 5184 c_0^2 c_1 c_3 c_4^2 \\ &- 2160 c_0 c_1 c_2^2 c_3 c_4 - 162 c_0 c_1^2 c_3^2 c_4 + 27 c_1^2 c_2^2 c_3^2 - 108 c_1^3 c_3^3 \\ &- 729 c_1^4 c_4^2 + 3888 c_0 c_1^2 c_2 c_4^2 - 108 c_1^2 c_2^3 c_4 + 486 c_1^3 c_2 c_3 c_4 \\ &\quad - 729 c_0^2 c_3^4 + 3888 c_0^2 c_2 c_3^2 c_4 - 108 c_0 c_2^3 c_3^2 + 486 c_0 c_1 c_2 c_3^3 = 0. \end{aligned} \tag{4.22}$$

For the j-invariant of those curves to be exponentially large, which is what we want for phenomenology, then the discriminant needs to be exponentially small; that seems to be a general lesson from elliptic curves given by those different forms of defining equations.

The matter curve $\Sigma_{(\mathbf{10})}$ is given by a generic cubic (4.18) in $\mathbb{P}^2$, but this is not much different from all the elliptic curves above. Any generic cubic can be cast into the Jacobi form (4.21) (e.g., [82]; recent appearance in physics literature includes [83]). Using the discriminant locus of the Jacobi form (4.22), one can then detect the discriminant locus in the coefficients of the general cubic form, and hence in the complex structure parameter space $\mathcal{M}_*$ of F-theory compactification. This procedure is easier when such a point as $[T : U : V] = [0 : 0 : 1] \in \mathbb{P}^2$ is in the curve $a_{5|0} = 0$ (i.e., $a^{5|0}_{003} = 0$); the left-hand side of (4.22) — a homogeneous function of $c_{0,1,2,3,4}$ of degree 6 — becomes a homogeneous function of $a^{5|0}_{***}$'s ($a^{5|0}_{003} = 0$) of degree 12. The most general case, where $a^{5|0}_{003}$ does not necessarily vanish, can be reduced to the $a^{5|0}_{003} = 0$ case above, by redefinition of the coordinates, $T \to T + solV$, $a^{5|0}_{300} sol^3 + a^{5|0}_{201} sol^2 + a^{5|0}_{102} sol + a^{5|0}_{003} = 0$. It appears, then, that the expression (4.22) would involve a cubic root of a function of the coefficients $a^{5|0}_{***}$'s, but those terms cancel, and the expression of the discriminant turns into a form

$$\propto \mathrm{polynomial}_1 \sqrt{\mathrm{polynomial}_3} + \mathrm{polynomial}_2. \tag{4.23}$$

The discriminant locus of the general cubic form should be the zero locus of an expression proportional to $(\mathrm{polynomial}_1)^2 \mathrm{polynomial}_3 - (\mathrm{polynomial}_2)^2$. This polynomial in the ten coefficients $a^{5|0}_{***}$ can be rewritten as a rational function of the seven coordinates z_a's of $\mathcal{M}_*$ modulo an overall factor that is not relevant in the present context. Once again, this rational function of z_a's needs to be exponentially small, in order for the solution to the hierarchical structure problem to work.

JHEP11(2015)065

The complex structure parameter space $\mathcal{M}_*$ has a codimension-1 locus of $\mathrm{Im}(\tau) = \infty$, or equivalently $j(\Sigma_{(\mathbf{10})}) = \infty$. Unless there is unipotent monodromy around this locus (an issue we come back to shortly), the distribution of ρ_I will remain featureless around this locus, and the fraction of vacua for the phenomenological solution is estimated by how finely the normal coordinate has to be tuned for phenomenology.[28] Hierarchically small Yukawa eigenvalues require that the value of the normal coordinate (the rational function in z_a's) be hierarchically small. Because a single tuning of $1/j(\Sigma_{(\mathbf{10})})$ already does the job (including the CKM mixing angles), however, the total tuning cost in this solution will not be as severe as 10^{-11} (or $10^{-11} \times 10^{-4.5}$) estimate for the naive individual tunings in (4.14).

It is worth noting that the idea of [76, 77] was to translate the hierarchically small values of Yukawa eigenvalues into a moderately large (but not hierarchically large) parameter in the exponent (like $\mathrm{Im}(\tau)$). In the F-theory implementation [61, 78–80] of this idea, however, the value of $\mathrm{Im}(\tau)$ is likely not to be the right measure of required fine-tuning, but the value of $1/j(\Sigma_{(\mathbf{10})}) \sim e^{2\pi i\tau}$ is, in the statistics of F-theory flux vacua, according to the argument above.

Let us briefly have a look at whether the distribution ρ_I on $\mathcal{M}_*$ has singularity at the $j(\Sigma_{(\mathbf{10})}) = \infty$ locus; if it does, then the right measure of fine-tuning will not be $e^{2\pi i\tau}$ but $1/\mathrm{Im}(\tau)$. Certainly the $\mathrm{Im}(\tau) = i\infty$ point is the locus of unipotent monodromy of one-cycles on $\Sigma_{(\mathbf{10})}$. There may also be some unipotent monodromy among three-cycles in the matter surface for SU(5)-**10** representation, because of the monodromy of one-cycles. The matter surface — a four-cycle — remains invariant in this limit, however. The author does not have a positive or negative evidence for non-trivial monodromy of horizontal four-cycles at the $j(\Sigma_{(\mathbf{10})}) = \infty$ locus of the complex structure moduli space $\mathcal{M}_*$; positive evidence is necessary in order to avoid the conclusion in the previous paragraph.

Acknowledgments

A Fourfolds for SU(5) × U(1) symmetry

This appendix is a brief summary note on Calabi-Yau fourfold geometry to be used for F-theory compactification when one wants to have SU(5) × U(1) symmetry in the effective theory below the Kaluza-Klein scale. There may be a few statements in the following that have not been written down in the literature, but those results can be derived by using procedure that has become almost standard these days. For this reason, only the results are stated, without detailed explanation.

[28] The distribution ρ_I for F-theory compactification has been used in this way for phenomenology already in [84].

Table 1. Toric vectors in $N_F = \mathbb{Z} \oplus \mathbb{Z}$ for $\mathrm{Bl}_{[1:0:0]}WP_{[1:2:3]}$ (weighted projective space $WP^2_{[1:2:3]}$ blown up at one point) and a Hirzebruch surface $F_1 = dP_1$. The two neighbouring lattice points of the polytope for ν'_Z in (a) [resp. ν'_0 in (b)] are $(1, 2)$ and $(1, 1)$ [resp. ν'_1 and ν'_2], which sum up to be ν'_Z [resp. ν'_0]; this means that D'_Z [resp. D'_0] can be used as a section. Those two neighbouring points are both vertices of the polytope in (b), while they are not in (a); this makes it impossible to introduce the twisting by $\mathcal{O}_{B_{n-1}}(\kappa^{1,2})$ in the case (a) without introducing an unintended non-Abelian symmetry $\mathrm{SU}(3) \times \mathrm{SU}(2)$.

In this article, we only consider elliptic fibration with a section for F-theory compactification; let $\hat{Y}_n$ be a non-singular Calabi-Yau n-fold, $\pi : \hat{Y}_n \longrightarrow B_{n-1}$ an elliptic fibration morphism, and we assume that there is a divisor σ_0 of $\hat{Y}_n$ which is one-to-one with the base B_{n-1} under π, except in complex codimension-two loci in B_{n-1}. Low-energy effective theory has a U(1) symmetry, if the elliptic fibration $\pi : \hat{Y}_n \longrightarrow B_{n-1}$ has more sections than just a single section σ_0 [24].

We restrict our attention to cases where toric surfaces are used to construct the elliptic curve E in the fibre. It is best to use a toric surface such as $WP_{[1:2:3]}$ and $F_1 = dP_1$ (Hirzebruch surface), where the polytope $\widetilde{\Delta}_F \subset (\mathbb{Z} \oplus \mathbb{Z}) \otimes \mathbb{R} =: N_F \otimes \mathbb{R}$ contains a vertex ν'_v whose two neighbouring lattice points on $\widetilde{\Delta}_F$, denoted by ν'_a and ν'_b, satisfy $\nu'_a + \nu'_b = \nu'_v$ [85]; the divisor corresponding to ν'_v then defines one point in E. In such toric surfaces as $\mathrm{Bl}_{[1:0:0]}WP_{[1:2:3]}$ and F_1 (whose toric data are shown in table 1), there is one more independent divisor which can be chosen to be degree-1 on E; this divisor defines another point in E. When such a toric surface is fibred over some base B_{n-1} to be an ambient space for $\hat{Y}_n$, those two points in E become sections of the elliptic fibration. The rest of this note deals only with the two toric surfaces above. See [26] for other choices of toric surfaces to be fibred.

A.1 $\mathrm{Bl}_{[1:0:0]}WP_{[1:2:3]}$-fibred ambient space

A Calabi-Yau n-fold Y_n is constructed as a hypersurface of an ambient space

$$\mathbb{P}\left\{\begin{array}{c}(-1\ 0\ 1\ 1)\\(0\quad 1\ 2\ 3)\end{array}\right\}[\mathcal{O}_B \oplus K_B \oplus \mathcal{O}_B \oplus \mathcal{O}_B]\,. \tag{A.1}$$

Here, the rank-4 fibre of the bundle over the base B_{n-1} is made projective[29] under the $\mathbb{C}^\times \times \mathbb{C}^\times$ action; one can choose two independent relations among the toric vectors in

[29] In order not to leave any ambiguity in the notation, we remark that the ordinary $WP_{[1:2:3]}$-fibred ambient space for a Calabi-Yau with elliptic fibration and a holomorphic section is denoted by $\mathbb{P}_{(1\,2\,3)}[\mathcal{O} \oplus \mathcal{O}_B(-2K_B) \oplus \mathcal{O}_B(-3K_B)] = \mathbb{P}_{(1\,2\,3)}[K_B \oplus \mathcal{O}_B \oplus \mathcal{O}_B]$.

JHEP11(2015)065

the form of $\sum_i \ell_i \nu'_i = 0 \in N_F = \mathbb{Z} \oplus \mathbb{Z}$, such as $-\nu'_W + \nu'_X + \nu'_Y = 0$ and $\nu'_Z + 2\nu'_X + 3\nu'_Y = 0$, and define the corresponding $\mathbb{C}^\times$ actions as $(\lambda \in \mathbb{C}^\times) : X_i \longrightarrow X_i \times \lambda^{\ell_i}$ for homogeneous coordinates X_i corresponding to the toric divisors D'_i. This ambient space is a $\mathrm{Bl}_{[1:0:0]} WP^2_{[1:2:3]}$-fibration over B_{n-1}.

A hypersurface Y_n of this ambient space is given by an equation

$$X^3W^2 + Y^2W + XYZWA_1 + X^2Z^2WA_2 + YZ^3A_3 + XZ^4A_4 = 0, \tag{A.2}$$

where $A_n \in \Gamma(B_{n-1}; \mathcal{O}_B(-nK_B))$ determines the complex structure of an elliptic fibred manifold Y_n. X, Y, Z and W are the homogeneous coordinates associated with divisors D_X, D_Y, D_Z and D_W, respectively, which are the D'_X, D'_Y D'_Z and D'_W divisors on the fibre, all over the base B_{n-1}. A section $D_Z|_{Y_n}$ is chosen as the zero section σ_0. Another section $\sigma_1 = D_W|_{Y_n} = \{W = 0\}|_{Y_n}$ does not intersect with the zero section σ_0. When the ambient space is blown down to the $WP_{[1:2:3]}$-fibred one, D_W is mapped to $(x, y) := (XW/Z^2, YW/Z^3) = (0, 0)$.

The n-fold Y_n develops a complex codimension-two locus of A_4 singularity (when the fibre of the ambient space is blown down to $WP_{[1:2:3]}$), when we require

$$A_n = s^{n-1} a_{6-n}, \qquad a_{n-1} \in \Gamma(B_{n-1}; \mathcal{O}_B(-nK_B - (n-1)S)) \tag{A.3}$$

for $n = 1, \cdots, 4$. S is a divisor of B_{n-1}, and s is a section of $\mathcal{O}_B(S)$ such that $S = \{s = 0\}$. A non-singular $\hat{Y}_n$ is constructed by a standard process of A_4 singularity resolution, followed by small resolutions associated with loci of charged matter fields; figure 2 (a) describes this process diagrammatically.[30] Let this blow-up morphism be $\nu : \hat{Y}_n \longrightarrow Y_n$; we also use the same ν for the morphism between the corresponding ambient spaces.

The zero section of $(\pi \cdot \nu) : \hat{Y}_n \longrightarrow B_{n-1}$ is given by $\sigma_0 := \nu^*(D_Z)|_{\hat{Y}_n}$; we will drop "$\nu^*$" or "$|_{\hat{Y}_n}$" in the following for simpler notations, however, unless subtleties are involved. Another section $\sigma_1 \sim D_W$ for $\pi : Y_n \longrightarrow B_{n-1}$ defines a section in $\hat{Y}_n$ except subtleties in the fibre of $S \subset B_{n-1}$. When we set

$$\sigma''_1 \sim \bar{D}_W - D_Z + K_B + (2E_1 + 4E_2 + 6E_3 + 3E_4)/5, \tag{A.4}$$

where $\bar{D}_W$ is the proper transform of D_W under $\nu : \hat{Y}_n \longrightarrow Y_n$, and $E_{1,2,3,4}$ the four exceptional divisors of $\nu : \hat{Y}_n \longrightarrow Y_n$, all of $\sigma''_1 \cdot \sigma_0$ and $\sigma''_1 \cdot E_{1,2,3,4}$ are mapped to the trivial divisor class in B_{n-1} under $(\pi \cdot \nu)_*$. References for the statements up to this point include [23, 87, 88].

There are three distinct groups of SU(5)-charged matter fields in this case [22], as summarised in table 2. The U(1)-charge of these SU(5)-charged matter fields can be determined by using the topological class of σ''_1 in (A.4); the results — shown in table 2 — indicates that the U(1) symmetry generated by σ''_1 shows up as the U(1) part of the $\mathrm{U}(3) \subset E_7$ structure group of the Higgs bundle in the field theory local model (Katz-Vafa type field theory) on $S \times \mathbb{R}^{3,1}$ (cf [22, 23]). The 6D anomaly cancellation condition

[30] $\nu'_{E1} = \nu'_S + \nu'_X + \nu'_Y$, $\nu'_{E2} = \nu'_{E1} + \nu'_X + \nu'_Y$, $\nu'_{E4} = \nu'_{E1} + \nu'_Y$, $\nu'_{E3} = \nu'_{E2} + \nu'_Y$. Then add ν'_W. A 1-simplex (2-dim cone) $< \nu'_W \nu'_{E3} >$ bisecting the cone $< \nu'_{E3} \nu'_X \nu'_Y >$ provides a small resolution of the conifold singularity over the $a_2 = a_3 = 0$ locus in B_{n-1}.

JHEP11(2015)065

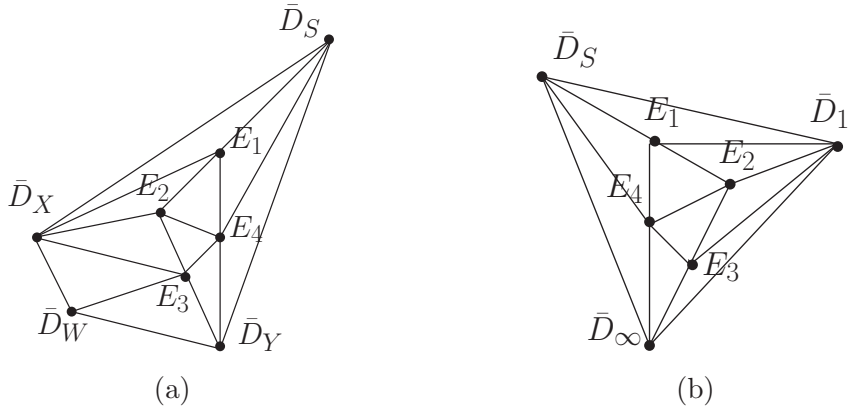

Figure 2. Blow-up procedure shown diagrammatically. Subdivision of a triangle using its centre of mass corresponds to a blow-up of the ambient space centred at a codimension-three locus, and a subdivision of an edge using its centre of mass to a blow-up of the ambient space centred at a codimension-two locus. These graphs can be seen as triangulation of cones, if the base B_{n-1} is also toric, and the divisor S a toric divisor, although we do not assume that B_{n-1} is toric in this summary note. The diagram (a) is for the $\mathrm{Bl}_{[1:0:0]}WP^2_{[1:2:3]}$-fibred ambient space and (b) for the F_1-fibred ambient space. Note in (a) that the triangulation of $\bar{D}_X$-E_3-$\bar{D}_Y$-$\bar{D}_W$ resolves the conifold singularity associated with the U(1)-charge ± 5 matter field; the graph (b) is the same as the blow-up procedure in [86].

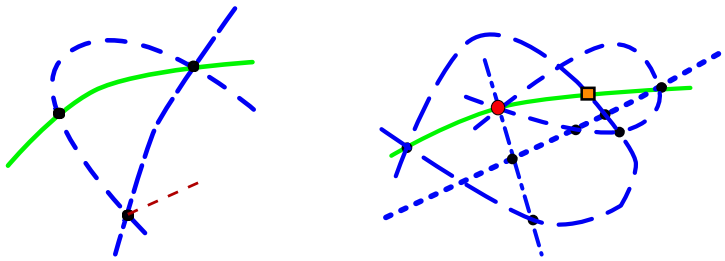

bdle	repr.	curve def. eq.	curve div. class	vanishing cycle
$\mathbf{3}$	$\mathbf{10}_{-1}$	$a_5\|_S = 0$	$(-K_B)\|_S$	$(-E_2 \cdot E_4)\|_{\hat{Y}_n}$
$\wedge^2\mathbf{3}$	$\bar{\mathbf{5}}_{-2}$	$(a_4a_3 - a_2a_5)\|_S = 0$	$(-3S - 5K_B)\|_S$	$\left(-(\bar{D}_Y - K_B - E_4) \cdot E_3\right)\|_{\hat{Y}_n}$
$\wedge^3\bar{\mathbf{3}}$	$\bar{\mathbf{5}}_{+3}$	$a_3\|_S = 0$	$(-2S - 3K_B)\|_S$	$(\bar{D}_X \cdot E_3)\|_{\hat{Y}_n}$

Table 2. Summary of geometry associated with the SU(5)-charged matter fields in the case of $\mathrm{Bl}_{[1:0:0]}WP^2_{[1:2:3]}$-fibred ambient space. The matter locus — codimension-1 in S — is given by the defining equation in the third column; this matter locus belongs to the divisor class on S shown in the fourth column. The last column shows the corresponding class of vanishing cycle (complex codimension-two in $\hat{Y}_n$). The first column shows the representation of the U(3) structure group of the Higgs bundle on S.

indicates that an SU(5)-neutral hypermultiplet with U(1)-charge ± 5 is localised in the fibre of a codimension-two $a_2 = a_3 = 0$ locus in B_{n-1}, and that they are all the matter fields charged under the SU(5) × U(1) symmetry (see [23, 89]).

This construction can be used for spontaneous R-parity violation. The hierarchical structure problem of Yukawa eigenvalues, however, cannot be solved by using this construction (without further symmetry or tuning of parameters), because all the "E_6"-type points on S contribute to the up-type Yukawa matrix in the low-energy effective theory. See figure 3 (a) for the configuration of matter curves.

JHEP11(2015)065

(a) (b)

Figure 3. (colour online) Configuration of matter curves and interaction points on the SU(5) 7-brane S shown schematically. The picture (a) is for the case of $\mathrm{Bl}_{[1:0:0]}WP^2_{[1:2:3]}$-fibred ambient space, and (b) for the case of F_1-fibred ambient space with the no.2 choice of the order of vanishing. Solid curve (green) is the matter curve for SU(5)-**10** representation in both (a) and (b). In the picture (a), the long dashed and dashed curves (both blue) are the matter curves for $\bar{\mathbf{5}}_3$ and $\bar{\mathbf{5}}_{-2}$, respectively. The dotted curve (red) is where SU(5)-neutral U(1)-charged fields are localised in B_3, "projected" on to S. In the picture (b), the long dashed, dashed, dotted and dash-dotted curves (all in blue) are the matter curves for $\bar{\mathbf{5}}_0$, $\bar{\mathbf{5}}_{-1}$, $\bar{\mathbf{5}}_1$ and $\bar{\mathbf{5}}_2$ representations, respectively. The "E_6"-type point for up-type Yukawa is indicated by a square (orange), while the point with F_1-fibre by a large circle (red).

A.2 F_1-fibred ambient space

$F_1 = dP_1$ can be used as fibre of the ambient space, instead of $\mathrm{Bl}_{[1:0:0]}WP^2_{[1:2:3]}$, in constructing a Calabi-Yau n-fold with a non-trivial Mordell-Weil group. We then use an ambient space

$$\mathbb{P}^{\left\{\begin{array}{c}(1\ 1\ 0\ 0)\\(0\ 1\ 1\ 1)\end{array}\right\}}\left[K_B \oplus \mathcal{O}_B \oplus \mathcal{O}_B(\kappa^1) \oplus \mathcal{O}_B(\kappa^2)\right], \tag{A.5}$$

where the fibre can be twisted by introducing two divisors κ^1 and κ^2 of the base B_{n-1} [90]. The fibre is F_1; the four line bundles above correspond to the toric vectors ν'_0, ν'_∞, ν'_1 and ν'_2 in table 1 (b), respectively. The zero locus of the line bundles are the divisors denoted by $D_{0,\infty,1,2}$, and the corresponding homogeneous coordinates are denoted by $X_{0,\infty,1,2}$. There are linear equivalence relations

$$D_1 - \kappa^1 \sim D_2 - \kappa^2, \qquad D_\infty \sim D_0 - K_B + D_2 - \kappa^2. \tag{A.6}$$

An elliptic fibred Calabi-Yau n-fold Y_n is given as a hypersurface of this ambient space by[31]

$$\begin{aligned} &X_\infty^2(A_{0,1}X_1 + A_{1,0}X_2) + X_\infty X_0(B_{-1,1}X_1^2 + B_{0,0}X_1X_2 + B_{1,-1}X_2^2) \\ &+ X_0^2(C_{-2,1}X_1^3 + C_{-1,0}X_1^2X_2 + C_{0,-1}X_1X_2^2 + C_{1,-2}X_2^3) = 0. \end{aligned} \tag{A.7}$$

[31] This equation can also be written down by using Affine charts for the fibre. In the chart corresponding to a cone $\langle \nu'_0, \nu'_1 \rangle$ [resp. $\langle \nu'_0, \nu'_2 \rangle$], Affine coordinates are $(u, \omega) = (X_1/X_2, X_2X_0/X_\infty)$ [resp. $(v, \omega') = (X_2/X_1, X_1X_0/X_\infty)$]. In the chart for the cone $\langle \nu'_\infty, \nu'_1 \rangle$ [resp. $\langle \nu'_\infty, \nu'_2 \rangle$], the Affine coordinates are $(u, w) = (X_1/X_2, X_\infty/(X_0X_2))$ [resp. $(v, w') = (X_2/X_1, X_\infty/(X_0X_1))$].

JHEP11(2015)065

Complex structure of Y_n is encoded in the choice of

$$\begin{aligned} &A_{n_1,n_2} \in \Gamma(B_{n-1}; \mathcal{O}(n_1\kappa^1 + n_2\kappa^2)), \\ &B_{n_1,n_2} \in \Gamma(B_{n-1}; \mathcal{O}(n_1\kappa^1 + n_2\kappa^2 - K_B)), \\ &C_{n_1,n_2} \in \Gamma(B_{n-1}; \mathcal{O}(n_1\kappa^1 + n_2\kappa^2 - 2K_B)). \end{aligned} \tag{A.8}$$

We take D_0 ($X_0 = 0$ locus) as the zero section[32] σ_0 of the elliptic fibration $\pi_Y : Y_n \longrightarrow B_{n-1}$. There is also a section corresponding to the degree-1 divisor $(D'_1 - D'_0)|_E$ of the fibre, which is denote by σ_1. It is geometrically given by

$$[X_\infty(B_{-1,1}X_1^2 + \cdots + B_{1,-1}X_2^2) + X_0(C_{-2,1}X_1^3 + \cdots + C_{1,-2}X_2^3) = 0] - 2[X_\infty = 0], \tag{A.9}$$

and belongs to the divisor class $(D_1 - D_0 + \kappa^2)$. Since

$$\pi_{Y*}(\sigma_1 \cdot \sigma_0) = [B_{\rm sym} = 0], \tag{A.10}$$

$$B_{\rm sym} := B_{1,-1}A_{0,1}^2 - B_{0,0}A_{0,1}A_{1,0} + B_{-1,1}A_{1,0}^2 \in \Gamma\left(B_{n-1}; \mathcal{O}(\kappa^1 + \kappa^2 - K_B)\right), \tag{A.11}$$

we take

$$\sigma_1'' := \sigma_1 - [B_{\rm sym} = 0] - \sigma_0 + K_B \sim (D_1 - \kappa^1 - 2D_0 + 2K_B) \tag{A.12}$$

as the generator of a U(1) symmetry in the low-energy effective theory.

The charge-± 2 matter fields under this U(1) symmetry are localised in the codimension-two locus of B_{n-1} given by[33]

$$\begin{aligned} &B_{\rm sym} = C_{\rm sym} = 0, \\ &C_{\rm sym} := C_{1,-2}A_{0,1}^3 - C_{0,-1}A_{0,1}^2A_{1,0} + C_{-1,0}A_{0,1}A_{1,0}^2 - C_{-2,1}A_{1,0}^3 \\ &\qquad\qquad \in \Gamma\left(B_{n-1}; \mathcal{O}(\kappa^1 + \kappa^2 - 2K_B)\right). \end{aligned} \tag{A.13}$$

Matter fields with charge ± 1 are localised in a class $4(\kappa^1 + \kappa^2 - 2K_B) \cdot (-\kappa^1 - \kappa^2 - 2K_B)$. All that has been stated so far is the same as (or obvious generalisation of) [25, 88].

Let us consider a case where an n-fold Y_n develops A_4 singularity at the $X_\infty = X_1 = 0$ point in the F_1 fibre over a divisor $S \subset B_{n-1}$, so that there is a stack of 7-branes for an SU(5) gauge theory along $S \subset B_{n-1}$. The sections A_{n_1,n_2}, B_{n_1,n_2} and C_{n_1,n_2}'s defining the complex structure of the n-fold Y_n need to have certain order of vanishing along the divisor $S \subset B_{n-1}$ then. There are a couple of different choices, as shown in table 3, at least in a study of local geometry. The no.3 choice of the order of vanishing, however, may have a problem, when a global geometry is studied; at least in a few examples using compact toric ambient spaces, we found that the singular fibre over S in a resolved n-fold $\hat{Y}_n$ becomes I_6

[32] It is a rational section, but not a holomorphic one, when $\kappa^1 \cdot \kappa^2$ is non-empty.

[33] Consider the case X_n is a threefold. In the I_2 fibre of a such a codimension-2 point in the base B_2, σ_0 is a point in one of the two $\mathbb{P}^1$'s, and σ_1 wraps that $\mathbb{P}^1$. In the I_2 fibre over a $A_{1,0} = A_{0,1} = 0$ point, however, σ_0 wraps one of the two $\mathbb{P}^1$'s (being a rational section when $\kappa^1 \cdot \kappa^2$ is non-empty), while σ_1 wraps the other $\mathbb{P}^1$.

type of Kodaira classification unintentionally. The rest of this summary note focuses on the no.2 choice of the order of vanishing. It is not clear whether the choice of toric vectors in section 3 of [25] corresponds to any one of the order of vanishing in table 3.

Under the no.2 choice of the order of vanishing, singular Y_n can be made non-singular (denoted by $\hat{Y}_n$) by successive blow-ups of the ambient space; the same blow-up procedure as in [91], shown in figure 3 (b), does the job in this case. The proper transforms of the divisor D_1, D_∞ and $D_S = \pi_Y^*(S)$ are denoted by $\bar{D}_1$, $\bar{D}_\infty$ and $\bar{D}_S$, respectively.

$$\begin{aligned} D_S &= \bar{D}_S + E_1 + E_2 + E_3 + E_4, \\ D_1 &= \bar{D}_1 + E_1 + 2E_2 + 2E_3 + E_4, \\ D_\infty &= \bar{D}_\infty + E_1 + 2E_2 + 3E_3 + 2E_4. \end{aligned}$$

When we choose

$$\sigma_1'' \sim (D_2 - \kappa^2 - 2D_0 + 2K_B) \tag{A.14}$$

as a U(1) generator, the conditions $(\pi_Y \cdot \nu)_*(\sigma_0 \cdot \sigma_1'') = (\pi_Y \cdot \nu)_*(E_{1,2,3,4} \cdot \sigma_1'') = 0 \in \mathrm{Pic}(B_{n-1})$ are satisfied.

SU(5)-charged matter fields are localised in five distinct codimension-1 loci in S, as summarised in table 4. There, we used the following notations, as in [65, 92]:

$$B_{1,-1} =: sb_{1,-1|1}, \quad C_{-1,0} =: sc_{-1,0|1}, \quad C_{0,-1} =: s^3 c_{0,-1|3}, \quad C_{1,-2} =: s^5 c_{1,-2|5}. \tag{A.15}$$

The divisor classes of $\bar{\mathbf{5}}$-representation matter fields sum up to be $(-8K_B - 5S)|_S$, which is vital to the 6D box anomaly cancellation. There are also SU(5)-neutral, but U(1)-charged

JHEP11(2015)065

matter fields. Their location — codimension-two in B_{n-1} — is inferred by using the 6D anomaly cancellation conditions; we are led to the following solution:

$$\text{charge } \pm 2 \quad (\kappa^1 + \kappa^2 - K_B) \cdot (\kappa^1 + \kappa^2 - 2K_B) - 5S \cdot \kappa^1 \subset B_{n-1}, \tag{A.16}$$

$$\text{charge } \pm 1 \quad 16K_B^2 - 4(\kappa^1 + \kappa^2)^2 - 10S \cdot (-\kappa^1 + \kappa^2 - 2K_B) \subset B_{n-1}. \tag{A.17}$$

A part of the $B_{\rm sym} = C_{\rm sym} = 0$ locus for the charge-± 2 fields — $5S \cdot \kappa^1$ — has been subtracted, which is reasonable because the $B_{\rm sym} = C_{\rm sym} = 0$ conditions are satisfied automatically at $A_{1,0} = s = 0$.

When F-theory is compactified to 3+1-dimensions in this way, by using a Calabi-Yau fourfold $\hat{Y}_{n=4}$, geometric configuration of the matter curves on S is schematically like figure 3 (b). Most of the intersection points of the matter curves in S are one of the "E_6"-type, D_6 type and A_6-type, but none of those local descriptions apply to the intersection points where matter curves for $\mathbf{10}_0$, $\bar{\mathbf{5}}_2$ and $\bar{\mathbf{5}}_{-1}$-representations meet. The fibre of $(\pi_Y \cdot \nu) : \hat{Y}_4 \longrightarrow B_3$ is a surface F_1 at such points in B_3. Tensionless strings may show up in the effective theory on 3+1-dimensions in this case [29–31]. For phenomenological purposes, it is thus safe to restrict our attention to cases where the divisor class $\kappa^1|_S$ is trivial (so that $A_{1,0}|_S$ remains non-zero on S).

This $\kappa^1|_S = 0$ condition implies, first of all, that the $\bar{\mathbf{5}}_2$–$\mathbf{5}_{-2}$ matter fields do not appear in the low-energy spectrum. When this set-up with a U(1) symmetry is used for spontaneous R-parity violation scenario, matter identification should be the following. First, the up-type Higgs needs to be identified with the doublet part of $\mathbf{5}_0$ so that the up-type Yukawa couplings are generated. Secondly, for the charged lepton Yukawa couplings to be generated, L and H_d need to originate from $\bar{\mathbf{5}}_1$ and $\bar{\mathbf{5}}_{-1}$ or vice versa. $\bar{D}$'s of the supersymmetric Standard Models need to be on the same matter curve as L's in order for the down-type Yukawa couplings to be generated.

The $\kappa^1|_S = 0$ condition also implies that the splitting of the matter curve of $\bar{\mathbf{5}}$ representation in this set-up cannot be used for the hierarchical structure problem of the up-type Yukawa matrix. In the absence of the matter curve of $\bar{\mathbf{5}}_2$ matter field and of the interaction points indicated by a large circle (red) in figure 3 (b), all the "E_6" type points arise in the form of $\mathbf{10}_0$–$\mathbf{10}_0$–$\bar{\mathbf{5}}_0$ interaction points at $c_{-1,0|1} = B_{0,0} = 0$. Therefore, the result of [61, 62] that the number of "E_6"-type points is even still holds true.

B SU(6) 7-branes for up-type Yukawa coupling

Reference [12] introduced a class of F-theory compactifications with a stack of SU(6) 7-branes at the divisor S in the base B_3, which accommodates SU(5) unification and generates its up-type Yukawa couplings. Some details of the construction of this class of compactifications were missing in [12], however. Thanks to the development in the study of F-theory since then, we can fill the missing details now.

Let us first note that the class of F-theory compactification with an SU(6) 7-brane locus above is somewhat different from general F-theory compactification characterised by the Tate condition for the I_6-type singular fibre. To see this, remember that the Tate

JHEP11(2015)065

condition for the I_6-type singular fibre in a non-singular elliptic fibration $\pi : \hat{Y}_n \longrightarrow B_{n-1}$ corresponds to the following set of the order of vanishing of the coefficients in the generalised Weierstrass form [92]:

$$0 = y^2 + x^3 + A_1 xy + A_2 x^2 + A_3 y + A_4 x + A_6, \tag{B.1}$$

$$A_1 \sim s^0, \quad A_2 \sim s^1, \quad A_3 \sim s^3, \quad A_4 \sim s^3, \quad A_6 \sim s^6; \tag{B.2}$$

here, $s \in \Gamma(B; \mathcal{O}_B(S))$, and the $\{s = 0\}$ locus corresponds to the divisor S. It is thus convenient to write the Weierstrass equation in the following form:

$$y^2 + x^3 + a_5 xy + a_4 s x^2 + a_3 s^3 y + a_2 s^3 x + a_0 s^6 = 0. \tag{B.3}$$

where $a_{0,2,3,4,5}$ are holomorphic sections of appropriate line bundles on B_{n-1}.

When we consider F-theory compactification of this type to 3+1-dimensions, using a Calabi-Yau fourfold, straightforward analysis reveals that the matter curves in S are given by

$$\Sigma_{(\wedge^2 \mathbf{6})} : \quad a_5|_S = 0, \qquad \Sigma_{(\mathbf{6})} : \quad (a_2^2 - a_2 a_5 a_3 + a_0 a_5^2)|_S = 0; \tag{B.4}$$

Katz-Vafa type field theory for these matter fields are SO(12) (D_6) and SU(7) (A_6) gauge theories, respectively. These two matter curves intersect at points $a_5|_S = a_2|_S = 0$; physics around these points (including Yukawa couplings) is captured by a field theory with SO(14) (D_7) gauge group. We cannot expect an up-type Yukawa coupling of the form $\Delta W \sim \mathbf{10}\cdot\mathbf{10}\cdot\mathbf{5}\cdot\epsilon\cdots$ in such a class of F-theory compactifications [12, 93].

An idea of ref. [12] is to use Heterotic compactification, and to translate and generalise it in the language of F-theory compactification. To be more explicit, imagine a Heterotic string compactification on an elliptic fibred Calabi-Yau threefold (Z, S, π), where $\pi : Z \longrightarrow S$, with a vector bundle $V_3 \oplus V_2$ whose structure group is $\mathrm{SU}(3) \times \mathrm{SU}(2) \subset E_8$. V_3 and V_2 are given by the Fourier-Mukai transform of spectral data $(C_3, \mathcal{N}_3)$ and $(C_2, \mathcal{N}_2)$, where C_3 and C_2 are divisors of Z that are 3-fold and 2-fold covering over S, respectively, and $\mathcal{N}_3$ and $\mathcal{N}_2$ are line bundles on C_3 and C_2, respectively. For generic complex structure of Z, the spectral surfaces C_3 and C_2 are given by

$$c_0 + c_2 x + c_3 y = 0, \qquad d_0 + d_2 x = 0, \tag{B.5}$$

respectively, where

$$c_k \in \Gamma(S; \mathcal{O}_S(kK_S + \eta_3)), \qquad d_k \in \Gamma(S; \mathcal{O}_S(kK_S + \eta_2)) \tag{B.6}$$

for some divisors $\eta_{2,3}$ of S. The F-theory dual of this compactification should be given by (Y_4, B_3), where the base threefold $B_3 = \mathbb{P}\left[\mathcal{O}_S(6K_S + \eta_3 + \eta_2) \oplus \mathcal{O}_S\right]$ is a $\mathbb{P}^1$-fibration over S, and the elliptic fibre of $\pi : Y_4 \longrightarrow B_3$ is given by [17, 58, 94–96]

$$y^2 = x^3 + f_0 x s^4 + g_0 s^6 + (c_0 s^3 + c_2 s x + c_3 y)(d_0 s^2 + d_2 x), \tag{B.7}$$

where s is an inhomogeneous coordinate of the $\mathbb{P}^1$-fibre in $B_3 \longrightarrow S$.

JHEP11(2015)065

Now, we generalise it to general B_3 and its effective divisor S, and define $\pi : Y_4 \longrightarrow B_3$ by the same equation as above; the coefficients f_0, g_0, c_k's and d_k's, however, are promoted to holomorphic sections on B_3 as follows:

$$c_k \in \Gamma(B_3; \mathcal{O}_B((k-4)K_B + a + (k-3)S)), \qquad f_0 \in \Gamma(B_3; \mathcal{O}_B(-4K_B - 4S), \tag{B.8}$$

$$d_k \in \Gamma(B_3; \mathcal{O}_B(-a + (k-2)(K_B + S))), \qquad g_0 \in \Gamma(B_3; \mathcal{O}_B(-6K_B - 6S), \tag{B.9}$$

where a is some divisor on B_3; this is a generalisation, in that the translation from Heterotic string compactification is reproduced by setting $(2K_S + \eta_2) = -a|_S$ and $(6K_S + \eta_2 + \eta_3) = S|_S = c_1(N_{S|B_3})$.

One can read out from the discriminant and singularity of this generalised Weierstrass form that there are three distinct matter curves,[34]

$$\Sigma_{(\wedge^3\mathbf{6})} : \ d_2|_S = 0, \tag{B.10}$$

$$\Sigma_{(\wedge^2\mathbf{6})} : \ c_3|_S = 0, \tag{B.11}$$

$$\Sigma_{(\mathbf{6})} : \ (c_3^2 d_0^3 + c_2^2 d_0^2 d_2 - 2c_0 c_2 d_0 d_2^2 + c_0^2 d_2^3 + c_3^2 d_0 d_2^2 f_0 - c_3^2 d_2^3 g_0)|_S = 0. \tag{B.12}$$

Those three curves intersect at $c_3|_S = d_2|_S = 0$ points in S. We can choose the gauge group of the Katz-Vafa type field theory (field theory local model) around these matter curves to be E_6, D_6, A_6; physics around a $c_3|_S = d_2|_S = 0$ point is described by an E_7 gauge theory; a non-trivial Higgs bundle background with the structure group $\mathrm{SU}(2) \times \mathrm{U}(1) \subset E_7$ breaks the E_7 symmetry down to SU(6); Yukawa coupling $\Delta W = \mathbf{6} \cdot \wedge^2\mathbf{6} \cdot \wedge^3\mathbf{6}$ is generated at each one of those $c_3|_S = d_2|_S = 0$ points.

Such an SU(6) 7-brane configuration in F-theory can be used for SU(5) unification by turning on a line bundle on S, so that the symmetry is reduced to SU(5); further breaking to the Standard Model gauge group is not impossible, although we stay away from such details. There are two possible particle identifications. The first possibility is to identify SU(5)-**10** matter fields with the $\wedge^3\mathbf{6}$ representation of SU(6), and $H(\mathbf{5})$ within **adj**. of SU(6) [12]; the other possibility is to find the **10** matter field in $\wedge^2\mathbf{6}$ of SU(6), when the $H(\mathbf{5})$ field also has to come from the same $\wedge^2\mathbf{6}$ representation of SU(6); the latter possibility was overlooked in [12]. In any one of those two possibilities, Yukawa couplings are generated along the entire matter curve ($\Sigma_{(\wedge^3\mathbf{6})}$ or $\Sigma_{(\wedge^2\mathbf{6})}$), not only at isolated points in the 7-brane S (cf [18]). This makes it impossible to exploit the approximately codimension-1 nature of Yukawa matrices from isolated Yukawa points [58–60]. The idea of [78–80] (or something similar to the one in [61]) may still be implemented in the latter identification with a tuning $j(\Sigma_{(\wedge^2\mathbf{6})}) \gg 1$; it is desirable to have a separate study to see if that is the case, however.

Before closing this section, we compute $h^{3,1}$ for Calabi-Yau fourfolds with such an SU(6) unification. We choose $(B_3, [S])$ to be $B_3 = \mathbb{P}^1 \times \mathbb{P}^2$ and $[S] = \mathrm{pt} \times \mathbb{P}^2$, so the result can be compared with $h^{3,1}$ for other classes of compactifications with a rank-5 symmetry

[34] The linearised analysis [97] is able to determine the defining equation of the spectral cover for associated bundles such as $(V_3 \otimes V_2)$ approximately. All the terms except those involving f_0 or g_0 in the defining equation of $\Sigma_{(\mathbf{6})}$ can be obtained in that way.

Table 5. $h^{3,1}$ of Calabi-Yau fourfolds for SU(6) unification, provided $B_3=\mathbb{P}^1\times\mathbb{P}^2$ and $[S]=\mathrm{pt}\times\mathbb{P}^2$.

(SO(10) and SU(5) × U(1)) in the main text. The choice of $(B_3,[S])$ above introduces a constraint[35] in the Heterotic string language: $(3K_S+\eta_2)+(3K_S+\eta_3)=0$. See table 5 for the results.[36]

C Monodromy around the U(1)-enhancement limit

C.1 $6g-3$ topological four-cycles

This appendix C begins with a brief review. We came to be interested in section 4.1 in a compact Calabi-Yau fourfold Y_4 with its complex structure parameter in $\mathcal{M}_*$ close to the $\mathcal{M}_*^{\mathrm{U}(1)}$ locus; Y_4 contains a local geometry of deformed conifold along a curve Σ, and this local geometry of Y_4 is modelled by a geometry Y_{local}, which is explained shortly. Four-cycles in Y_{local} as well as their lift to the global geometry Y_4 was studied in [57]; results of [57] that we need in section 4.1 are reviewed here. The review is followed by analysis of monodromy of those cycles and period integrals.

The local geometry model Y_{local}, which is denoted by $\widetilde{X}^\flat$ in [57], is realised as a hypersurface of the total space of a rank-4 vector bundle over a Riemann surface Σ,

$$\mathcal{L}^{\otimes 3}\oplus\mathcal{L}^{\otimes 3}\oplus\mathcal{L}^{\otimes 2}\oplus\mathcal{L}^{\otimes 4}\longrightarrow\Sigma, \tag{C.1}$$

where the Riemann surface Σ satisfies $6|(2g(\Sigma)-2)$, and $\mathcal{L}^{\otimes 6}=K_\Sigma$. The defining equation of Y_{local} in this ambient space is

$$YA_3=XA_4+A_6; \tag{C.2}$$

Y, A_3, X and A_4 are the coordinates of the rank-4 fibre of the bundle in (C.1), and

$$A_6\in\Gamma(\Sigma;K_\Sigma)\cong\mathbb{C}^g=:\mathcal{M}_*^{\mathrm{local}} \tag{C.3}$$

[35] Intuitively, this constraint means that the instanton number is distributed equally into the hidden and visible sectors; $(6K_S+\eta_0)=0=-(6K_S+\eta_\infty)$.

[36] Computation was done by partially using a reasoning available in the Heterotic dual supergravity regime. An elliptic fibred Calabi-Yau threefold over base $\mathbb{P}^2$ for Heterotic string compactification has 273 moduli (272 for complex structure and 1 for the volume of T^2-fibre), first of all. Automorphism of the Calabi-Yau three-fold has already been exploited. The hidden sector E_8 vector bundle comes with 1502 moduli, which is verified easily in F-theory language. We counted the vector bundle moduli of SU(2)×SU(3) in the visible sector by counting the degree of freedom in the spectral surfae:

$$\mathrm{SU}(2):\quad \frac{(n_2+11)(n_2+10)}{2}+\frac{(n_2+5)(n_2+4)}{2}-1, \tag{B.13}$$

$$\mathrm{SU}(3):\quad \frac{(n_3+11)(n_3+10)}{2}+\frac{(n_3+5)(n_3+4)}{2}+\frac{(n_3+2)(n_3+1)}{2}-1, \tag{B.14}$$

where n_2 and n_3 parametrise the distribution of instanton numbers in the SU(2), SU(3) vector bundles through $\eta_2=n_2H_{\mathbb{P}^2}$, $\eta_3=n_3H_{\mathbb{P}^2}$.

JHEP11(2015)065

governs the complex structure of this local geometry; this $A_6 \in \Gamma(\Sigma; K_\Sigma)$ descends from $A_6 \in \Gamma(B_3; \mathcal{O}_B(-6K_B))$ on the compact set-up by simple restriction on $\Sigma \subset B_3$. $\mathcal{L}^{\otimes 6} := \mathcal{O}_\Sigma(-6K_B|_\Sigma)$ is the same as K_Σ, because of the adjunction formula for $\Sigma := \{A_3 = A_4 = 0\} \subset B_3$. The g-dimensional space $\mathcal{M}_*^{\text{local}}$ is regarded as the g directions normal to $\mathcal{M}_*^{\text{U}(1)}$ in $\mathcal{M}_*$, at least when B_3 is a Fano variety.

Reference [57] identified $6g-3$ four-cycles in this local fourfold geometry Y_{local}. Let $Z := \partial\overline{Y_{\text{local}}}$ be the boundary, which is a seven dimensional manifold over $\mathbb{R}$. Using a long exact sequence

$$0 \longrightarrow H_4(Z;\mathbb{Z}) \longrightarrow H_4(Y_{\text{local}};\mathbb{Z}) \longrightarrow H_4^{BM}(Y_{\text{local}};\mathbb{Z}) \longrightarrow H_3(Z;\mathbb{Z}) \longrightarrow 0, \tag{C.4}$$

it turns out that both $H_4(Y_{\text{local}};\mathbb{Q})$ and $H_4^{BM}(Y_{\text{local}};\mathbb{Q})$ are of dimension $4g-3$; kernels and cokernels of the homomorphisms in the exact sequence above introduces a filtration structure

$$H_4(Y_{\text{local}};\mathbb{Q}) \supset \left(H_4(Y_{\text{local}};\mathbb{Q})\right)^0 =: \text{Span}_{\mathbb{Q}}\left\{\widetilde{A}_{i=1,\cdots,g}, \widetilde{A}'^{j=1,\cdots,g}\right\}, \tag{C.5}$$

$$H_4(Y_{\text{local}};\mathbb{Q}) \,/\, \left(H_4(Y_{\text{local}};\mathbb{Q})\right)^0 =: \text{Span}_{\mathbb{Q}}\left\{[\widetilde{B}_\ell] \mid \ell = 1,\cdots,2g-3\right\}, \tag{C.6}$$

and

$$H_4^{BM}(Y_{\text{local}};\mathbb{Q}) \supset \left(H_4^{BM}(Y_{\text{local}};\mathbb{Q})\right)^0 =: \text{Span}_{\mathbb{Q}}\left\{\widetilde{B}'_\ell \mid \ell = 1,\cdots,2g-3\right\}, \tag{C.7}$$

$$H_4^{BM}(Y_{\text{local}};\mathbb{Q}) \,/\, \left(H_4^{BM}(Y_{\text{local}};\mathbb{Q})\right)^0 =: \text{Span}_{\mathbb{Q}}\left\{[\widetilde{C}]^{i=1,\cdots,g},\ [\widetilde{C}']_{j=1,\cdots,g}\right\}; \tag{C.8}$$

Overall, $2g + (2g-3) + 2g$ four-cycles, $\widetilde{A}$'s, $\widetilde{B}$'s and $\widetilde{C}$'s are identified in either $H_4(Y_{\text{local}})$ or $H_4^{BM}(Y_{\text{local}})$. The intersection pairing $H_4(Y_{\text{local}};\mathbb{Q}) \times H_4^{BM}(Y_{\text{local}};\mathbb{Q}) \longrightarrow \mathbb{Q}$ vanishes on $\left(H_4(Y_{\text{local}};\mathbb{Q})\right)^0 \times \left(H_4^{BM}(Y_{\text{local}};\mathbb{Q})\right)^0$.

The four-cycles $\tilde{A}_i$'s and $\widetilde{A}'^j$'s are the nearly vanishing S_3 cycle (often referred to as the A-cycle) of deformed conifold fibred over the one-cycles α_i's and β^j of the genus g curve Σ. Four-cycles $\widetilde{B}_\ell$'s ($\ell = 1,\cdots,2g-3$), on the other hand, are topologically S_4, and arise in the form of S_3 fibred over intervals I_ℓ on Σ; the interval I_ℓ ($\ell = 1,\cdots,2g-3$) is stretched between a pair of points $p_0, p_\ell \in \Sigma$, where $\{p_0, p_{\ell=1,\cdots,2g-3}\} \subset \Sigma$ are the zeros of the section $A_6 \in \Gamma(\Sigma; K_\Sigma)$. Choice of the interval I_ℓ (between p_0 and p_ℓ) comes with freedom of $+H_1(\Sigma;\mathbb{Z})$; this is how the filtration structure arises in $H_4(Y_{\text{local}};\mathbb{Z})$; by choosing an interval I_ℓ, a representative four-cycle $\widetilde{B}_\ell$ is chosen for a quotient class $[\widetilde{B}_\ell]$. Geometric description of the four-cycles $\widetilde{C}$'s is given later in this appendix.

Period integral is defined for all of these $6g-3$ four-cycles in Y_{local}; their period integrals should depend on the g independent moduli of $\mathcal{M}_*^{\text{local}}$. Let $\{\lambda^i\}_{i=1,\cdots,g}$ be the 1-forms of Σ normalised so that $\int_{\alpha_i}\lambda^j = \delta_i^{\ j}$. By parameterising A_6 on Σ (and parameterising also $\mathcal{M}_*^{\text{local}}$) as

$$A_6 = \sum_i z_i \lambda^i, \tag{C.9}$$

we can write down the period integrals for the four-cycles $\widetilde{A}$'s as

$$\Pi_{\widetilde{A}_i} = z_i, \qquad \Pi_{\widetilde{A}'^j} = \tau^{jk} z_k, \tag{C.10}$$

JHEP11(2015)065

where $\tau^{jk} := \int_{\beta^j} \lambda^k$ is the period matrix of the curve Σ. The period integrals for the four-cycles $\widetilde{B}_\ell$'s are given by

$$\Pi_{\widetilde{B}_\ell} = \tilde{\mu}(p_\ell)^i z_i, \tag{C.11}$$

using the lift of Abel-Jacobi map

$$\tilde{\mu} : \Sigma \ni q \longmapsto \left(\int_{p_0}^{q} \lambda^1, \int_{p_0}^{q} \lambda^2, \cdots, \int_{p_0}^{q} \lambda^g \right) \in \mathbb{C}^g; \tag{C.12}$$

although the Abel-Jacobi map itself depends only on the parameters in $\mathcal{M}_*^{\mathrm{U}(1)}$, dependence on the $\mathcal{M}_*^{\mathrm{local}}$ parameters in $\Pi_{\widetilde{B}_\ell}$ comes in through p_ℓ's as well as z_i's. When the interval I_ℓ from p_0 to p_ℓ is changed by $H_1(\Sigma;\mathbb{Z})$, the period integral $\Pi_{\widetilde{B}_\ell}$ changes by $n^i \Pi_{\widetilde{A}_i} + m_j \Pi_{\widetilde{A}'^j}$ for some $n^i, m_j \in \mathbb{Z}$. This transformation constitutes a part of the modular group [57].

Some of the four-cycles $\widetilde{A}$'s in $H_4(Y_{\mathrm{local}})$ in the local geometry may not be regarded as topological cycles $H_4(Y_4)$ in the global geometry; all the $\widetilde{A}$'s can be deformed to be topological cycles in $Z = \partial\overline{Y_{\mathrm{local}}}$, and such a four-cycle may, in principle, be obtained as a boundary of a five-cycle in $Y_4 \backslash Y_{\mathrm{local}}$. The relation $(-\Delta h^{3,1}) = g$ for the global geometry Y_4 (which holds at least when B_3 is a Fano), and its consequence $\tilde{h}^{2,1} = 0$, in particular, implies that all of the $2g$ four-cycles $\widetilde{A}$'s remain to be topological four-cycles of the global geometry Y_4. Similarly, the four-cycles $\widetilde{C}$'s in $H_4^{BM}(Y_{\mathrm{local}})$ can be regarded as topological cycles of Y_4, only when their boundaries in $H_3(\partial\overline{Y_{\mathrm{local}}})$ are obtained also as boundaries of some cycles in $H_4^{BM}(Y_4 \backslash \overline{Y_{\mathrm{local}}})$. The Poincare duality indicates, however, that all of these $2g$ four-cycles $\widetilde{C}$'s are also lifted to those in the global geometry Y_4, at least when B_3 is Fano. In the conifold transition at the $A_6 \longrightarrow 0$ limit, those $2g + (2g-3) + 2g$ topological four-cycles shrink, and one four-cycle ($\mathbb{P}^1$ for small resolution over the curve Σ) emerges in the global geometry Y_4; $-\Delta h^{3,1} = -\Delta h^{1,3} = g$, and $-\Delta h^{2,2} = (4g-3) - 1 = 4(-\Delta h^{3,1} - \Delta h^{1,1})$. See [57] for more information.

C.2 Monodromy

In order to study monodromy of those four-cycles in the local geometry Y_{local}, we assume that Σ is a hyperelliptic curve in this appendix C.2:

$$t^2 = P(s); \qquad P(s) = -\prod_{i=1}^{2g+2} (s - s_i); \tag{C.13}$$

we further assume that all the s_i's are real valued, and

$$0 < s_1 < s_2 \ll s_3 < s_4 \ll \cdots \ll s_{2g-1} < s_{2g} \ll s_{2g+1} < s_{2g+2}. \tag{C.14}$$

although a higher genus curve Σ is not always in the form of a hyperelliptic curve, complex structure of Σ can be continuously deformed from the one chosen above; since we are interested primarily in questions of topological nature, it is enough to study for Σ given above.

Before getting into the study of monodromy, we first need to have a concrete construction of the cycles $\widetilde{C}^i$'s ($i = 1, \cdots, g$), whose monodromy we are interested in. Math

JHEP11(2015)065

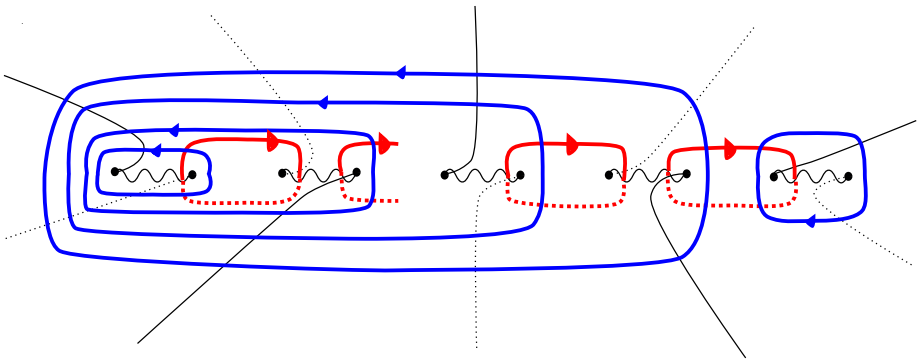

Figure 4. (colour online) A hyperelliptic curve Σ is obtained by gluing together two sheets of this s-plane ($\mathbb{C} \cup \{\infty\}$) along the branch cuts (wavy lines) between s_1–s_2, s_3–s_4, $\cdots$, s_{2g+1}–s_{2g+2}; this picture is drawn for the case with $g = 4$. Description of line bundles $\mathcal{L}^{\otimes k}$ requires branch cuts in the $U^{(s)}$ patch; the cuts for this purpose are drawn in thin (solid or dotted) lines in this figure. Thick grey (red) loops, from left to right, are the cycles α_1, α_2 (drawn partially), α_{g-1} and α_g. Thick dark (blue) loops, from left to right, are β^1, β^2, β^{g-1} and β^g; one more remaining loop in the thick dark (blue) line at the right end of this picture is β'^g; β^g and β'^g are isomorphic in Σ, but they are not within the $U^{(s)}$ patch.

preparation is thus in order here. The line bundle $K_\Sigma = \mathcal{L}^{\otimes 6}$ can be described by three Zariski open patches of Σ.

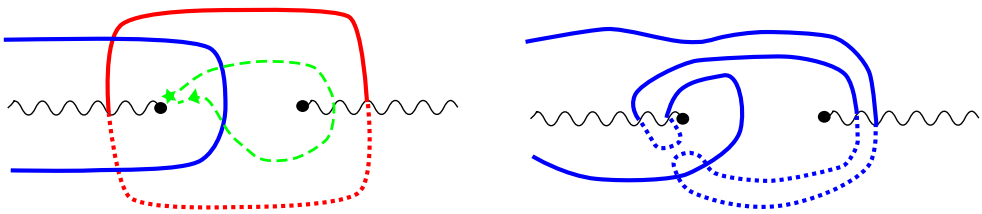
$$U^{(s)}: \quad t \neq 0, \infty; \qquad U^{(t)}: \quad P'(s) \neq 0,\ s \neq \infty; \qquad U^{(\infty)}: \quad s \neq 0, s_i. \tag{C.15}$$

Sections of K_Σ are written down in the form of $A = a^{(s)}ds$, $A^{(t)}dt$ and $A^{(\infty)}d(1/s)$ in the $U^{(s)}$, $U^{(t)}$ and $U^{(\infty)}$ patch, respectively; these trivialisation descriptions are identified by using transition functions:

$$a^{(t)} = \frac{2t}{P'(s)}a^{(s)}, \qquad a^{(\infty)} = (-s^2)a^{(s)}. \tag{C.16}$$

$H^0(\Sigma; K_\Sigma)$ is of g dimensions, and are of the form[37]

$$A_6^{(s)}ds = \frac{c_0 + c_1 s + \cdots + c_{g-1}s^{g-1}}{t}ds = \frac{c_0(1/s)^{g-1} + \cdots c_{g-1}}{(t/s^{g+1})}d(1/s) = A_6^{(\infty)}d(1/s). \tag{C.17}$$



The fibre coordinates Y of $\mathcal{L}^{\otimes 3}$ and X of $\mathcal{L}^{\otimes 2}$, for example, become $Y^{(s)}$, $Y^{(t)}$ and $Y^{(\infty)}$, and $X^{(s)}$, $X^{(t)}$ and $X^{(\infty)}$, respectively, in the trivialisation patches, and are identified between the overlapping patches as in

$$Y^{(t)} = \left(\frac{2t}{P'(s)}\right)^{3/6} Y^{(s)}, \qquad X^{(t)} = \left(\frac{2t}{P'(s)}\right)^{2/6} X^{(s)}. \tag{C.18}$$

Branch cuts are introduced in these $U^{(s)}$, $U^{(t)}$ and $U^{(\infty)}$; see figure 4 for the branch cuts in the $U^{(s)}$ patch; the coordinates $Y^{(s)}$ and $X^{(s)}$ at one point in $U^{(s)} \subset \Sigma$ and the coordinates

[37] There must be a linear relation between $\{c_0, c_1, \cdots, c_{g-1}\}$ and z_i's ($i = 1, \cdots, g$) in (C.9), but we do not need to know it in detail.

JHEP11(2015)065

(a) (b)

Figure 5. (colour online) (a) A loop γ_k ($k = 1, \cdots, g-1$) in the $\mathcal{M}_*^{\rm local} \cong \mathbb{C}^g$ parameter space is given by continuously changing the parameter a_k in the s-plane, starting from $s = s_{2k}$, going around $s = s_{2k+1}$ and returning to $s = s_{2k}$, as shown by a dashed (green) arrow line in this picture. At the end of this deformation procedure, the loop β^k has been deformed in the way shown in (b) by a thick solid (blue) line.

$Y^{(s)\prime}$ and $X^{(s)\prime}$ at the same point that we reach after circling around a branch point (where $t = 0$) by phase $+2\pi$ are identified through

$$Y^{(s)\prime} = Y^{(s)} \times \zeta_6^{-3}, \qquad X^{(s)\prime} = X^{(s)} \times \zeta_6^{-2}; \qquad \zeta_6 := e^{\frac{2\pi i}{6}}. \tag{C.19}$$

Fibre coordinates need to be identified through similar relations also across the branch cuts in $U^{(t)}$ and $U^{(\infty)}$. Equations (C.18) are made well-defined in this way. The same holds true also for the fibre coordinates A_3 and A_4.

Let us take a point $q \in U^{(s)} \subset \Sigma$. The local fourfold geometry $Y_{\rm local}$ has a three-dimensional fibre

$$Y^{(s)} A_3^{(s)} = X^{(s)} A_4^{(s)} + A_6^{(s)}; \tag{C.20}$$

$Y^{(s)}$, $A_3^{(s)}$, $X^{(s)}$ and $A_4^{(s)}$ are coordinates, while $A_6^{(s)}$ is a parameter. This is a deformed conifold, and there is a canonical choice of compact three-cycle and a semi-canonical choice of non-compact three-cycle intersecting at one point; they are referred to as A-cycle and B-cycle; the choice of the B-cycle is not canonical, in that the B-cycle is deformed to be $B+A$ topologically, when the complex phase of the parameter $A_6^{(s)}$ changes as $A_6^{(s)} \longrightarrow A_6^{(s)} \times e^{i\alpha}$, $\alpha \in [0, 2\pi]$, as well-known in deformed conifold.

Now, we are ready to provide description of the $2g$ remaining four-cycles, $\widetilde{C}^{i=1,\cdots,g}$ and $\widetilde{C}'_{j=1,\cdots,g}$ in $Y_{\rm local}$. Since this task is topological in nature, we can choose the parameter $A_6 \in \mathcal{M}_*^{\rm local}$ arbitrarily; we choose it to be

$$A_6 = A_6^* := \epsilon \frac{(s - s_*)^{g-1}}{t} ds, \qquad s_{2g+2} \ll s_* \in \mathbb{R} \tag{C.21}$$

for now. First of all, the cycles $\widetilde{A}_{i=1,\cdots,g}$ and $\widetilde{A}'^{j=1,\cdots,g}$ are the A-cycle fibred over the one-cycles $\alpha_{i=1,\cdots,g}$ and $\beta^{j=1,\cdots,g}$ in Σ, as in the appendix C.1; see figure 4 for how to choose the basis of $H_1(\Sigma; \mathbb{Z})$. Secondly, for this choice of A_6^*, the cycles $\widetilde{B}_{\ell=1,\cdots,2g-3}$ are all located in the $s \sim s_* \gg s_{2g+2}$ region; we see after constructing $\widetilde{C}$'s that $\widetilde{B}_\ell$'s and $\widetilde{A}$–$\widetilde{C}$'s are mutually orthogonal in the intersection form. Finally, we claim that the B-cycle of the deformed conifold comes back to itself, not to $B + mA$ with $m \neq 0$, after a point $q \in \Sigma$ moves along any one of $\{\alpha_i, \beta^j\}$. To verify this claim, first note that the loop β^k crosses

JHEP11(2015)065

the branch cut in $U^{(s)}$ for k-times in the counter-clockwise direction; this means that the fibre coordinate of $\mathcal{L}^{\otimes a}$ at the end of a loop along β^k is $\zeta_6^{-a\times k} = e^{-2\pi i\times\frac{a\cdot k}{6}}$ times the one at the beginning of the loop. The parameter $(A_6^*)^{(s)}$, on the other hand, changes its phase by $e^{-2\pi ik}$ due to the factor $1/t$. Those two phases on both sides of (C.20) cancel, and there is no net change in the phase of the deformation parameter (not even a multiple of 2π) along the loop β^k. Thus, the B-cycle comes back to itself. The B-cycle fibred over β^k $(k=1,\cdots,g)$ forms a four-cycle $\widetilde{C}^k$. Similarly, we note that the loop α_k crosse the branch cuts in $U^{(s)}$ for (-1) times in the counter-clockwise direction. The parameter $(A_6^*)^{(s)}$ changes its phase by $e^{+2\pi i}$ due to the factor $1/t$, on the other hand. Those two effects cancel, and there is no net change in the phase. Thus, the B-cycle comes back to itself at the end of the loop α_k. This is how a four-cycle $\widetilde{C}'_k$ is obtained $(k=1,\cdots,g)$. By construction, $\widetilde{A}_i\cdot\widetilde{C}^j=\delta_i^{\ j}$, $\widetilde{A}'^k\cdot\widetilde{C}'_h=\delta^k_{\ h}$, and the intersection number vanishes for all other combinations of $\widetilde{A}$'s and $\widetilde{C}$'s.

Finally, we study monodromy of those four-cycles in $Y_{\rm local}$. Monodromy is studied for loops departing and returning to a reference point in $\mathcal{M}_*^{\rm local}=\mathbb{C}^g$, and we choose

$$A_6=A_6^{**}:=\epsilon\frac{(s-s_2)(s-s_4)\cdots(s-s_{2(g-1)})}{t}ds \tag{C.22}$$

as the reference point.[38,39] At this reference point, let $\widetilde{A}_k$ and $\widetilde{A}'^k$ $(k=1,\cdots,g)$ be the four-cycle given by the A-cycle along α_k and β^k, respectively. $g-1$ more four-cycles $\widetilde{C}^k$ $(k=1,\cdots,g-1)$ are the B-cycle fibred over $\beta^k+k\alpha_k$ in Σ; this loop in Σ crosses $+k$ times along β^k and $k\times(-1)$ times along $k\alpha_k$, and there is no net change in the phase of A_6^{**} along the loop. One more four-cycle, $\widetilde{C}^g$, is the B-cycle fibred over a one-cycle $\beta'^g\sim\beta^g$ on Σ shown in figure 4. We will focus on monodromy associated with those $3g$ four-cycles.

It is convenient to adopt the following parameterisation of $\mathcal{M}_*^{\rm local}\cong H^0(\Sigma;K_\Sigma)$:

$$A_6=\epsilon\frac{(s-a_1)(s-a_2)\cdots(s-a_{g-1})}{t}ds,\qquad\{(\epsilon,a_1,\cdots,a_{g-1})\}\in\mathbb{C}^g. \tag{C.23}$$

The reference point A_6^{**} corresponds to choosing $a_k=s_{2k}$ for $k=1,\cdots,g-1$. Loops γ_k for $k=1,\cdots,g-1$ in $\mathcal{M}_*^{\rm local}$ are such that a_k is changed continuously in the s-plane in the way designated in figure 5 (a), while the value of ϵ and all other a_m's $(m=1,\cdots,g-1$ but $m\neq k)$ are held fixed. One can keep track of topology of the four-cycles $\widetilde{A}$'s and $\widetilde{C}$'s along the loop γ_k in $\mathcal{M}_*^{\rm local}$, by deforming the one-cycles $\beta^m+m\alpha_m$ $(m=1,\cdots,g-1)$ and β'^g so that the zero of $A_6^{(s)}$ is avoided. This is enough to conclude that all the $3g$ four-cycles, namely, $\widetilde{A}$'s, $\widetilde{A}'$'s and $\widetilde{C}$'s, remain the same at the end of a loop γ_k except $\widetilde{C}^k$. Furthermore, because the one-cycle β^k needs to be deformed as in figure 5 (b) at the end

[38]The point A_6^* in $\mathcal{M}_*^{\rm local}$ is useful in that all the $6g-3$ four-cycles can be constructed systematically. The point A_6^{**} is more convenient as the reference point of the monodromy study. This is just a matter of convenience.

[39]The degree $2g-2$ divisor corresponding to this choice of $A_6=A_6^{**}$ is a collection of the $g-1$ points $\{(s,t)=(s_{2i},0)\mid i=1,\cdots,g-1\}\subset\Sigma$ with multiplicity 2 for all of them. They are the $2g-2$ points $\{p_0,\cdots,p_{2g-3}\}$ used in construction of the four-cycles $\widetilde{B}_\ell$'s [57].

JHEP11(2015)065

of the loop γ_k, there is a non-trivial monodromy

$$\gamma_k : \left(\widetilde{A}_k, \widetilde{C}^k\right) \to \left(\widetilde{A}_k, \widetilde{C}^k\right) \begin{pmatrix} 1 & 1 \\ & 1 \end{pmatrix}, \qquad \left(\widetilde{A}_{m\neq k}, \widetilde{A}'^j, \widetilde{C}^{m\neq k}\right) \to \left(\widetilde{A}_{m\neq k}, \widetilde{A}'^j, \widetilde{C}^{m\neq k}\right). \tag{C.24}$$

We study monodromy along one more loop γ_ϵ in $\mathcal{M}_*^{\text{local}}$, which is to change the phase of the parameter ϵ by 2π, while all the a_m's with $m = 1, \cdots, g-1$ are held fixed. Topological cycles $\widetilde{A}_k$'s for $k = 1, \cdots, g$ remain the same under the complex structure deformation along γ_ϵ. Topological cycles $\widetilde{C}^k$'s are not, however. These cycles are all in the form of the B-cycle fibred over some one-cycle in Σ; after complex structure deformation along γ_ϵ, the original B-cycle comes back as $B + A$-cycle. This means that

$$\gamma_\epsilon : \widetilde{C}^{k\neq g} \longmapsto \widetilde{C}^k + k\widetilde{A}_k + \widetilde{A}'^k, \qquad \widetilde{C}^g \longmapsto \widetilde{C}^g + \widetilde{A}'^g. \tag{C.25}$$

This is enough to conclude that the period integrals depend on ϵ as

$$\Pi_{\widetilde{A}_k}, \quad \Pi_{\widetilde{A}'^k} \sim \epsilon, \qquad \Pi_{\widetilde{C}^{k\neq g}} \sim \left(\tau^{km} z_m + k z_k\right) \ln(\epsilon), \qquad \Pi_{\widetilde{C}^g} \sim (\tau^{gm} z_m) \ln(\epsilon). \tag{C.26}$$

It is a much more involved problem to determine the full monodromy group repreesnted on the space of $6g-3$ four-cycles, and also the period integrals. We do not do so in this article, since we do not need such a thorough analysis for the sketchy argument in the main text.

計画研究 B04 班

課題名「テラスケール物理における世代構造の研究」

研究組織

(1) 研究代表者

久野純治（HISANO, Junji）
名古屋大学・基礎理論研究センター・教授
研究者番号：60300670

(2) 研究分担者

前川展祐（MAEKAWA, Nobuhiro）
名古屋大学・基礎理論研究センター・准教授
研究者番号：40273429

進藤哲央（SHINDOU, Tetsuo）
工学院大学・基礎・教養教育部門・准教授
研究者番号：60553039

(3) 連携研究者

棚橋誠治（TANABASHI, Masaharu）
名古屋大学・理学研究科・教授
研究者番号：00270398

戸部和弘(TOBE, Kazuhiro)
名古屋大学・理学研究科・准教授
研究者番号：20451510

(4) 協力研究者

津村浩二（TSUMURA, Koji）
大村裕司（OMURA, Yuji）
阿部智広（ABE, Tomohiro）
F. Beye
永田夏海（NAGATA, Natumi）
村松祐（MURAMATSU, Yu）
榎本成志（ENOMOTO, Seishi）
冬頭かおり（FUYUTO, Kaori）
他、名古屋大学学生、ポスドクなど。

交付決定額

計画研究 B04 班に配分された交付額を表 1 に示す。

表 1. 交付決定額（配分額）　（金額単位：円）

年度	直接経費	間接経費	合計
平成 23 年度	3,300,000	990,000	4,290,000
平成 24 年度	7,600,000	2,280,000	9,880,000
平成 25 年度	7,700,000	2,310,000	10,010,000
平成 26 年度	7,300,000	2,190,000	9,490,000
平成 27 年度	7,300,000	2,190,000	9,490,000
総計	33,200,000	9,960,000	43,160,000

研究成果

1．研究開始当初の背景

クォーク・レプトンの持つ世代の階層構造の存在は、素粒子標準模型における大きな謎の 1 つである。この謎を解決するにはクォーク・レプトンがいかにして質量を獲得したのかを

理解する必要ﾊﾞあるとともに、素粒子模型の入れ物となる時空の構造の解明ﾊﾞ不可欠でﾞある。素粒子質量の起源を司るヒッグﾞス粒子、そして時空構造から予言される超対称粒子やカルザﾞー・ク ライン粒子ﾊﾞ LHC 実験でﾞ発見されればﾞ、世代構造の理解に向けて大きな一歩となる。

レﾌﾟトンやハドﾞロンの低エネルギﾞーでﾞの精密測定実験に加え、LHC 実験によって新粒子の質量や相互作用の測定ﾊﾞなされればﾞテラスケール物理の全貌ﾊﾞ明らかになり、世代の理解ﾊﾞさらに深まる。新粒子ﾊﾞ世代に依存した相互作用を持つかもしれないからだﾞ。特にその存在ﾊﾞ有望視されている超対称性や余剰次元はクォーク・レﾌﾟトンのﾊﾟートナーの粒子の存在を予言し、それらの相互作用や質量に新たな世代構造ﾊﾞ現れる。クォーク・レﾌﾟトンの質量の階層構造は余剰次元におけるクォーク・レﾌﾟトンの配位から導かれるという指摘ﾊﾞなされている。大統一理論の痕跡ﾊﾞ世代に依存して超対称粒子の相互作用に現れることﾊﾞ議論されている。テラスケール物理は豊富な世代の情報を持っており、その理解を通してテラスケール物理の背後にある物理を探ることﾊﾞでﾞきる。

テラスケール物理における世代構造の理解は宇宙の物質・反物質非対称性の起源の理解につなﾊﾞる。三世代を予言した小林・益川理論は観測されている素粒子過程の物質・反物質非対 称性(CP 非対称性)をよく説明する一方でﾞ、宇宙の物質・反物質非対称性を説明するには不十分でﾞある。LHC 実験でﾞ複数のヒッグﾞス粒子やクォーク・レﾌﾟトンのﾊﾟートナーの粒子ﾊﾞ発見されればﾞ、新たな CP 非対称性の起源の可能性ﾊﾞ出てくる。新粒子の性質、特にその粒子ﾊﾞ導く CP 非対称性を研究することにより、テラスケール物理による宇宙の物質(ﾊﾞリオン数)生成の可能 性や、ニュートリノ質量起源と密接な関係のあるシーソー機構によるレﾌﾟトジﾞェネシス(宇宙のレﾌﾟトン数生成)の理解ﾊﾞ大きく進むと期待される。

２．研究の目的

クォーク・レﾌﾟトンの持つ世代の階層構造の存在は、素粒子物理学の大きな謎の 1 つでﾞある。素粒子模型の入れ物でﾞある時空の構造ﾊﾞ LHC 実験により明らかになればﾞ世代構造の理解に向けて大きな一歩となる。本研究計画は、テラスケール物理における世代構造の解明、テラスケールを超える新しい素粒子像の構築、そして宇宙の物質・反物質非対称性の起源の解明を目指す。

レﾌﾟトンやハドﾞロンの低エネルギﾞーでﾞの精密測定結果に加え、LHC 実験によって新粒子の質量 や相互作用の測定結果を用いることでﾞ、テラスケール物理のもつ世代構造の全貌を明らかにする。時空構造と関係のある超対称性や余剰次元ﾊﾞクォーク・レﾌﾟトンのﾊﾟートナーの粒子の存在を予言し、テラスケール物理は標準模型よりも遙かに豊かな世代構造を持つ。その構造を明らかにすることでﾞ、さらにテラスケール物理の背後にある物理を探る。力と物質の統一の大統 一理論の構築、余剰次元空間内でﾞのクォーク・レﾌﾟトンの配位による世代構造の出現、ニュートリノ質量の起源を解明する。これによりテラスケール物理を超えた、新しい素粒

子像の構築を行う。

テラスケール物理における世代構造の理解は宇宙の物質・反物質非対称性の起源の解明に繋がる。新粒子の性質、特にその粒子の持つ物質・反物質非対称性を研究することにより、テラスケール物理による宇宙の物質(バリオン数)生成の可能性を明らかにし、また、ニュートリノ質量起源と密接な関係のあるシーソー機構によるレプトジェネシス(宇宙のレプトン数生成)の解明を行う。

3．研究の方法

(1) レプトン、ハドロンの電気双極子能率や希過程の探索から超対称模型や余剰次元模型の構造、期待される質量スペクトラム、そして LHC 実験での事象のパターンを明らかにする。
(2) 代表的なテラスケールの模型において宇宙のバリオン数生成が可能であるかどうかを明らかにし、そこから LHC 実験や低エネルギー実験においてどの様なシグナルがでるのかを明らかにする。
(3) 中性子やミューオン(g-2)などテラスケール物理に 感度ある観測量を際評価し、そのテラスケール物理の予言をする際の不定性を明らかにする。
(4) LHC 実験において超対称粒子やカルザー・クライン粒子が発見された際には、新粒子のスペクトラムをもとに模型を選別し、残された可能性をさらに絞り込むための研究を行う。
(5) 超対称粒子が発見された際には、そこから期待されるよりニュートリノ質量の起源、レプトジェネシス、大統一理論に向けてより基本的な理論 の構築を行い、陽子崩壊、レプトンやハドロンの電気双極子能率や希過程など低エネルギー実験によるその検証の可能性を検討する。
(6) 新しいテラススケール物理が発見されなかった場合 今日までの素粒子物理学の考察から考えて、テラスケールを大きく超えてまで新しい物理が存在しないことは考えにくい。新しい物理のスケールを探るべく、低エネルギー実験、LHC 実験と矛盾のない理論を再検討し、より高いエネルギースケールを間接的ならも探ることのできるレプトンやハドロンの電気双極子能率や希過程でその理論がその兆候が検出可能かどうか を明らかにする。

4．研究成果

(1) フレーバーの物理

標準模型を超える理論に電気双極子能率(EDM)は感度がある。久野は、クォークの EDM、カラーEDM の中性子 EDM への寄与を QCD 和則、次元 6 までの CP 対称性を破る相互作用のウィルソン係数のくりこみ群の方程式の導出など、中性子の EDM の系統的な評価のための研究を行

った。また標準模型を超える理論として、観測されたヒッグス粒子の質量から期待される超対称性の破れが 100TeV 程度の MSSM、電弱バリオン数生成を導く四世代模型やヒッグス拡張模型などの模型における EDM を評価し、模型に制限を与えるとともに、将来実験での検証の可能性の議論をした。

久野は、超対称性の破れが 100TeV 程度の模型の可能性として新たな物質場やゲージ場の導入が考えられ、その MSSM とは異なるフレーバーの物理の予言が有ることを示した。また、進藤は、超対称性シーソー模型におけるレプトンフレーバーを破る過程の研究を行った。LHC で測定された 125GeV のヒッグス質量をインプットとしてあつかった場合に，$\mu \to e\gamma$ や $\tau \to \mu\gamma$ などのプロセスに対し，どのような予言が得られるかを明らかにした。また、進藤はニュートリノ質量が TeV である可能性を探り、模型の構築を行った。

(2) ヒッグスセクターの物理

久野は、SU(2)二重項のヒッグス場以外で ρ パラメータを自然に 1 する可能性として SU(2)七重項がある。SU(2)七重項を含む現実的な模型を構築し、その現象論的予言を明らかにした。

また、久野はヒッグス場と電弱相互作用をする暗黒物質との有効理論を構築し、そこから期待される現象の整理を行った。

進藤は、ヒッグスセクターの拡張により、ニュートリノ質量が量子補正によって生じる模型を構築し、その現象論的研究を行った。LHC 等の実験によって模型が検証可能であることを示した。また，電弱バリオン数生成に必要な強い 1 次相転移が可能であることをあきらかにした。また、別の拡張ヒッグス模型において久野は電弱バリオン数生成により宇宙のバリオン数生成の説明が可能かを明らかにした。

(3) 大統一模型の研究

X ボゾンによる陽子崩壊は大統一理論の検証において非常に重要である。久野はその予言の信頼度を上げるため、超対称模型の枠組みで GUT スケールでの量子効果、陽子崩壊の演算子への 2 ループでの量子補正を評価し予言に取り込んだ。また、観測されたヒッグス粒子の質量を説明する可能性として、新たな物質場を導入や大きな超対称性の破れの導入がある。これらの模型における陽子崩壊の予言を明らかにし、将来実験との関係を明らかにした。また、前川は物質場が大統一の場にどのように埋め込まれているかを陽子崩壊の様々なモードの分岐比の研究から明らかにできることを示した。

世代対称性を持つ E6 大統一理論は自発的に CP 対称性を破るとクォークセクターは小林-益川位相の起源を説明しつつ超対称 CP 問題を解く等多くの利点が知られていたがニュートリノは現実と合わないと思われていたが、前川はニュートリノに関しても現実を再現するだけで無く後に確認された Ue3 に対 する予言も通常の E6 大統一理論と同様になっていることを示した。またこの模型における宇宙のレプトン数生成の可能性を明らかにした。

(Received 18 April 2012; published 26 June 2012)

We study the neutron electric dipole moment in the presence of the *CP*-violating operators up to dimension five in terms of the QCD sum rules. It is found that the operator product expansion calculation is robust when exploiting a particular interpolating field for a neutron, while there exist some uncertainties on the phenomenological side. By using input parameters obtained from the lattice calculation, we derive a conservative limit for the contributions of the *CP*-violating operators. We also show the detail of the derivation of the sum rules.

I. INTRODUCTION

A variety of experimental efforts [1] has precisely determined the elements of the Cabibbo-Kobayashi-Maskawa (CKM) matrix [2,3], which is a source of *CP* violation in the standard model (SM). All of *CP*-violating processes ever observed are well-explained in terms of the single physical phase in the CKM matrix. The SM, which is based on the $SU(3)_C \times SU(2)_L \times U(1)_Y$ gauge symmetry, allows another *CP*-violating interaction: the θ term in the QCD sector. The *CP*-violating phenomena caused by the interaction are, however, quite different from those induced by the CKM phase; the QCD θ term gives rise to the *CP* violation in the flavor-conserving processes, while the CKM phase induces the *CP* violation in the flavor-changing ones. Furthermore, TeV-scale physics beyond the SM, such as the minimal supersymmetric standard model, often provides other *CP*-violating sources. In fact, additional *CP*-violating interactions are necessary from the cosmological point of view, since the observed baryon asymmetry in the Universe is not explained within the SM interactions.

The electric dipole moment (EDM) of the neutron is one of the physical quantities that are quite sensitive to the *CP* violation in the flavor-conserving interaction. Since there has been no experimental evidence for its existence so far, a severe constraint is imposed on the *CP*-violating interactions. The currently most stringent limit for the neutron EDM is given by the Institut Laue-Langevin experiment [4]:

$$|d_n| < 2.9 \times 10^{-26}\ e\,\mathrm{cm} \qquad (90\%\ \mathrm{C.L.}). \tag{1}$$

Moreover, several experimental projects which use ultracold neutrons are now under development and expected to have much improved sensitivities. For example, the nEDM Collaboration at the Paul Scherrer Institute [5] plans to deliver a sensitivity of $\sim 5 \times 10^{-27}\ e$ cm and eventually to reach into the regime of $10^{-28}\ e$ cm. Similar sensitivities are expected to be achieved by the nEDM Collaboration at the Spallation Neutron Source at the U.S. Oak Ridge National Laboratory [6], the CryoEDM experiment [7], the NOP Collaboration at J-PARC [8], and the experiment at KEK-RCNP-TRIUMF [9]. Such high sensitivities provide an opportunity to probe the flavor-conserving *CP*-violating interactions in the TeV-scale physics beyond the SM. Furthermore, we may probe the flavor violation in the new physics indirectly. Even if the new flavor-violating interactions are introduced in the new physics, the relative *CP* phase between them and the CKM matrix may contribute to the EDM [10].

In order to translate the experimental limits for the neutron EDM into constraints on the *CP* violation on the Lagrangian at the parton level, one needs to obtain a relation between these two quantities. There are some attempts to derive the relation based on the naive dimensional analysis, the chiral perturbation theory, and the QCD sum rules, though they are considered to have large uncertainties. It is ultimately desired that the lattice QCD simulation would evaluate it in the future. There has been discussion of evaluation of the neutron EDM with lattice simulation [11].

In this work, we evaluate the neutron EDM with the QCD sum rules [12], including the *CP*-violating operators up to dimension five. It is considered that the QCD sum rules allow us to derive the relation more systematically than the naive dimensional analysis and the chiral perturbation theory [13]. Similar attempts have been already made in the previous works, e.g., in a series of papers by Pospelov and Ritz [14,15], and references therein. We also derive the sum rules for the neutron EDM, while we use the lattice QCD simulation result for the low-energy constant in the numerical evaluation of the neutron EDM. It is found that this gives a more conservative estimate than carrying out all of the evaluation within the framework of the QCD sum rules. This approach provides a way of eliminating theoretical errors from the calculation, while there still

 © 2012 American Physical Society

remains uncertainty resulting from the QCD sum rule technique itself.

This paper is organized as follows. In Sec. II, we review the *CP*-violating interactions at the parton level up to dimension five. From Sec. III, the analysis of the neutron EDM with the QCD sum rules starts. In Sec. III, we discuss phenomenological aspects of the correlator of the interpolating field to a neutron and, in Sec. IV, show the properties of the neutron-interpolating field. In Sec. V, the quark propagators are derived on the *CP*-violating and electromagnetic background. They are used to evaluate the operator product expansion (OPE) for the correlator in Sec. VI. The sum rules for the neutron EDM are derived in Sec. VII. We found that there is a difference between results in Refs. [14,15] and ours. In Sec. VIII, we extract the low-energy constant from the lattice QCD simulation result. In Sec. IX, our numerical results for the neutron EDM are derived. In Sec. X, the neutron EDM is discussed assuming that the Peccei-Quinn symmetry solves the strong *CP* problem [16]. Section XI is devoted to conclusion and discussion.

In the appendix, we show some useful formulas to derive the quark condensates in the *CP*-violating background. In Appendix A 1, we estimate the effect of the *CP*-violating interactions on the generic quark bilinear condensate $\langle 0|\bar{q}\Gamma q|0\rangle$, with Γ a 4×4 constant matrix, as well as on the quark and gluon background fields. In Appendix A 2, validity of the usage of the classical equations of motion of quarks in evaluation of the quark condensates is discussed. In Appendix A 3, the Wilson-line operators for the quark fields are discussed in the Fock-Schwinger gauge.

II. EFFECTIVE LAGRANGIAN

Let us first express the flavor-conserving *CP*-violating terms in the low-energy effective Lagrangian for the system consisting of light quarks and a gluon. We include all of the *CP*-violating operators up to dimension five:

$$\mathcal{L}_{\not CP} = -\sum_{q=u,d,s} m_q \bar{q} i\theta_q \gamma_5 q + \theta_G \frac{\alpha_s}{8\pi} G^A_{\mu\nu}\tilde{G}^{A\mu\nu} - \frac{i}{2}\sum_{q=u,d,s} d_q \bar{q}(F\cdot\sigma)\gamma_5 q - \frac{i}{2}\sum_{q=u,d,s}\tilde{d}_q \bar{q} g_s (G\cdot\sigma)\gamma_5 q. \tag{2}$$

Here, m_q represents the quark masses, $F_{\mu\nu}$ and $G^A_{\mu\nu}$ are the electromagnetic and gluon field strength tensors, respectively, g_s is the strong coupling constant ($\alpha_s = g_s^2/4\pi$), $F\cdot\sigma \equiv F_{\mu\nu}\sigma^{\mu\nu}$, $G\cdot\sigma \equiv G^A_{\mu\nu}\sigma^{\mu\nu}T^A$, and $\tilde{G}^A_{\mu\nu} \equiv \frac{1}{2}\epsilon_{\mu\nu\rho\sigma}G^{A\rho\sigma}$ with $\epsilon^{0123} = +1$. T^A denotes the generators in the $SU(3)_C$ algebra. The second, third, and fourth terms in Eq. (2) are called the effective QCD θ term and the electric and chromoelectric dipole moments (CEDMs) for quarks, respectively. The EDMs and CEDMs for quarks are dimension-five operators, and they are sensitive to the TeV-scale physics beyond the SM. The coefficients of the *CP*-violating operators (θ_q, θ_G, d_q, and $\tilde{d}_q$) are all assumed to be quite small, and we keep only the terms up to the first order of these parameters.

The first two terms in Eq. (2) are mutually related by the chiral rotation. Consider the following infinitesimal chiral rotation:

$$q \to q' = (1 - i\epsilon\rho_q\gamma_5)q, \tag{3}$$

where ϵ is an infinitesimal real constant and ρ_q are certain parameters for each quark. The Noether current associated with the transformation is given as

$$J_{5\mu} = \sum_{q=u,d,s}\rho_q \bar{q}\gamma_\mu\gamma_5 q. \tag{4}$$

The divergence of this current does not vanish. Instead,

$$\partial^\mu J_{5\mu} = \frac{\alpha_s}{4\pi}\Big(\sum_q \rho_q\Big)G^A_{\mu\nu}\tilde{G}^{A\mu\nu} + \sum_q 2im_q\rho_q\bar{q}\gamma_5(1 + i\theta_q\gamma_5)q - \sum_q \rho_q[d_q\bar{q}(F\cdot\sigma)q + \tilde{d}_q\bar{q}g_s(G\cdot\sigma)q]. \tag{5}$$

Hereafter we choose ρ_q as

$$\rho_q = \theta_q/\theta_Q, \qquad \theta_Q \equiv \sum_{q=u,d,s}\theta_q. \tag{6}$$

Then, if we take the infinitesimal parameter in Eq. (3) as $\epsilon = \theta_Q/2$, the Lagrangian in Eq. (2) varies by

$$\delta\mathcal{L} = \partial^\mu J_{5\mu}\cdot\frac{\theta_Q}{2} = \sum_q m_q\bar{q}i\theta_q\gamma_5 q + \theta_Q\frac{\alpha_s}{8\pi}G^a_{\mu\nu}\tilde{G}^{a\mu\nu}, \tag{7}$$

which implies that

$$\mathcal{L}_{\not CP} \to \mathcal{L}'_{\not CP} = \bar{\theta}\frac{\alpha_s}{8\pi}G^A_{\mu\nu}\tilde{G}^{A\mu\nu} - \frac{i}{2}\sum_{q=u,d,s} d_q\bar{q}(F\cdot\sigma)\gamma_5 q - \frac{i}{2}\sum_{q=u,d,s}\tilde{d}_q\bar{q}g_s(G\cdot\sigma)\gamma_5 q, \tag{8}$$

where $\bar{\theta} = \theta_G + \theta_Q$.

Therefore, it is found that the γ_5-mass terms are always reduced to the ordinary ones, and it is $\bar{\theta}$ that is regarded as a physical parameter. Of course, one may in turn rotate out the θ term into the imaginary mass term through an appropriate chiral rotation.

In addition, there remains still some arbitrariness in the quark mass phases θ_q, since they are redefined into another through an $SU(3)$ chiral rotation. In this paper, we choose an appropriate set of θ_q so that the choice significantly reduces the *CP*-violating contribution to the vacuum expectation values of the quark bilinear. We take the condition in Ref. [17] to determine θ_q; that is, after the θ term

rotated into the γ_5-mass term, the following relation should be satisfied:

$$\langle \Omega_{\not CP} | \mathcal{L}_{\not CP} | M^A \rangle = 0 \qquad (M^A = \pi, K, \eta). \tag{9}$$

The above condition is evaluated by using the partially conserved axial-vector current (PCAC) relations. In the current case, it is sufficient to examine the conditions for π^0 and η^0. By using the PCAC relations, one may readily deduce the conditions for the CP-violating parameters from Eq. (9):

$$\begin{aligned} \bar{\theta}(m_u\rho_u - m_d\rho_d) &= \tfrac{1}{2}m_0^2(\tilde{d}_u - \tilde{d}_d), \\ \bar{\theta}(m_u\rho_u + m_d\rho_d - 2m_s\rho_s) &= \tfrac{1}{2}m_0^2(\tilde{d}_u + \tilde{d}_d - 2\tilde{d}_s). \end{aligned} \tag{10}$$

In the calculation we parametrize the condensate $\langle \bar{q} g_s (G \cdot \sigma) q \rangle$ as [18]

$$\langle \bar{q} g_s (G \cdot \sigma) q \rangle = -m_0^2 \langle \bar{q} q \rangle. \tag{11}$$

With the relation $\sum_q \rho_q = 1$, we then determine the quark mass phases as follows:

$$\begin{aligned} \rho_u &= \frac{m_*}{m_u}\left[1 + \frac{m_0^2}{2\bar{\theta}}\left\{\frac{\tilde{d}_u - \tilde{d}_d}{m_d} + \frac{\tilde{d}_u - \tilde{d}_s}{m_s}\right\}\right], \\ \rho_d &= \frac{m_*}{m_d}\left[1 + \frac{m_0^2}{2\bar{\theta}}\left\{\frac{\tilde{d}_d - \tilde{d}_u}{m_u} + \frac{\tilde{d}_d - \tilde{d}_s}{m_s}\right\}\right], \\ \rho_s &= \frac{m_*}{m_s}\left[1 + \frac{m_0^2}{2\bar{\theta}}\left\{\frac{\tilde{d}_s - \tilde{d}_u}{m_u} + \frac{\tilde{d}_s - \tilde{d}_d}{m_d}\right\}\right], \end{aligned} \tag{12}$$

where

$$m_* \equiv \frac{m_u m_d m_s}{m_u m_d + m_d m_s + m_u m_s}. \tag{13}$$

III. PHENOMENOLOGICAL BEHAVIOR OF THE CORRELATOR

The QCD sum rules are based on an analysis of the correlator of interpolating fields.[1] In the method, OPE allows one to consistently separate the long- and short-distance contributions to the correlator, and the long-distance contributions are evaluated by condensations of quarks and a gluon. By comparing the evaluated correlator with the phenomenological model, the properties for the low-lying parts of the hadronic spectrum are derived. The Borel transformation is applied to the correlator there. In this section, we first discuss the phenomenological model for the correlator.

In the present case, the interpolating field must have the same quantum numbers as those of the neutron, and it is denoted by $\eta_n(x)$ hereafter. On a background with CP-violating sources, the matrix element of the interpolating field between the vacuum and the one-particle neutron state is given as

$$\langle \Omega_{\not CP} | \eta_n(x) | N_{\not CP}(\boldsymbol{p}, s) \rangle = Z^{(1/2)}_{n,\not CP} \cdot u_{n,CP}(\boldsymbol{p}, s) e^{-ip\cdot x}, \tag{14}$$

where $|\Omega_{\not CP}\rangle$ and $|N_{\not CP}(\boldsymbol{p}, s)\rangle$ indicate the vacuum and the one-particle neutron state on the CP-violating background, respectively. The spinor $u_{n,\not CP}(\boldsymbol{p}, s)$ is the on-shell neutron wave function which satisfies the Dirac equation:

$$(\not{p} - m_{n,\not CP} \cdot e^{-i\alpha_n\gamma_5}) u_{n,\not CP}(\boldsymbol{p}, s) = 0. \tag{15}$$

Here we include a phase factor $e^{-i\alpha_n\gamma_5}$ into the mass term, which in general might appear as CP is broken in the vacuum. Since $Z^{(1/2)}_{n,\not CP}$ and $m_{n,\not CP}$ are both even in terms of the CP-violating parameters [11], up to the first order of them,

$$Z^{(1/2)}_{n,\not CP} = Z^{(1/2)}_n, \qquad m_{n,\not CP} = m_n, \tag{16}$$

where m_n is the mass of the neutron and $\lambda_n \equiv Z^{(1/2)}_n$ is the coupling between the physical neutron state and the interpolating field without CP-violating sources. Then the solution of Eq. (15) turns out to be

$$u_{n,\not CP}(\boldsymbol{p}, s) = e^{(i/2)\alpha_n\gamma_5} u_n(\boldsymbol{p}, s), \tag{17}$$

with $u_n(\boldsymbol{p}, s)$ an ordinary spinor wave function which satisfies $(\not{p} - m_n) u_n(\boldsymbol{p}, s) = 0$. As a result, Eq. (14) leads to

$$\langle \Omega_{\not CP} | \eta_n(x) | N_{\not CP}(\boldsymbol{p}, s) \rangle = \lambda_n e^{(i/2)\alpha_n\gamma_5} u_n(\boldsymbol{p}, s) e^{-ip\cdot x}. \tag{18}$$

The low-energy constant λ_n is to be determined later.

Now we analyze the correlator of the interpolating fields from the phenomenological viewpoint. It is defined as

$$\Pi(q) \equiv i \int d^4x e^{iq\cdot x} \langle \Omega_{\not CP} | T\{\eta_n(x) \bar{\eta}_n(0)\} | \Omega_{\not CP} \rangle_F, \tag{19}$$

where the subscript F implies that the correlator is evaluated on an electromagnetic field background. Our goal is to extract the EDM of the neutron from the correlator. The phase factor in Eq. (18), however, causes a mixture between electric and magnetic dipole moment structures and makes it difficult to pick out only the EDM from the QCD sum rules. So we first examine the Lorentz structures of the correlator and select a term independent of the phase α_n, i.e., chiral-invariant. As discussed in Ref. [14], up to the leading order on the background electromagnetic field, the correlator $\Pi(q)$ is estimated by inserting an effective vertex such as

$$\mathcal{L}_n = -\frac{i}{2} d_n \bar{N}(F \cdot \sigma)\gamma_5 N = \frac{d_n}{2} \bar{N} \tilde{F} \cdot \sigma N. \tag{20}$$

Here, N [$\equiv N(x)$] denotes the renormalized neutron field which is approximately equivalent to $\lambda_n^{-1} e^{-i\alpha_n\gamma_5/2} \eta_n(x)$, and d_n is the EDM of the neutron. A similar procedure to those in Ref. [14] shows that terms with an odd number of Dirac matrices are independent of the phase factor α_n, and furthermore, those proportional to $\{\tilde{F} \cdot \sigma, \not{q}\}$ are the unique choice in this case. Therefore we focus only on such terms

[1] There are many review articles about the QCD sum rules. For example, see Ref. [19].

in the following calculation. Then, the phenomenological expression of the correlator is found to be[2]

$$\Pi^{(\mathrm{phen})}(q) = \tfrac{1}{2} f(q^2)\{\tilde{F}\cdot\sigma, \not{q}\} + \cdots, \tag{21}$$

where dots indicate terms with other Lorentz structures and

$$f(q^2) = \left(\frac{\lambda_n^2 d_n m_n}{(q^2 - m_n^2)^2} + \frac{A(q^2)}{q^2 - m_n^2} + B(q^2)\right) \tag{22}$$

with $A(q^2)$ and $B(q^2)$ functions which have no pole at $q^2 = m_n^2$. As noted in Ref. [14], since we are effectively dealing with a three-point function, it might be inconsistent to parametrize the continuum contribution in terms of a usual ansatz for the spectral function with a certain threshold in the QCD sum rules. We just neglect the contribution with expecting its significance to be small enough. Furthermore, we assume that the function $A(q^2)$ has little dependence on q^2 and regard it as a constant when we conduct the Borel transformation.

IV. NEUTRON-INTERPOLATING FIELD

In this section, we give a discussion on the choice of the neutron-interpolating field which we use for the QCD sum rule calculation. The field must have the same quantum numbers as the neutron. The most general interpolator for the neutron on the ordinary CP-even background is parametrized as

$$\eta_n(x) = j_1(x) + \beta j_2(x), \tag{23}$$

where

$$j_1(x) = 2\epsilon_{abc}(d_a^T(x)C\gamma_5 u_b(x))d_c(x) \tag{24}$$

and

$$j_2(x) = 2\epsilon_{abc}(d_a^T(x)Cu_b(x))\gamma_5 d_c(x). \tag{25}$$

Here the subscripts a, b, and c denote the color indices, and C is the charge conjugation matrix. The interpolator $j_1(x)$ is often used in lattice simulations. While $j_2(x)$ vanishes in the nonrelativistic limit, it should be included to the whole interpolating field since we deal with light quarks. The unphysical parameter β is to be fixed later so that the calculation is transparent.

When the calculation is carried out on the CP-violating background, however, the interpolating fields include additional components. This point is easily understood when one considers the chiral rotation discussed in Sec. II. As we have seen in Sec. II, the chiral rotation (3) transforms the Lagrangian $\mathcal{L}$ into another. The same transformation, in turn, changes the interpolators $j_1(x)$ and $j_2(x)$ into other ones as

$$\begin{aligned} j_1(x) &\to j_1(x) - i\epsilon[(\rho_u + \rho_d)i_1(x) + \rho_d i_2(x)], \\ j_2(x) &\to j_2(x) - i\epsilon[(\rho_u + \rho_d)i_2(x) + \rho_d i_1(x)], \end{aligned} \tag{26}$$

where

$$\begin{aligned} i_1(x) &= 2\epsilon_{abc}(d_a^T(x)Cu_b(x))d_c(x), \\ i_2(x) &= 2\epsilon_{abc}(d_a^T(x)C\gamma_5 u_b(x))\gamma_5 d_c(x). \end{aligned} \tag{27}$$

Therefore, with generic CP-violating terms as in Eq. (2), the interpolators acquire mixing terms as

$$\begin{aligned} \tilde{j}_1(x) &= j_1(x) + i\epsilon i_1(x) + i\delta i_2(x), \\ \tilde{j}_2(x) &= j_2(x) + i\epsilon i_2(x) + i\delta i_1(x), \\ \tilde{i}_1(x) &= i_1(x) + i\epsilon j_1(x) + i\delta j_2(x), \\ \tilde{i}_2(x) &= i_2(x) + i\epsilon j_2(x) + i\delta j_1(x), \end{aligned} \tag{28}$$

with ϵ and δ the small constants which are suppressed by the CP-violating parameters. Furthermore, the above expressions are rewritten as

$$\begin{aligned} \tilde{j}_1(x) &= (1 + i\delta\gamma_5)[j_1(x) + i\epsilon i_1(x)], \\ \tilde{j}_2(x) &= (1 + i\delta\gamma_5)[j_2(x) + i\epsilon i_2(x)], \\ \tilde{i}_1(x) &= (1 + i\delta\gamma_5)[i_1(x) + i\epsilon j_1(x)], \\ \tilde{i}_2(x) &= (1 + i\delta\gamma_5)[i_2(x) + i\epsilon j_2(x)], \end{aligned} \tag{29}$$

because

$$i_1(x) = \gamma_5 j_2(x), \qquad i_2(x) = \gamma_5 j_1(x). \tag{30}$$

Now that we concentrate on the chiral-invariant structure in the correlator of the neutron-interpolating field as discussed in Sec. III, the infinitesimal chiral rotation factor $(1 + i\delta\gamma_5)$ is ignorable. After all, the neutron-interpolating field which we deal with has the following structure:

$$\eta_n(x) = j_1(x) + \beta j_2(x) + i\epsilon[i_1(x) + \beta i_2(x)]. \tag{31}$$

The small constant ϵ is determined by the condition that the interpolating field $\eta_n(x)$ has a vanishing correlator with the current $\xi_n(x)$ defined as follows:

$$\xi_n(x) = i_1(x) + \beta i_2(x) + i\epsilon[j_1(x) + \beta j_2(x)]. \tag{32}$$

In what follows, however, we sweep away the contribution of the mixture terms in the interpolating field by choosing an appropriate value for the parameter β. In the subsequent sections, we calculate the correlator of $\eta_n(x)$ by using the OPE method. The correlator is expressed by the sum of the correlators for each component interpolator as

$$\begin{aligned} &\langle\Omega_{\not{CP}}|T\{\eta_n(x)\bar{\eta}_n(0)\}|\Omega_{\not{CP}}\rangle_F \\ &\quad= \langle j_1, \bar{j}_1\rangle + \beta[\langle j_1, \bar{j}_2\rangle + \langle j_2, \bar{j}_1\rangle] + \beta^2\langle j_2, \bar{j}_2\rangle \\ &\qquad + i\epsilon[\gamma_5\langle j_2, \bar{j}_1\rangle + \langle j_1, \bar{j}_2\rangle\gamma_5] + i\epsilon\beta[\{\langle j_1, \bar{j}_1\rangle, \gamma_5\} \\ &\qquad + \{\langle j_2, \bar{j}_2\rangle, \gamma_5\}] + i\epsilon\beta^2[\gamma_5\langle j_1, \bar{j}_2\rangle + \langle j_2, \bar{j}_1\rangle\gamma_5], \end{aligned} \tag{33}$$

[2]In the published versions of Refs. [14,15], the coefficient of the double pole in Eq. (22) is different from ours by a factor of 2, while that in the revised arXiv versions is consistent with ours.

where

$$\langle a, \bar{b}\rangle \equiv \langle \Omega_{\not{C}P}|T\{a(x)\bar{b}(0)\}|\Omega_{\not{C}P}\rangle_F. \tag{34}$$

As discussed in Sec. III, we focus on parts of the correlators which have the Lorentz structures with an odd number of gamma matrices. Such terms anticommute with γ_5. Thus, in this case, the above expression leads to

$$\begin{aligned}&\langle \Omega_{\not{C}P}|T\{\eta_n(x)\bar{\eta}_n(0)\}|\Omega_{\not{C}P}\rangle_F|_{\gamma\ \text{odd}}\\ &= \langle j_1, \bar{j}_1\rangle + \beta[\langle j_1, \bar{j}_2\rangle + \langle j_2, \bar{j}_1\rangle] + \beta^2\langle j_2, \bar{j}_2\rangle\\ &\quad + i\epsilon(1-\beta^2)[\langle j_1, \bar{j}_2\rangle - \langle j_2, \bar{j}_1\rangle]\gamma_5.\end{aligned} \tag{35}$$

This equation shows that the mixing terms in the interpolating field do not affect the correlator if one sets β to be ± 1. As we will see later, for our calculation, $\beta = +1$ is an appropriate choice, since this choice eliminates the subleading terms with an infrared logarithm, which yields ambiguity due to the infrared cutoff.[3] With this choice, one may simultaneously exclude the contribution of the mixing terms. Thus, we will not calculate such mixing contributions with keeping in mind that we will finally take $\beta = +1$ when we derive the QCD sum rules.[4] That is to say, we deal with the correlator

$$\begin{aligned}&\langle \Omega_{\not{C}P}|T\{\eta_n(x)\bar{\eta}_n(0)\}|\Omega_{\not{C}P}\rangle_F\\ &= \langle j_1, \bar{j}_1\rangle + \beta[\langle j_1, \bar{j}_2\rangle + \langle j_2, \bar{j}_1\rangle] + \beta^2\langle j_2, \bar{j}_2\rangle,\end{aligned} \tag{37}$$

and after the computation, we set $\beta = +1$.

V. QUARK PROPAGATORS ON THE *CP*-VIOLATING BACKGROUND

When evaluating the correlator (19) in the OPE, we need to obtain the quark propagators on the CP-violating background with an electromagnetic background field F. They are defined as follows:

$$[S^q_{ab}(x)]_{\alpha\beta} \equiv \langle \Omega_{\not{C}P}|T[q_{a\alpha}(x)\bar{q}_{b\beta}(0)]|\Omega_{\not{C}P}\rangle_F, \tag{38}$$

where α and β denote spinor indices. Expanding the propagators as

$$\begin{aligned}[S^q_{ab}(x)]_{\alpha\beta} &= [S^{q(0)}_{ab}(x)]_{\alpha\beta} + \chi^q_{a\alpha}(x)\bar{\chi}^q_{b\beta}(0)\\ &\quad + [S^q_{ab}(x)]_{\alpha\beta}|_{1\text{photon}} + [S^q_{ab}(x)]_{\alpha\beta}|_{1\text{gluon}} + \cdots,\end{aligned} \tag{39}$$

we evaluate each term in x space. The first term is the free propagator, and the second term describes the correlator of the quark background fields, with $\chi^q_{a\alpha}(x)$ a classical Grassmann field which indicates the quark background field. The third and fourth terms represent the propagators including one photon and gluon, respectively. In the derivation of the quark propagators we use the classical equations of motion for quark fields given as

$$\begin{aligned}i\not{D}q &= m_q(1 + i\theta_q\gamma_5)q + \frac{i}{2}\sum_{q=u,d,s} d_q(F\cdot\sigma)\gamma_5 q\\ &\quad + \frac{i}{2}\sum_{q=u,d,s}\tilde{d}_q g_s(G\cdot\sigma)\gamma_5 q,\\ -i\bar{q}\overleftarrow{\not{D}} &= m_q\bar{q}(1 + i\theta_q\gamma_5) + \frac{i}{2}\sum_{q=u,d,s} d_q\bar{q}(F\cdot\sigma)\gamma_5\\ &\quad + \frac{i}{2}\sum_{q=u,d,s}\tilde{d}_q g_s\bar{q}(G\cdot\sigma)\gamma_5,\end{aligned} \tag{40}$$

where $D_\mu = \partial_\mu - ie_q A_\mu - ig_s G^A_\mu T^A$ and $\bar{q}\overleftarrow{\not{D}} = \partial_\mu\bar{q}\gamma^\mu + ie_q\bar{q}\not{A} + ig_s\bar{q}G^A T^A$. The electromagnetic and gluon fields are denoted as A_μ and G^A_μ, respectively, with e_q the quark charge.

The first term in Eq. (39), $[S^{q(0)}_{ab}(x)]_{\alpha\beta}$, is readily evaluated by using the equations of motion without electromagnetic and gluon background fields. The result is

$$S^{q(0)}_{ab}(x) = \frac{i\delta_{ab}}{2\pi^2}\frac{\not{x}}{(x^2)^2} - \frac{m_q\delta_{ab}}{4\pi^2 x^2}(1 - i\theta_q\gamma_5), \tag{41}$$

where we keep the terms up to the first order of the quark mass m_q.

Next, we evaluate the third and fourth terms in Eq. (39). These terms again are obtained from the equations of motion (40). In this calculation, it is convenient to use the Fock-Schwinger gauge [21] for both the electromagnetic and the gluon fields:

$$x^\mu A_\mu(x) = x^\mu G^A_\mu(x) = 0. \tag{42}$$

In this gauge, the fields are expanded by their field strength, such as

$$\begin{aligned}A_\mu(x) &= \frac{1}{2\cdot 0!}x^\nu F_{\nu\mu}(0) + \frac{1}{3\cdot 1!}x^\alpha x^\nu(D_\alpha F_{\nu\mu}(0))\\ &\quad + \frac{1}{4\cdot 2!}x^\alpha x^\beta x^\nu(D_\alpha D_\beta F_{\nu\mu}(0)) + \cdots.\end{aligned} \tag{43}$$

By using the expression, the gauge covariant form of the propagators is obtained as follows:

$$\begin{aligned}S^q_{ab}(x)|_{1\text{photon}} &= -\frac{ie_q}{32\pi^2}\delta_{ab}\Big[\frac{1}{x^2}\{\not{x}, F\cdot\sigma\}\\ &\quad - im_q(1 - i\theta_q\gamma_5)F\cdot\sigma\log(-\Lambda^2_{\text{IR}}x^2)\Big]\\ &\quad - \frac{d_q}{8\pi^2}\delta_{ab}\Big[\frac{\not{x}\tilde{F}\cdot\sigma\not{x}}{(x^2)^2} + \frac{m_q}{2x^2}\{\not{x}, \tilde{F}\cdot\sigma\}\Big],\end{aligned} \tag{44}$$

[3]The choice of β for the sum rules including only the QCD θ term is discussed in Ref. [20]. They argue that the optimal choice of β is $-1 \le \beta \le 0$ rather than 1, which is consistent with the conventional choices favored from a viewpoint of evaluation of λ_n. The discussion is, however, not applicable to the present case, since our sum rules contain several unknown parameters.

[4]The neutron-interpolating field for $\beta = +1$ is simply expressed as

$$\eta_n(x) = \tfrac{1}{2}\epsilon^{abc}(d^T_a C\sigma_{\mu\nu}d_b)\sigma^{\mu\nu}\gamma_5 u_c. \tag{36}$$

$$S^q_{ab}(x)|_{1\text{gluon}} = -\frac{ig_s}{32\pi^2}\left[\frac{1}{x^2}\{\not{x}, G_{ab}\cdot\sigma\} - im_q(1-i\theta_q\gamma_5)G_{ab}\cdot\sigma\log(-\Lambda^2_{\rm IR}x^2)\right] - \frac{\tilde{d}_q g_s}{8\pi^2}\left[\frac{\not{x}\tilde{G}_{ab}\cdot\sigma\not{x}}{(x^2)^2} + \frac{m_q}{2x^2}\{\not{x}, \tilde{G}_{ab}\cdot\sigma\}\right], \quad (45)$$

with $G^{\mu\nu}_{ab} = G^{A\mu\nu}T^A_{ab}$. Here, a certain infrared (IR) cutoff $\Lambda_{\rm IR}$ is introduced in logarithmic terms. It was replaced to the quark masses when deriving the propagator from the equation motions. However, the contribution to the OPE with small quark momenta around the quark masses should not be included so that the IR cutoff is introduced.

Finally, we translate the quark and gluon background fields into their condensates. Here we just give resultant expressions for the relations between them. The details of the derivation is presented in Appendix A 1.

A single quark line, $\chi^q_{a\alpha}(x)\bar{\chi}^q_{b\beta}(0)$, is related with the quark condensate as

$$\chi^q_{a\alpha}(x)\bar{\chi}^q_{b\beta}(0) = \langle\Omega_{\not{C}P}|q_{a\alpha}(x)\bar{q}_{b\beta}(0)|\Omega_{\not{C}P}\rangle_F, \quad (46)$$

and it is to be expressed in terms of $\langle\bar{q}q\rangle$ as follows:

$$\chi^q_{a\alpha}(x)\bar{\chi}^q_{b\beta}(0) = -\frac{\delta_{ab}}{12}(1+i\theta_G\rho_q\gamma_5)_{\alpha\beta}\langle\bar{q}q\rangle + \frac{i}{48}\delta_{ab}\not{x}m_q\langle\bar{q}q\rangle - \frac{i}{96}\delta_{ab}\left[\bar{\theta}m_q\rho_q e_q\chi + d_q + \left(\kappa - \frac{1}{2}\xi\right)e_q\tilde{d}_q\right] \times\{\tilde{F}\cdot\sigma, \not{x}\}_{\alpha\beta}\langle\bar{q}q\rangle + \frac{i}{96}m_q e_q\chi\delta_{ab}\{F\cdot\sigma, \not{x}\}_{\alpha\beta}\langle\bar{q}q\rangle - \frac{i}{24}e_q\chi\delta_{ab}(\tilde{F}\cdot\sigma\gamma_5[1+i\rho_q\theta_G\gamma_5])_{\alpha\beta}\langle\bar{q}q\rangle. \quad (47)$$

Here, χ, κ, and ξ are the parameters for the quark condensates defined as [22]

$$\langle\bar{q}\sigma_{\mu\nu}q\rangle_F = e_q\chi F_{\mu\nu}\langle\bar{q}q\rangle, \quad (48)$$

$$g_s\langle\bar{q}G^A_{\mu\nu}T^A q\rangle_F = e_q\kappa F_{\mu\nu}\langle\bar{q}q\rangle, \quad (49)$$

$$2g_s\langle\bar{q}\gamma_5\tilde{G}^A_{\mu\nu}T^A q\rangle_F = ie_q\xi F_{\mu\nu}\langle\bar{q}q\rangle. \quad (50)$$

Also, in our calculation, we need the interaction part of the quark and gluon background fields,

$$g_s\chi^q_{a\alpha}(x)\bar{\chi}^q_{b\beta}(0)[G_{\mu\nu}]_{cd} = \langle g_s q_{a\alpha}(x)[G_{\mu\nu}]_{cd}\bar{q}_{b\beta}(0)\rangle_{F,\not{C}P}, \quad (51)$$

and it leads to the following equation:

$$g_s\chi^q_{a\alpha}(x)\bar{\chi}^q_{b\beta}(0)[G_{\mu\nu}]_{cd} = -\frac{1}{32}\left(\delta_{ad}\delta_{bc} - \frac{1}{3}\delta_{ab}\delta_{cd}\right)\langle\bar{q}q\rangle\left[e_q\left(\kappa F_{\mu\nu} - \frac{i}{2}\xi\tilde{F}_{\mu\nu}\gamma_5\right)(1+i\theta_G\rho_q\gamma_5) - \frac{i}{4}m_q e_q\not{x}\left(\kappa F_{\mu\nu} + \frac{1}{2}\bar{\theta}\rho_q\xi\tilde{F}_{\mu\nu}\right) - \frac{i}{24}m_q m_0^2\epsilon_{\mu\nu\rho\sigma}x^\rho\gamma^\sigma\gamma_5 - \frac{i}{24}\bar{\theta}m_q\rho_q m_0^2(x_\mu\gamma_\nu\gamma_5 - x_\nu\gamma_\mu\gamma_5) - \frac{1}{12}m_0^2\sigma_{\mu\nu} - \frac{i}{12}m_0^2\theta_G\rho_q\sigma_{\mu\nu}\gamma_5\right]_{\alpha\beta}. \quad (52)$$

VI. OPE ANALYSIS OF THE CORRELATOR

A. Leading order

Now we calculate the correlation function of the interpolating fields $\eta_n(x)$ in terms of the OPE. First, we carry out the leading-order calculation for the correlator

$$\Pi(x) = \langle\Omega_{\not{C}P}|T\{\eta_n(x)\bar{\eta}_n(0)\}|\Omega_{\not{C}P}\rangle_F. \quad (53)$$

As in Eq. (37), this correlator is decomposed into four correlators. We deal with them inclusively by using the following notation:

$$\Pi_{kl}(x) = \langle\Omega_{\not{C}P}|T\{j_k(x)\bar{j}_l(0)\}|\Omega_{\not{C}P}\rangle_F \qquad (k,l=1,2). \quad (54)$$

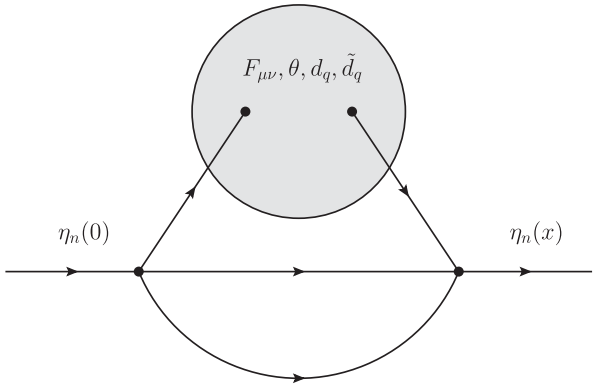

FIG. 1. Diagram which yields the leading contribution without emitting either a gluon or a photon.

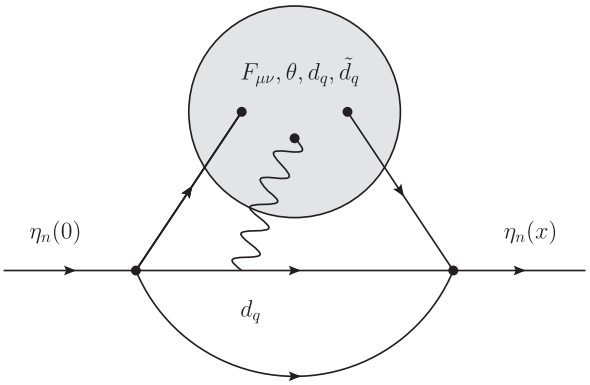

FIG. 2. Diagram which yields the leading and the next-to-leading-order contributions with emitting a photon. Those contributions vanish when $\beta = +1$.

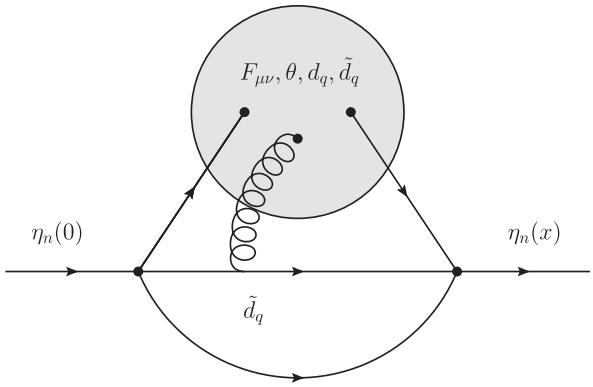

FIG. 3. Diagram which yields the leading and the next-to-leading-order contributions with emitting a gluon. Those contributions vanish when $\beta = +1$.

In Figs. 1–3, the diagrams which contribute to the correlators are illustrated. We denote each contribution to the correlators by the upper indices, i.e., $\Pi^{(I)}(x)$ or $\Pi^{(I)}_{kl}(x)$ with $I = 1, 2, 3$. From now on, we use the following abbreviation:

$$\bar{S}^{q}(x) \equiv C S^{qT}(x) C^{\dagger}, \tag{55}$$

with C the charge conjugation matrix.

Let us begin with evaluating $\Pi^{(1)}_{kl}(x)$. Each $\Pi^{(1)}_{kl}(x)$ is expressed in terms of the propagators $S^{q}_{ab}(x)$ as

$$\begin{aligned}
\Pi^{(1)}_{11}(x) &= 4\epsilon_{abc}\epsilon_{a'b'c'}\{-\mathrm{Tr}[\gamma_5 S^{u}_{ba'}(x)\gamma_5 \bar{S}^{d}_{ab'}(x)]S^{d}_{cc'}(x) + S^{d}_{cb'}(x)\gamma_5 \bar{S}^{u}_{ba'}(x)\gamma_5 S^{d}_{ac'}(x)\},\\
\Pi^{(1)}_{12}(x) &= 4\epsilon_{abc}\epsilon_{a'b'c'}\{-\mathrm{Tr}[\gamma_5 S^{u}_{ba'}(x)\bar{S}^{d}_{ab'}(x)]S^{d}_{cc'}(x)\gamma_5 + S^{d}_{cb'}(x)\bar{S}^{u}_{ba'}(x)\gamma_5 S^{d}_{ac'}(x)\gamma_5\},\\
\Pi^{(1)}_{21}(x) &= 4\epsilon_{abc}\epsilon_{a'b'c'}\{-\mathrm{Tr}[S^{u}_{ba'}(x)\gamma_5 \bar{S}^{d}_{ab'}(x)]\gamma_5 S^{d}_{cc'}(x) + \gamma_5 S^{d}_{cb'}(x)\gamma_5 \bar{S}^{u}_{ba'}(x) S^{d}_{ac'}(x)\},\\
\Pi^{(1)}_{22}(x) &= 4\epsilon_{abc}\epsilon_{a'b'c'}\{-\mathrm{Tr}[S^{u}_{ba'}(x)\bar{S}^{d}_{ab'}(x)]\gamma_5 S^{d}_{cc'}(x)\gamma_5 + \gamma_5 S^{d}_{cb'}(x)\bar{S}^{u}_{ba'}(x) S^{d}_{ac'}(x)\gamma_5\}.
\end{aligned} \tag{56}$$

When the propagators include neither a photon- nor gluon-emitting term, the expressions reduce to

$$\begin{aligned}
\Pi^{(1)}_{11}(x) &= 24\{\mathrm{Tr}[\gamma_5 S^{u}(x)\gamma_5 \bar{S}^{d}(x)]S^{d}(x) + S^{d}(x)\gamma_5 \bar{S}^{u}(x)\gamma_5 S^{d}(x)\},\\
\Pi^{(1)}_{12}(x) &= 24\{\mathrm{Tr}[\gamma_5 S^{u}(x)\bar{S}^{d}(x)]S^{d}(x)\gamma_5 + S^{d}(x)\bar{S}^{u}(x)\gamma_5 S^{d}(x)\gamma_5\},\\
\Pi^{(1)}_{21}(x) &= 24\{\mathrm{Tr}[S^{u}(x)\gamma_5 \bar{S}^{d}(x)]\gamma_5 S^{d}(x) + \gamma_5 S^{d}(x)\gamma_5 \bar{S}^{u}(x) S^{d}(x)\},\\
\Pi^{(1)}_{22}(x) &= 24\{\mathrm{Tr}[S^{u}(x)\bar{S}^{d}(x)]\gamma_5 S^{d}(x)\gamma_5 + \gamma_5 S^{d}(x)\bar{S}^{u}(x) S^{d}(x)\gamma_5\},
\end{aligned} \tag{57}$$

where

$$S^{q}_{ab}(x) = \delta_{ab} S^{q}(x). \tag{58}$$

As discussed in Sec. III, we focus on the terms proportional to $\{\tilde{F}\cdot\sigma, \not{q}\}$. For this reason we extract only the terms including $\{\tilde{F}\cdot\sigma, \not{x}\}$. They are found to be

$$\begin{aligned}
\Pi^{(1)}_{11}(x) &= \frac{i}{16\pi^4}\langle\bar{q}q\rangle\frac{1}{(x^2)^3}\{\tilde{F}\cdot\sigma, \not{x}\}\Big[(4e_d m_d\rho_d - e_u m_u\rho_u)\chi\bar{\theta} + \chi\{(e_d m_u\rho_u - e_u m_d\rho_d)\theta_Q + (e_u m_d\rho_u - e_d m_u\rho_d)\theta_G\}\\
&\quad + (6d_d - d_u) + \Big(\kappa - \frac{1}{2}\xi\Big)(6e_d\tilde{d}_d - e_u\tilde{d}_u)\Big],\\
\Pi^{(1)}_{12}(x) &= \Pi^{(1)}_{21}(x) = \frac{i}{16\pi^4}\langle\bar{q}q\rangle\frac{1}{(x^2)^3}\{\tilde{F}\cdot\sigma, \not{x}\}\Big[(4e_d m_d\rho_d - e_u m_u\rho_u)\chi\bar{\theta} + (2d_d - d_u) + \Big(\kappa - \frac{1}{2}\xi\Big)(2e_d\tilde{d}_d - e_u\tilde{d}_u)\Big],\\
\Pi^{(1)}_{22}(x) &= \frac{i}{16\pi^4}\langle\bar{q}q\rangle\frac{1}{(x^2)^3}\{\tilde{F}\cdot\sigma, \not{x}\}\Big[(4e_d m_d\rho_d - e_u m_u\rho_u)\chi\bar{\theta} + \chi\{(e_u m_d\rho_d - e_d m_u\rho_u)\theta_Q + (e_d m_u\rho_d - e_u m_d\rho_u)\theta_G\}\\
&\quad + (6d_d - d_u) + \Big(\kappa - \frac{1}{2}\xi\Big)(6e_d\tilde{d}_d - e_u\tilde{d}_u)\Big].
\end{aligned} \tag{59}$$

Thus, $\Pi^{(1)}(x)$ is given as

$$\Pi^{(1)}(x) = \frac{i}{16\pi^4}\langle\bar{q}q\rangle\frac{1}{(x^2)^3}\{\tilde{F}\cdot\sigma, \not{x}\}\Big[(1+\beta)^2(4e_d m_d\rho_d - e_u m_u\rho_u)\chi\bar{\theta} + (1-\beta^2)\chi\{(e_d m_u\rho_u - e_u m_d\rho_d)\theta_Q + (e_u m_d\rho_u - e_d m_u\rho_d)\theta_G\} + 2(3+2\beta+3\beta^2)d_d - (1+\beta)^2 d_u + \left(\kappa - \frac{1}{2}\xi\right)\{2(3+2\beta+3\beta^2)e_d\tilde{d}_d - (1+\beta)^2 e_u\tilde{d}_u\}\Big], \tag{60}$$

and for $\beta = +1$, the above expression reduces to

$$\Pi^{(1)}(x) = \frac{i}{4\pi^4}\langle\bar{q}q\rangle\frac{1}{(x^2)^3}\{\tilde{F}\cdot\sigma, \not{x}\}\Big[(4e_d m_d\rho_d - e_u m_u\rho_u)\chi\bar{\theta} + (4d_d - d_u) + \left(\kappa - \frac{1}{2}\xi\right)(4e_d\tilde{d}_d - e_u\tilde{d}_u)\Big]. \tag{61}$$

Next, we evaluate $\Pi^{(2)}$. Here, we again use the expressions in Eq. (57), while one of the propagators in each correlator is $S^q(x)|_{1\text{photon}}$ in this case. The result is given as

$$\begin{aligned}
&\Pi^{(2)}_{11}(x) = \frac{i}{8\pi^4}(2d_d - d_u)\langle\bar{q}q\rangle\frac{1}{(x^2)^3}\{\tilde{F}\cdot\sigma, \not{x}\}, \qquad \Pi^{(2)}_{12}(x) = \Pi^{(2)}_{21}(x) = -\frac{i}{8\pi^4}d_d\langle\bar{q}q\rangle\frac{1}{(x^2)^3}\{\tilde{F}\cdot\sigma, \not{x}\},\\
&\Pi^{(2)}_{22}(x) = \frac{i}{8\pi^4}d_u\langle\bar{q}q\rangle\frac{1}{(x^2)^3}\{\tilde{F}\cdot\sigma, \not{x}\},
\end{aligned} \tag{62}$$

and they lead to

$$\Pi^{(2)}(x) = \frac{i}{8\pi^4}[2(1-\beta)d_d - (1-\beta^2)d_u]\langle\bar{q}q\rangle\frac{1}{(x^2)^3}\{\tilde{F}\cdot\sigma, \not{x}\}. \tag{63}$$

Therefore, we find that $\Pi^{(2)}$ vanishes when we take $\beta = +1$:

$$\Pi^{(2)}(x) = 0. \tag{64}$$

Finally, we study $\Pi^{(3)}$. In this case, we use the equations in Eq. (56). By using Eq. (52), we find the resultant expressions as

$$\begin{aligned}
\Pi^{(3)}_{11}(x) &= \frac{i}{16\pi^4}\left[-e_d\tilde{d}_d\left(\kappa - \frac{1}{2}\xi\right) + (e_d\tilde{d}_u - e_u\tilde{d}_d)\left(\kappa + \frac{1}{2}\xi\right)\right]\langle\bar{q}q\rangle\frac{1}{(x^2)^3}\{\tilde{F}\cdot\sigma, \not{x}\},\\
\Pi^{(3)}_{12}(x) &= \Pi^{(3)}_{21}(x) = \frac{i}{16\pi^4}e_d\tilde{d}_d\left(\kappa - \frac{1}{2}\xi\right)\langle\bar{q}q\rangle\frac{1}{(x^2)^3}\{\tilde{F}\cdot\sigma, \not{x}\},\\
\Pi^{(3)}_{22}(x) &= \frac{i}{16\pi^4}\left[-e_d\tilde{d}_d\left(\kappa - \frac{1}{2}\xi\right) - (e_d\tilde{d}_u - e_u\tilde{d}_d)\left(\kappa + \frac{1}{2}\xi\right)\right]\langle\bar{q}q\rangle\frac{1}{(x^2)^3}\{\tilde{F}\cdot\sigma, \not{x}\}.
\end{aligned} \tag{65}$$

Thus, $\Pi^{(3)}(x)$ is given as

$$\Pi^{(3)}(x) = \frac{i}{16\pi^4}\langle\bar{q}q\rangle\frac{1}{(x^2)^3}\{\tilde{F}\cdot\sigma, \not{x}\}\Big[-(1-\beta)^2\left(\kappa - \frac{1}{2}\xi\right)e_d\tilde{d}_d + (1-\beta^2)\left(\kappa + \frac{1}{2}\xi\right)(e_d\tilde{d}_u - e_u\tilde{d}_d)\Big]. \tag{66}$$

Again, the correlator turns out to vanish for $\beta = +1$:

$$\Pi^{(3)}(x) = 0. \tag{67}$$

Taking the above discussion into account, we conclude that the correlator $\Pi(x)$ is given as

$$\Pi(x) = \frac{i}{16\pi^4}\langle\bar{q}q\rangle\frac{1}{(x^2)^3}\{\tilde{F}\cdot\sigma, \not{x}\}\Big[(1+\beta)^2(4e_d m_d\rho_d - e_u m_u\rho_u)\chi\bar{\theta} + (1-\beta^2)\chi\{(e_d m_u\rho_u - e_u m_d\rho_d)\theta_Q + (e_u m_d\rho_u - e_d m_u\rho_d)\theta_G\} + (10+6\beta^2)d_d - (3+2\beta-\beta^2)d_u + \tilde{d}_d\Big\{2\Big[(3+2\beta+3\beta^2) - \frac{1}{2}(1-\beta)^2\Big]e_d\left(\kappa - \frac{1}{2}\xi\right) - (1-\beta^2)e_u\left(\kappa + \frac{1}{2}\xi\right)\Big\} + \tilde{d}_u\Big\{(1-\beta^2)e_d\left(\kappa + \frac{1}{2}\xi\right) - (1+\beta)^2 e_u\left(\kappa - \frac{1}{2}\xi\right)\Big\}\Big], \tag{68}$$

and its Fourier transform is

$$\Pi(q) = i\int d^4x e^{iq\cdot x}\Pi(x)$$
$$= \frac{1}{64\pi^2}\langle\bar{q}q\rangle\log\left(\frac{-q^2}{\Lambda^2}\right)\{\tilde{F}\cdot\sigma, \not{q}\}\Big[(1+\beta)^2(4e_dm_d\rho_d - e_um_u\rho_u)\chi\bar{\theta} + (1-\beta^2)\chi\{(e_dm_u\rho_u - e_um_d\rho_d)\theta_Q$$
$$+ (e_um_d\rho_u - e_dm_u\rho_d)\theta_G\} + (10+6\beta^2)d_d - (3+2\beta-\beta^2)d_u + \tilde{d}_d\Big\{2\Big[(3+2\beta+3\beta^2) - \frac{1}{2}(1-\beta)^2\Big]$$
$$\times e_d\left(\kappa - \frac{1}{2}\xi\right) - (1-\beta^2)e_u\left(\kappa+\frac{1}{2}\xi\right)\Big\} + \tilde{d}_u\Big\{(1-\beta^2)e_d\left(\kappa+\frac{1}{2}\xi\right) - (1+\beta)^2e_u\left(\kappa-\frac{1}{2}\xi\right)\Big\}\Big]. \quad (69)$$

Here, a certain ultraviolet mass scale Λ is introduced, though it is irrelevant to our final result. When one sets $\beta = +1$, this expression reduces to

$$\Pi(q)^{(\mathrm{OPE})} = \frac{1}{16\pi^2}\langle\bar{q}q\rangle\log\left(\frac{-q^2}{\Lambda^2}\right)\{\tilde{F}\cdot\sigma, \not{q}\}\Big[(4e_dm_d\rho_d - e_um_u\rho_u)\chi\bar{\theta} + (4d_d - d_u) + \left(\kappa - \frac{1}{2}\xi\right)(4e_d\tilde{d}_d - e_u\tilde{d}_u)\Big]. \quad (70)$$

Equation (69) corresponds to Eqs. (9–12) in Ref. [15]. After taking $\beta = +1$, we find that the CEDM contribution, i.e., the last term in Eq. (70), differs from those in the reference by a factor of 4. In addition, the sign in front of ξ is opposite to the one in Ref. [15].

B. Next-to-leading order

Figures 2 and 3 yield the next-to-leading-order (NLO) contributions. By using the propagator given in Eq. (44), we evaluate the contribution by the diagram in Fig. 2 as

$$\Pi^{(2)}_{11}(x)_{\mathrm{NLO}} = \frac{i}{32\pi^4}\langle\bar{q}q\rangle\frac{1}{(x^2)^2}\log(-\Lambda^2_{\mathrm{IR}}x^2)\{\tilde{F}\cdot\sigma, \not{x}\}[e_dm_d\rho_d\bar{\theta} + (e_um_u\rho_d - e_dm_d\rho_u)\theta_G + (e_dm_d\rho_d - e_um_u\rho_u)\theta_Q],$$
$$\Pi^{(2)}_{12}(x)_{\mathrm{NLO}} = \Pi^{(2)}_{21}(x)_{\mathrm{NLO}} = -\frac{i}{32\pi^4}\langle\bar{q}q\rangle\frac{1}{(x^2)^2}\log(-\Lambda^2_{\mathrm{IR}}x^2)\{\tilde{F}\cdot\sigma, \not{x}\}e_dm_d\rho_d\bar{\theta},$$
$$\Pi^{(2)}_{22}(x)_{\mathrm{NLO}} = \frac{i}{32\pi^4}\langle\bar{q}q\rangle\frac{1}{(x^2)^2}\log(-\Lambda^2_{\mathrm{IR}}x^2)\{\tilde{F}\cdot\sigma, \not{x}\}[e_dm_d\rho_d\bar{\theta} - (e_um_u\rho_d - e_dm_d\rho_u)\theta_G - (e_dm_d\rho_d - e_um_u\rho_u)\theta_Q], \quad (71)$$

and therefore, $\Pi^{(2)}(x)_{\mathrm{NLO}}$ is found to be

$$\Pi^{(2)}(x)_{\mathrm{NLO}} = \frac{i}{32\pi^4}\langle\bar{q}q\rangle\frac{1}{(x^2)^2}\log(-\Lambda^2_{\mathrm{IR}}x^2)\{\tilde{F}\cdot\sigma, \not{x}\}[(1-\beta)^2e_dm_d\rho_d\bar{\theta} + (1-\beta^2)\{(e_um_u\rho_d - e_dm_d\rho_u)\theta_G$$
$$+ (e_dm_d\rho_d - e_um_u\rho_u)\theta_Q\}]. \quad (72)$$

The gluon contribution illustrated in Fig. 3 is also calculated by using the propagator displayed in Eq. (45). The resultant expressions are

$$\Pi^{(3)}_{11}(x)_{\mathrm{NLO}} = -\frac{i}{64\pi^4}\langle\bar{q}q\rangle\frac{1}{(x^2)^2}\log(-\Lambda^2_{\mathrm{IR}}x^2)\{\tilde{F}\cdot\sigma, \not{x}\}\Big[e_dm_d\rho_d\left(\kappa+\frac{1}{2}\xi\right)\bar{\theta} + (e_dm_u\rho_d - e_um_d\rho_u)\left(\kappa-\frac{1}{2}\xi\right)\theta_G$$
$$+ (e_um_d\rho_d - e_dm_u\rho_u)\left(\kappa-\frac{1}{2}\xi\right)\theta_Q\Big],$$
$$\Pi^{(3)}_{12}(x)_{\mathrm{NLO}} = \Pi^{(3)}_{21}(x)_{\mathrm{NLO}} = \frac{i}{64\pi^4}\langle\bar{q}q\rangle\frac{1}{(x^2)^2}\log(-\Lambda^2_{\mathrm{IR}}x^2)\{\tilde{F}\cdot\sigma, \not{x}\}\bar{\theta}e_dm_d\rho_d\left(\kappa+\frac{1}{2}\xi\right),$$
$$\Pi^{(3)}_{22}(x)_{\mathrm{NLO}} = -\frac{i}{64\pi^4}\langle\bar{q}q\rangle\frac{1}{(x^2)^2}\log(-\Lambda^2_{\mathrm{IR}}x^2)\{\tilde{F}\cdot\sigma, \not{x}\}\Big[e_dm_d\rho_d\left(\kappa+\frac{1}{2}\xi\right)\bar{\theta} - (e_dm_u\rho_d - e_um_d\rho_u)\left(\kappa-\frac{1}{2}\xi\right)\theta_G$$
$$- (e_um_d\rho_d - e_dm_u\rho_u)\left(\kappa-\frac{1}{2}\xi\right)\theta_Q\Big], \quad (73)$$

and then,

$$\Pi^{(3)}(x)_{\rm NLO} = -\frac{i}{64\pi^4}\langle\bar{q}q\rangle\frac{1}{(x^2)^2}\log(-\Lambda_{\rm IR}^2x^2)\{\tilde{F}\cdot\sigma,\not{x}\}\Big[(1-\beta)^2\bar{\theta}e_dm_d\rho_d\Big(\kappa+\frac{1}{2}\xi\Big) + (1-\beta^2)\{(e_dm_u\rho_d - e_um_d\rho_u)\theta_G + (e_um_d\rho_d - e_dm_u\rho_u)\theta_Q\}\Big(\kappa-\frac{1}{2}\xi\Big)\Big]. \quad (74)$$

From the results in Eqs. (72) and (74), it is found that taking $\beta = +1$ makes the NLO contributions vanish, as mentioned before. Thus, we find that the correlator given in Eq. (70) is valid up to the next-to-leading order.

VII. QCD SUM RULES

In order to derive the QCD sum rules for the present case, we first extract the coefficient functions of $\{\tilde{F}\cdot\sigma,\not{q}\}$ from both the phenomenological and the OPE correlators, $\Pi^{(\rm phen)}$ in Eq. (21) and $\Pi^{(\rm OPE)}$ in Eq. (70), respectively:

$$C^{(\rm phen)}(Q^2) \equiv \frac{1}{2}\Big[\frac{\lambda_n^2d_nm_n}{(Q^2+m_n^2)^2} - \frac{A}{Q^2+m_n^2}\Big], \quad (75)$$

$$C^{(\rm OPE)}(Q^2) \equiv \frac{1}{16\pi^2}\langle\bar{q}q\rangle\Theta\log\Big(\frac{Q^2}{\Lambda^2}\Big), \quad (76)$$

with $Q^2 \equiv -q^2$ and

$$\Theta \equiv (4e_dm_d\rho_d - e_um_u\rho_u)\chi\bar{\theta} + (4d_d - d_u) + (\kappa - \tfrac{1}{2}\xi)(4e_d\tilde{d}_d - e_u\tilde{d}_u). \quad (77)$$

In Eq. (75), we neglect the continuum contribution and think of A as a constant, as discussed above. The QCD sum rules are obtained by equating the coefficient functions after the Borel transformation, i.e.,

$$\mathcal{B}[C^{(\rm phen)}(Q^2)] = \mathcal{B}[C^{(\rm OPE)}(Q^2)], \quad (78)$$

where the Borel transformation of the function $f(Q^2)$ is defined as

$$\mathcal{B}[f(Q^2)] \equiv \lim_{\substack{Q^2,n\to\infty,\\ Q^2/n=M^2}} \frac{(Q^2)^{n+1}}{n!}\Big(\frac{-d}{dQ^2}\Big)^n f(Q^2), \quad (79)$$

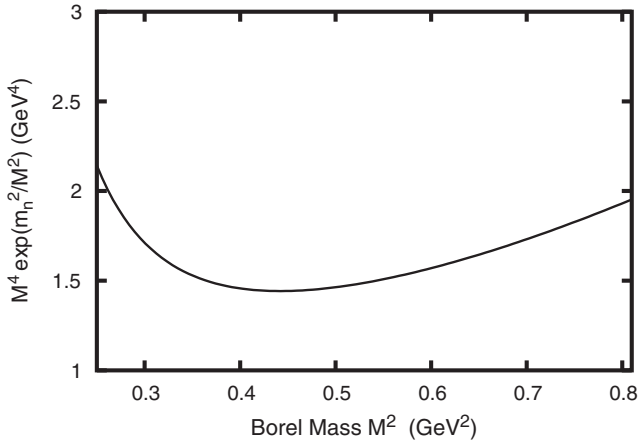

FIG. 4. Dependence of our sum rules on Borel mass M^2. The range of M is set to be 0.5 GeV $\leq M \leq$ 0.9 GeV.

with M so-called the Borel mass. Then, we finally derive the sum rules as follows:

$$\lambda_n^2d_nm_n - AM^2 = -\Theta\langle\bar{q}q\rangle\frac{M^4}{8\pi^2}e^{(m_n^2/M^2)}. \quad (80)$$

All we have to do is now reduced to determining the Borel mass M and the coupling λ_n, as well as estimating the parameter A.

To illustrate the dependence of the sum rules on the Borel mass, we plot $M^4e^{(m_n^2/M^2)}$, which is included in the right-hand side of Eq. (80), as a function of the Borel mass squared M^2 in Fig. 4. Here, the range of M is set to be 0.5 GeV $\leq M \leq$ 0.9 GeV. From the figure we find that the Borel mass dependence of our sum rule is moderate in the range of 0.6 GeV $\lesssim M \lesssim$ 0.8 GeV.

VIII. DETERMINATION OF λ_n FROM THE LATTICE

The low-energy constant λ_n determines the normalization of the QCD sum rules so that the uncertainties are directly linked to the final result. We extract its numerical value from the lattice QCD calculation presented in Ref. [23], in which the QCD matrix elements for the proton decay rate are evaluated. In fact, they evaluate a similar quantity for proton, though the isospin symmetry allows us to interpret it for the present purpose.

First, we introduce a generic notation for three-quark operators with an arbitrary spin structure:

$$\mathcal{O}^{\Gamma\Gamma'}(x,t) \equiv \epsilon_{abc}[d_a^T(x,t)C\Gamma u_b(x,t)]\Gamma' d_c(x,t), \quad (81)$$

with Γ and Γ' arbitrary 4×4 matrices. In the current case, the relevant matrices are $R = P_R \equiv \frac{1}{2}(1+\gamma_5)$ or $L = P_L \equiv \frac{1}{2}(1-\gamma_5)$. Now we define parameters α_1 and α_2 as follows:

$$\langle 0|\mathcal{O}^{RL}|N(\boldsymbol{p},s)\rangle = \alpha_1P_Lu_n(\boldsymbol{p},s),$$
$$\langle 0|\mathcal{O}^{LL}|N(\boldsymbol{p},s)\rangle = \alpha_2P_Lu_n(\boldsymbol{p},s). \quad (82)$$

The phase definition is fixed such that α_1 and α_2 are both real and $\alpha_1 < 0$. The parity transformation of the above equations implies that

$$\langle 0|\mathcal{O}^{LR}|N(\boldsymbol{p},s)\rangle = -\alpha_1P_Ru_n(\boldsymbol{p},s),$$
$$\langle 0|\mathcal{O}^{RR}|N(\boldsymbol{p},s)\rangle = -\alpha_2P_Ru_n(\boldsymbol{p},s). \quad (83)$$

The interpolating fields j_1 and j_2 are expressed in terms of the operators as

$$j_1(x) = 2(\mathcal{O}^{RL}(x) + \mathcal{O}^{RR}(x) - \mathcal{O}^{LL}(x) - \mathcal{O}^{LR}(x)), \quad (84)$$

$$j_2(x) = 2(\mathcal{O}^{LR}(x) - \mathcal{O}^{LL}(x) + \mathcal{O}^{RR}(x) - \mathcal{O}^{RL}(x)). \quad (85)$$

Thus their matrix elements between the vacuum and one-particle states are given as

$$\langle 0|j_1|N(\boldsymbol{p},s)\rangle = 2(\alpha_1 - \alpha_2)u_n(\boldsymbol{p},s), \tag{86}$$

$$\langle 0|j_2|N(\boldsymbol{p},s)\rangle = -2(\alpha_1 + \alpha_2)u_n(\boldsymbol{p},s), \tag{87}$$

and they lead to

$$\langle 0|\eta_n|N(\boldsymbol{p},s)\rangle = 2[(\alpha_1 - \alpha_2) - \beta(\alpha_1 + \alpha_2)]u_n(\boldsymbol{p},s). \tag{88}$$

From the equation we may relate λ_n with the parameters α_1 and α_2:

$$\lambda_n(\mu) = 2[(\alpha_1 - \alpha_2) - \beta(\alpha_1 + \alpha_2)], \tag{89}$$

with μ the renormalization scale. The parameters α_1 and α_2 at $\mu = 2$ GeV are estimated in Ref. [23] as

$$\alpha_1 = -0.0112 \pm 0.0012_{(\mathrm{stat})} \pm 0.0022_{(\mathrm{syst})}\ \mathrm{GeV}^3, \tag{90}$$

$$\alpha_2 = 0.0120 \pm 0.0013_{(\mathrm{stat})} \pm 0.0023_{(\mathrm{syst})}\ \mathrm{GeV}^3. \tag{91}$$

For $\beta = 1$, $\lambda_n(\mu = 2\ \mathrm{GeV})$ is given as

$$\begin{aligned}\lambda_n &= -4\alpha_2 \\ &= -0.0480 \pm 0.0052_{(\mathrm{stat})} \pm 0.0092_{(\mathrm{syst})}\ \mathrm{GeV}^3.\end{aligned} \tag{92}$$

Since the QCD parameter used here is evaluated at $\mu = 1$ GeV, we need to translate the above value of λ_n into that of $\mu = 1$ GeV. The one-loop correction for λ_n is

$$\lambda_n(\mu = 1\ \mathrm{GeV}) = \left(\frac{\alpha_s(1\ \mathrm{GeV})}{\alpha_s(m_c)}\right)^{-(2/9)}\left(\frac{\alpha_s(m_c)}{\alpha_s(2\ \mathrm{GeV})}\right)^{-(6/25)} \times \lambda_n(\mu = 2\ \mathrm{GeV}), \tag{93}$$

which results in a reduction factor of $\simeq 0.91$. As a result, we obtain

$$\lambda_n = -0.0436 \pm 0.0047_{(\mathrm{stat})} \pm 0.0084_{(\mathrm{syst})}\ \mathrm{GeV}^3 \tag{94}$$

for $\beta = +1$.

Let us compare the value of λ_n obtained here with those used in the previous works. In Ref. [14], for example, they exploit the values for λ_n evaluated in Ref. [24][5] by using the QCD sum rules. Two Dirac-γ structures, $\mathbb{1}$ and $\not{p}$, provide different sum rules. As evaluated in Ref. [24], these two sum rules yield relatively small values for λ_n; the lattice QCD value is several times larger than the values evaluated by using the QCD sum rules. The author in Ref. [24] also estimates the error for these values. It is about 30% for the sum rules result while 20% for the lattice QCD result. The lattice QCD result might have an uncertainty in the chiral extrapolation. Since there is no more guiding principle for judging which estimation is valid, we exploit the lattice QCD result in Eq. (94), because this choice leads to a rather conservative constraint for CP-violating sources.

[5]Note that the notation used in Ref. [24] is different from ours:

$$\lambda_n = 2\lambda_{\mathcal{O}} = \frac{2}{(2\pi)^2}\tilde{\lambda}_{\mathcal{O}}. \tag{95}$$

Also, notice that there is some difference between the results described in Ref. [24] and the corresponding expressions shown in Ref. [14].

IX. RESULTS

Now we estimate the neutron EDM by using the results obtained above. First of all, we rewrite the sum rules in Eq. (80) in a simple form:

$$c_0 + c_1 x = f(x), \tag{96}$$

where $x = M^2$ and

$$f(x) \equiv \frac{x^2}{8\pi^2}\exp\left(\frac{m_n^2}{x}\right), \quad c_0 \equiv \frac{d_n\lambda_n^2 m_n}{-\Theta\langle\bar{q}q\rangle}, \quad c_1 \equiv \frac{-A}{-\Theta\langle\bar{q}q\rangle}. \tag{97}$$

The right-hand side of Eq. (96) describes the behavior of the coefficient function obtained from the OPE calculation, while the left-hand side represents the phenomenological one. The first and second terms in the left-hand side correspond to the double and single pole contributions, i.e., the first and second terms in Eq. (22), respectively. Once given a Borel mass point $x = M^2$, one may readily pick out c_0 and c_1 from the tangent line to the function $f(x)$ at the point. Then, they are expressed as the functions of x as

$$\begin{aligned}c_0(x) &= \frac{1}{8\pi^2}(m_n^2 x - x^2)\exp\left(\frac{m_n^2}{x}\right), \\ c_1(x) &= \frac{1}{8\pi^2}(2x - m_n^2)\exp\left(\frac{m_n^2}{x}\right).\end{aligned} \tag{98}$$

From these expressions, it is found that the single pole contribution vanishes at $x = m_n^2/2$. Since the parameter A is unknown, this choice of x is favorable in order to estimate the double pole contribution. Then, at this point the value of c_0 is

$$c_0 = 1.8 \times 10^{-2} \quad (\text{for } x = m_n^2/2), \tag{99}$$

and, therefore, the neutron EDM d_n is evaluated as

$$d_n = \frac{-c_0\langle\bar{q}q\rangle}{\lambda_n^2 m_n}\Theta = 1.2 \times 10^{-1}\Theta. \tag{100}$$

Here we take $\langle\bar{q}q\rangle = -(0.225\ \mathrm{GeV})^3$.

The choice of the Borel mass, $M^2 = m_n^2/2$, is, however, quite arbitrary, and deviation from the above result due to the different choice of the Borel mass should be taken into account as a theoretical uncertainty. In Fig. 5, we plot the ratio of the single and double pole contributions as a function of M^2. From this figure, we find that the single pole contribution rapidly increases when the Borel mass is varied from $M^2 = m_n^2/2$. We here assume our sum rules to be valid within the region of the Borel mass in which the single pole contribution is less than 30% of the double pole contribution. This assumption leads to $0.36\ \mathrm{GeV}^2 < M^2 < 0.50\ \mathrm{GeV}^2$, and, in this region, d_n takes the following values:

$$d_n = 1.2^{+0.6}_{-0.3} \times 10^{-1}\Theta. \tag{101}$$

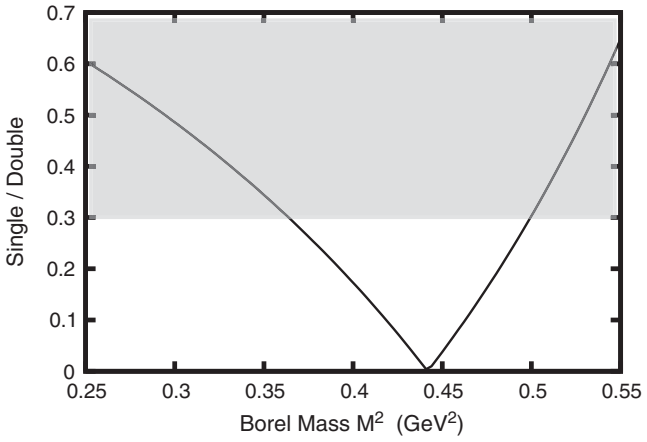

FIG. 5. Ratio of single and double pole contributions as a function of Borel mass M^2. The shaded region illustrates that single pole contribution is more than 30% of double pole contribution.

Here, the lower value corresponds to the upper limit of the Borel mass, and vice versa.

Next, we discuss the uncertainty of the OPE calculation. In this case, the truncation of the OPE leads to the uncertainty. Let us estimate it by evaluating the relative size of the higher-order contributions. Among them, the four-quark condensates such as $\langle\bar{q}q\bar{q}q\rangle$ are expected to yield sizable contributions, since they are free from loop suppression. On the assumption that these contributions vanish when one takes the quark masses to be zero, we expect that they are suppressed by at least a factor of $\langle\bar{q}q\rangle^{(2/3)}/M^2 \simeq 0.1$. Therefore, the uncertainty of the OPE calculation is estimated to be $\mathcal{O}(10)\%$.

Taking the above discussion into account, we finally evaluate the neutron EDM with theoretical uncertainty as follows:

$$d_n = 1.2^{+0.6}_{-0.3} \pm 0.1^{+0.7}_{-0.4} \times 10^{-1}\Theta, \tag{102}$$

where the first uncertainty stems from the phenomenological calculation while the second one comes from the approximation in the OPE. We also include uncertainties originate from those in λ_n [see Eq. (94)], which is indicated by the third error in the above equation.[6] After all, it is found that there is almost an $\mathcal{O}(1)$ factor of uncertainty in our sum rule calculation.

Let us compare the result with those obtained by using the values of λ_n calculated with the QCD sum rules. In Ref. [22], the authors adopt $\lambda_n^2 = 1.05/(2\pi)^4$ GeV^3 for $\beta = -1$ from the QCD sum rules derived for the nucleon mass. The λ_n for $\beta = -1$ is equal to that for $\beta = 1$ in the nonrelativistic quark limit. In Ref. [25], it is shown that the neutron EDM prediction in the nonrelativistic quark model with the $SU(6)$ spin-flavor symmetry is derived in the QCD sum rules using the value of λ_n. By substituting the value into Eq. (100), one obtains $d_n = 3.3 \times 10^{-1}\Theta$. The "realistic" value of λ_n evaluated by the QCD sum rules in Ref. [24], $\lambda_n \simeq 0.022$ GeV^3, leads to a slightly larger result: $d_n = 4.6 \times 10^{-1}\Theta$. Thus, the overall factors of d_n of these results are several times larger than that of our result.

For convenience, we substitute the numerical values for the QCD parameters in Eq. (101). Here we take $m_0^2 = 0.8\,\text{GeV}^2$, $\chi = -5.7 \pm 0.6\,\text{GeV}^{-2}$, $\xi = -0.74 \pm 0.2$, and $\kappa = -0.34 \pm 0.1$ [18,26]. Then, with those parameters the center values, we find

$$d_n = 4.2 \times 10^{-17}\bar{\theta}[e\ \text{cm}] + 0.47 d_d - 0.12 d_u + e(-0.18\tilde{d}_u + 0.18\tilde{d}_d - 0.008\tilde{d}_s). \tag{103}$$

The contributions from $\bar{\theta}$ and the quark CEDMs to d_n may be changed furthermore by about $\pm 10\%$, mainly due to the theoretical uncertainty of χ.

X. UNDER THE PECCEI-QUINN SYMMETRY

It is known that $O(1)$ $\bar{\theta}$ induces a too large neutron EDM, the strong CP problem. The Peccei-Quinn (PQ) symmetry is one of the solutions for the strong CP problem. If the PQ symmetry is introduced, $\bar{\theta}$ vanishes dynamically. However, if the quark CEDMs are nonvanishing, a linear term is induced to the axion potential [27],

$$V(\bar{\theta}) = K'\bar{\theta} - \tfrac{1}{2}K\bar{\theta}^2, \tag{104}$$

where K is the topological susceptibility

$$K = -i\lim_{k\to 0} i\int d^4x e^{ikx}\left\langle T\left[\frac{\alpha_s}{8\pi}G\tilde{G}(x)\frac{\alpha_s}{8\pi}G\tilde{G}(0)\right]\right\rangle \tag{105}$$

and K' is calculated by

$$K' = -i\lim_{k\to 0} i\int d^4x e^{ikx} \times \left\langle T\left[\frac{\alpha_s}{8\pi}G\tilde{G}(x)\frac{i}{2}\sum_{q=u,d,s}\tilde{d}_q\bar{q}g_s(G\cdot\sigma)\gamma_5 q(0)\right]\right\rangle. \tag{106}$$

Minimizing the axion potential, an effective θ term is induced from the quark CEDM:

$$\bar{\theta}_{\text{ind}} = -\frac{K'}{K} = \frac{m_0^2}{2}\sum_{q=u,d,s}\frac{\tilde{d}_q}{m_q}. \tag{107}$$

Taking the induced θ term into account, the neutron EDM in the presence of the PQ symmetry is estimated as

$$d_n^{\text{PQ}} = 1.2^{+0.6}_{-0.3} \pm 0.1^{+0.7}_{-0.4} \times 10^{-1}\Theta^{\text{PQ}}, \tag{108}$$

where

$$\Theta^{\text{PQ}} = 4d_d - d_u + \left(\frac{m_0^2}{2}\chi + \kappa - \frac{1}{2}\xi\right)(4e_d\tilde{d}_d - e_u\tilde{d}_u). \tag{109}$$

The contributions from the strange quark CEDM are canceled in the presence of the PQ symmetry [15]. Again, we

[6]We approximate the error in λ_n as the rms of the statistical and systematic errors displayed in Eq. (94).

substitute the numerical values for the QCD parameters as presented in the previous section. The result is

$$d_n^{\rm PQ} = 0.47 d_d - 0.12 d_u + e(0.35\tilde{d}_d + 0.17\tilde{d}_u). \quad (110)$$

XI. CONCLUSION AND DISCUSSION

We have studied the neutron EDM induced by the *CP*-violating interactions up to the dimension-five operators. In order to derive the relation between the *CP*-violating interactions and the neutron EDM, we have used the QCD sum rule technique. There are several phenomenological parameters to estimate the relation numerically. Pospelov and Ritz also analyzed the neutron EDM by using the QCD sum rules [14,15], and they determined the low-energy constant λ_n within the framework in the QCD sum rules. On the other hand, we have extracted the λ_n parameter from lattice calculations. This approach allows us to reduce a theoretical uncertainty and leads to a conservative constraint on the *CP* violations. Our result is about 70% smaller compared with the one obtained by Pospelov and Ritz. There still remains a sizable uncertainty resulting from the QCD sum rules itself due to a choice of the Borel mass scale. We have estimated the uncertainty from the Borel mass scale by assuming that the single pole contribution is less than 30% of the double pole contributions. This assumption leads to the theoretical error of about $\mathcal{O}(1)$.

Finally, we briefly comment on the contribution of the *CP*-violating dimension-six operators. Among the dimension-six operators, the following operator, called the Weinberg operator:

$$\mathcal{L}_{\not CP} = \tfrac{1}{3} w f_{ABC} G^A_{\mu\nu} \tilde{G}^{B\nu\lambda} G^{C\mu}_{\lambda},$$

might be comparable to the quark EDM and CEDM contributions, since they suffer from the chiral suppression. The other *CP*-violating dimension-six operators are effective four-quark operators of light quarks, which are negligible in the neutron EDM in typical high-energy models, since the Wilson coefficients are suppressed by the quark masses.[7] In our QCD sum rule calculation it is found that the contribution from the Weinberg operator is $\mathcal{O}(\langle\bar{q}q\rangle^2)$ and thus subdominant. There are a lot of discussions on the significance of the Weinberg operator [29], though no consensus has been reached yet.

ACKNOWLEDGMENTS

One of the authors (J. H.) appreciates useful discussion with Yasumichi Aoki. H.), and also by World Premier International Research Center Initiative (WPI Initiative), MEXT, Japan. The work of N. N. is supported by the Japan Society for the Promotion of Science for Young Scientists.

[7] If the *CP*-violating four-quark operators include heavy quarks, the CEDMs for the light quarks and the Weinberg operators are radiatively induced by integration of the heavy quarks as shown in Ref. [28].

APPENDIX

In this appendix, we list some techniques which we use to carry out the calculation.

1. Quark condensates on the *CP*-violating background

In this section, we discuss the effects of the *CP*-violating interactions on the quark condensates as well as on the quark and gluon background fields. We begin by estimating it for the generic quark bilinear condensate $\langle 0|\bar{q}\Gamma q|0\rangle$, with Γ a 4×4 constant matrix for which the quark bilinear $\bar{q}\Gamma q$ is an Hermitian operator. Then, by using the results obtained there, we derive the relations between the quark condensates and the background fields.

First, we evaluate the quark bilinear $\bar{q}\Gamma q$ on the *CP*-violating background. The contribution of the QCD θ term at the leading order is evaluated as [30]

$$\langle 0|\bar{q}\Gamma q|0\rangle_{\theta_G} = i\int d^4x \langle 0|T\{\bar{q}(0)\Gamma q(0)\theta_G \frac{\alpha_s}{8\pi} \times G^a_{\mu\nu}(x)\tilde{G}^{a\mu\nu}(x)\}|0\rangle + \mathcal{O}(\theta^2). \quad (A1)$$

Substituting Eq. (5) into the above expression, we obtain

$$\langle 0|\bar{q}\Gamma q|0\rangle_{\theta_G} = i\int d^4x \langle 0|T\Big\{\bar{q}(0)\Gamma q(0)\frac{\theta_G}{2}\Big[\partial^\mu J_{5\mu}(x) - 2i\sum_{q=u,d,s} m_q\rho_q\bar{q}(x)\gamma_5 q(x)\Big]\Big\}|0\rangle + \mathcal{O}(\theta^2), \quad (A2)$$

with $\rho_q = \theta_q/\theta_Q$. The first term in the equation is calculated with the aid of the integration by parts:

$$\begin{aligned} & i\int d^4x\langle 0|T\Big\{\bar{q}(0)\Gamma q(0)\frac{\theta_G}{2}\partial^\mu J_{5\mu}(x)\Big\}|0\rangle \\ &= -\frac{i\theta_G}{2}\int d^4x\langle 0|[J^0_5(x),\bar{q}(0)\Gamma q(0)]\delta(x^0)|0\rangle \\ &= \frac{i\theta_G}{2}\rho_q\langle 0|\bar{q}\{\gamma_5,\Gamma\}q|0\rangle. \end{aligned} \quad (A3)$$

For the second term, we insert the intermediate states and keep only the contributions of the one-particle states of the pseudo Nambu-Goldstone bosons π^0 and η^0:

$$\begin{aligned} & -i\sum_{q=u,d,s}\int d^4x\langle 0|T\{\bar{q}(0)\Gamma q(0)\theta_G m_q\rho_q\bar{q}(x)i\gamma_5 q(x)\}|0\rangle \\ &= -\frac{\theta_G}{f_\pi m_\pi^2}(m_u\rho_u - m_d\rho_d)\langle\bar{q}q\rangle\langle 0|\bar{q}\Gamma q|\pi^0\rangle \\ &\quad -\frac{\theta_G}{\sqrt{3}f_\pi m_\eta^2}(m_u\rho_u + m_d\rho_d - 2m_s\rho_s)\langle\bar{q}q\rangle\langle 0|\bar{q}\Gamma q|\eta^0\rangle, \end{aligned} \quad (A4)$$

where f_π is the pion decay constant[8] and m_π and m_η denote the masses of π^0 and η^0, respectively.[9] As a result, we obtain

$$\begin{aligned}\langle 0|\bar{q}\Gamma q|0\rangle_{\theta_G} = {} & \frac{i\theta_G}{2}\rho_q\langle 0|\bar{q}\{\gamma_5,\Gamma\}q|0\rangle \\ & - \frac{\theta_G}{f_\pi m_\pi^2}(m_u\rho_u - m_d\rho_d)\langle\bar{q}q\rangle\langle 0|\bar{q}\Gamma q|\pi^0\rangle \\ & - \frac{\theta_G}{\sqrt{3}f_\pi m_\eta^2}(m_u\rho_u + m_d\rho_d - 2m_s\rho_s) \\ & \times\langle\bar{q}q\rangle\langle 0|\bar{q}\Gamma q|\eta^0\rangle. \end{aligned} \tag{A6}$$

Other contributions also may be evaluated through a similar procedure. For the contribution of the γ_5-mass terms,

$$\begin{aligned}\langle 0|\bar{q}\Gamma q|0\rangle_{\theta_q} = {} & -\frac{\theta_Q}{f_\pi m_\pi^2}(m_u\rho_u - m_d\rho_d)\langle\bar{q}q\rangle\langle 0|\bar{q}\Gamma q|\pi^0\rangle \\ & - \frac{\theta_Q}{\sqrt{3}f_\pi m_\eta^2}(m_u\rho_u + m_d\rho_d - 2m_s\rho_s) \\ & \times\langle\bar{q}q\rangle\langle 0|\bar{q}\Gamma q|\eta^0\rangle, \end{aligned} \tag{A7}$$

while for the contribution of the quark CEDM terms,

$$\begin{aligned}\langle 0|\bar{q}\Gamma q|0\rangle_{q\mathrm{CEDM}} = {} & \frac{1}{f_\pi m_\pi^2}\frac{m_0^2}{2}(\tilde{d}_u - \tilde{d}_d)\langle\bar{q}q\rangle\langle 0|\bar{q}\Gamma q|\pi^0\rangle \\ & + \frac{1}{\sqrt{3}f_\pi m_\eta^2}\frac{m_0^2}{2}(\tilde{d}_u + \tilde{d}_d - 2\tilde{d}_s) \\ & \times\langle\bar{q}q\rangle\langle 0|\bar{q}\Gamma q|\eta^0\rangle. \end{aligned} \tag{A8}$$

Furthermore, it is found that the quark EDMs induce no contribution.

Taking all of the contributions into account, we obtain the CP-violating contribution to the quark condensates as

$$\begin{aligned}&\langle 0|\bar{q}\Gamma q|0\rangle_{\not{C}P} \\ &= \frac{i\theta_G}{2}\rho_q\langle 0|\bar{q}\{\gamma_5,\Gamma\}q|0\rangle + \frac{1}{f_\pi m_\pi^2}\Bigg[\frac{m_0^2}{2}(\tilde{d}_u - \tilde{d}_d) \\ &\quad - \bar{\theta}(m_u\rho_u - m_d\rho_d)\Bigg]\langle\bar{q}q\rangle\langle 0|\bar{q}\Gamma q|\pi^0\rangle \\ &\quad + \frac{1}{\sqrt{3}f_\pi m_\eta^2}\Bigg[\frac{m_0^2}{2}(\tilde{d}_u + \tilde{d}_d - 2\tilde{d}_s) \\ &\quad - \bar{\theta}(m_u\rho_u + m_d\rho_d - 2m_s\rho_s)\Bigg]\langle\bar{q}q\rangle\langle 0|\bar{q}\Gamma q|\eta^0\rangle \\ &= \frac{i\theta_G}{2}\rho_q\langle 0|\bar{q}\{\gamma_5,\Gamma\}q|0\rangle. \end{aligned} \tag{A9}$$

[8]We use the PCAC relation for π^0,

$$\partial_\mu J_A^\mu(x) = -f_\pi m_\pi^2\pi(x), \tag{A5}$$

and a similar relation for η^0.

[9]The effect of the π^0-η^0 mixing is suppressed by a small factor of $(m_u - m_d)/m_s$, and we ignore it for brevity.

Here, the second equality comes from the conditions in Eq. (10). Thus, the choice of the quark mass phases in Eq. (12) reduces the contribution of the CP-violating interactions to the vacuum condensates into a quite simple expression.

Note that the CP-violating contribution to the quark condensates vanishes in the basis where the θ term is completely rotated out into the imaginary mass term. Thus, the choice of this basis, which is often adopted in the chiral Lagrangian approach, simplifies the calculation. In our paper, however, we remain in a general basis in order to display each contribution explicitly.

Next, we discuss the way of translating the quark and gluon background fields into their condensates. To begin with, we consider a single quark line $\chi^q_{a\alpha}(x)\bar{\chi}^q_{b\beta}(0)$. In this case, it is related with the quark condensate as follows:

$$\chi^q_{a\alpha}(x)\bar{\chi}^q_{b\beta}(0) = \langle\Omega_{\not{C}P}|q_{a\alpha}(x)\bar{q}_{b\beta}(0)|\Omega_{\not{C}P}\rangle_F. \tag{A10}$$

Using the Fierz identity, the right-hand side of the expression leads to

$$\begin{aligned}&\langle\Omega_{\not{C}P}|q_{a\alpha}(x)\bar{q}_{b\beta}(0)|\Omega_{\not{C}P}\rangle_F \\ &= -\frac{\delta_{ab}}{12}\Big[\langle\bar{q}(0)q(x)\rangle_{F,\not{C}P} + \gamma_5\langle\bar{q}(0)\gamma_5 q(x)\rangle_{F,\not{C}P} \\ &\quad + \gamma^\mu\langle\bar{q}(0)\gamma_\mu q(x)\rangle_{F,\not{C}P} - \gamma^\mu\gamma_5\langle\bar{q}(0)\gamma_\mu\gamma_5 q(x)\rangle_{F,\not{C}P} \\ &\quad + \frac{1}{2}\sigma^{\mu\nu}\langle\bar{q}(0)\sigma_{\mu\nu}q(x)\rangle_{F,\not{C}P}\Big]_{\alpha\beta}. \end{aligned} \tag{A11}$$

These quark condensate terms are evaluated by conducting the short-distance expansion of the quark field in the Fock-Schwinger gauge as

$$q(x) = q(0) + x^\mu D_\mu q(0) + \cdots. \tag{A12}$$

We note that in this gauge one does not need to care about Wilson-line operators for the quark fields. (See Appendix A 3.)

In the case of CP-even vacuum, the Lorentz and CP invariance of vacuum tell us that

$$\langle\bar{q}\gamma_5 q\rangle = \langle\bar{q}\gamma_\mu q\rangle = \langle\bar{q}\gamma_\mu\gamma_5 q\rangle = 0. \tag{A13}$$

On the other hand, on an electromagnetic background, $\langle\bar{q}\sigma_{\mu\nu}q\rangle$ may have a nonzero vacuum expectation value proportional to the electromagnetic field strength $F_{\mu\nu}$. The electromagnetic field dependence for quark condensates is given as

$$\langle\bar{q}\sigma_{\mu\nu}q\rangle_F = \chi_q F_{\mu\nu}\langle\bar{q}q\rangle, \tag{A14}$$

where χ_q is called the quark condensate magnetic susceptibility [22]. Similar parametrization is used for the condensates including the gluon background field:

$$g_s\langle\bar{q}G^A_{\mu\nu}T^A q\rangle_F = \kappa_q F_{\mu\nu}\langle\bar{q}q\rangle, \tag{A15}$$

$$2g_s\langle\bar{q}\gamma_5\tilde{G}^A_{\mu\nu}T^A q\rangle_F = i\xi_q F_{\mu\nu}\langle\bar{q}q\rangle. \tag{A16}$$

As in Ref. [22], we assume χ_q, κ_q, and ξ_q to be proportional to the quark charge:

$$\chi_q = e_q\chi, \qquad \kappa_q = e_q\kappa, \qquad \xi_q = e_q\xi. \tag{A17}$$

This assumption corresponds to neglecting of the closed-loop contribution with gluon exchange.

Now let us consider the effect of the CP-violating interaction in Eq. (2) to the quark condensates. By using Eq. (A9) and the expansion in Eq. (A12), we evaluate each quark condensate on the CP-violating background as follows (with omitting the subscriptions F and $\not{C}P$ for simplicity as long as it is not confusing):

$$\langle\bar{q}(0)q(x)\rangle = \langle\bar{q}q\rangle, \tag{A18}$$

$$\langle\bar{q}(0)\gamma_5 q(x)\rangle = \langle\bar{q}\gamma_5 q\rangle_{\not{C}P} = i\theta_{G\rho q}\langle\bar{q}q\rangle, \tag{A19}$$

$$\begin{aligned}\langle\bar{q}(0)\gamma_\mu q(x)\rangle &= x^\nu\langle\bar{q}\gamma_\mu D_\nu q\rangle \\ &= \frac{1}{2}x^\nu\langle\bar{q}\{\gamma_\mu D_\nu + \gamma_\nu D_\mu\}q\rangle \\ &\quad + \frac{1}{2}x^\nu\langle\bar{q}\{\gamma_\mu D_\nu - \gamma_\nu D_\mu\}q\rangle \\ &= \frac{1}{4}x^\nu g_{\mu\nu}\langle\bar{q}\not{D}q\rangle + \frac{i}{4}x^\nu\langle\bar{q}\not{D}, \sigma_{\mu\nu}]q\rangle \\ &= -\frac{i}{4}m_q x_\mu\langle\bar{q}q\rangle,\end{aligned} \tag{A20}$$

where we use the classical equations of motion in the quark condensates and move the covariant derivatives with help of total derivative. The validity of this procedure is discussed in Appendix A 2. Furthermore,

$$\begin{aligned}\langle\bar{q}(0)\gamma_\mu\gamma_5 q(x)\rangle &= x^\nu\langle\bar{q}\gamma_\mu D_\nu\gamma_5 q\rangle \\ &= \frac{1}{4}x^\nu g_{\mu\nu}\langle\bar{q}\not{D}\gamma_5 q\rangle + \frac{i}{4}x^\nu\langle\bar{q}[\not{D}, \sigma_{\mu\nu}]\gamma_5 q\rangle \\ &= \frac{i}{2}m_q e_q\chi(\bar{\theta}\rho_q F_{\mu\nu} + \tilde{F}_{\mu\nu})x^\nu\langle\bar{q}q\rangle \\ &\quad + \frac{i}{2}\left(d_q + \left[\kappa - \frac{1}{2}\xi\right]e_q\tilde{d}_q\right)x^\nu F_{\mu\nu}\langle\bar{q}q\rangle,\end{aligned} \tag{A21}$$

and

$$\begin{aligned}\langle\bar{q}(0)\sigma_{\mu\nu}q(x)\rangle &= \langle\bar{q}\sigma_{\mu\nu}q\rangle \\ &= \langle\bar{q}\sigma_{\mu\nu}q\rangle_{CP\text{ even}} + \langle\bar{q}\sigma_{\mu\nu}q\rangle_{\not{C}P} \\ &= e_q\chi[F_{\mu\nu} - \theta_G\rho_q\tilde{F}_{\mu\nu}]\langle\bar{q}q\rangle.\end{aligned} \tag{A22}$$

Taking the above discussion into account and using the relation

$$F_{\mu\nu}x^\mu\gamma^\nu\gamma_5 = +\tfrac{1}{4}\{\tilde{F}\cdot\sigma, \not{x}\} \tag{A23}$$

and

$$F\cdot\sigma = i\tilde{F}\cdot\sigma\gamma_5, \tag{A24}$$

we finally obtain the expression for the single quark line as follows:

$$\begin{aligned}\chi^q_{a\alpha}(x)\bar{\chi}^q_{b\beta}(0) &= -\frac{\delta_{ab}}{12}(1 + i\theta_G\rho_q\gamma_5)_{\alpha\beta}\langle\bar{q}q\rangle + \frac{i}{48}\delta_{ab}\not{x}_{\alpha\beta}m_q\langle\bar{q}q\rangle - \frac{i}{96}\delta_{ab}\left[\bar{\theta}m_q\rho_q e_q\chi + d_q + \left(\kappa - \frac{1}{2}\xi\right)e_q\tilde{d}_q\right] \\ &\quad\times\{\tilde{F}\cdot\sigma, \not{x}\}_{\alpha\beta}\langle\bar{q}q\rangle + \frac{i}{96}m_q e_q\chi\delta_{ab}\{F\cdot\sigma, \not{x}\}_{\alpha\beta}\langle\bar{q}q\rangle - \frac{i}{24}e_q\chi\delta_{ab}(\tilde{F}\cdot\sigma\gamma_5[1 + i\rho_q\theta_G\gamma_5])_{\alpha\beta}\langle\bar{q}q\rangle.\end{aligned} \tag{A25}$$

Last, we evaluate the interaction part of the quark and gluon background fields:

$$g_s\chi^q_{a\alpha}(x)\chi^{-q}_{b\beta}(0)[G_{\mu\nu}]_{cd} = \langle g_s q_{a\alpha}(x)[G_{\mu\nu}]_{cd}\bar{q}_{b\beta}(0)\rangle_{F,\not{C}P}. \tag{A26}$$

Again, we use the Fierz identity and the short-distance expansion of the quark field, and through a similar calculation, we find the following results:

$$\begin{aligned}g_s\chi^q_{a\alpha}(x)\bar{\chi}^q_{b\beta}(0)[G_{\mu\nu}]_{cd} &= -\frac{1}{32}\left(\delta_{ad}\delta_{bc} - \frac{1}{3}\delta_{ab}\delta_{cd}\right)\langle\bar{q}q\rangle\times\left[e_q\left(\kappa F_{\mu\nu} - \frac{i}{2}\xi\tilde{F}_{\mu\nu}\gamma_5\right)(1 + i\theta_G\rho_q\gamma_5)\right. \\ &\quad - \frac{i}{4}m_q e_q\not{x}\left(\kappa F_{\mu\nu} + \frac{1}{2}\bar{\theta}\rho_q\xi\tilde{F}_{\mu\nu}\right) - \frac{i}{24}m_q m_0^2\epsilon_{\mu\nu\rho\sigma}x^\rho\gamma^\sigma\gamma_5 - \frac{i}{24}\bar{\theta}m_q\rho_q m_0^2(x_\mu\gamma_\nu\gamma_5 - x_\nu\gamma_\mu\gamma_5) \\ &\quad \left. - \frac{1}{12}m_0^2\sigma_{\mu\nu} - \frac{i}{12}m_0^2\theta_G\rho_q\sigma_{\mu\nu}\gamma_5\right]_{\alpha\beta}.\end{aligned} \tag{A27}$$

2. EQUATIONS OF MOTION

Let us discuss the validity of using classical equations of motion for quark condensates. We investigate the following quantity:

$$\langle 0|\bar{q}\Gamma(i\not{D} - m_q)q|0\rangle_\theta, \tag{A28}$$

where Γ is a (c-number) 4×4 matrix. The subscript indicates that this quantity is evaluated in the θ vacuum. One may readily generalize the discussion here for the case with other CP-violating sources. The discussion presented in this section is based on Ref. [31].

First, we define the generating functional $Z[\eta]_\theta$ on the same background:

$$Z[\eta]_\theta \equiv \int \mathcal{D}\bar{q}\mathcal{D}q \exp\left[i \int d^4x \{\mathcal{L} + \eta\bar{q}\Gamma(i\not{\partial} - m_q)q\}\right]. \tag{A29}$$

Here, the Lagrangian density $\mathcal{L}$ is

$$\mathcal{L} = \bar{q}(i\not{\partial} - m_q)q. \tag{A30}$$

The functional derivative of the generating function with respect to the function η yields Eq. (A28), that is,

$$\langle 0|\bar{q}\Gamma(i\not{\partial} - m_q)q|0\rangle_\theta \propto \frac{\delta Z[\eta]_\theta}{\delta\eta(0)}\bigg|_{\eta=0}. \tag{A31}$$

Now we replace the integration variable $\bar{q}$ with a new integration variable $\bar{q}'$ as

$$\bar{q} \to \bar{q}' = \bar{q} - \eta\bar{q}\Gamma. \tag{A32}$$

Since this step does not change the integral, then we obtain

$$Z[\eta] = \int \mathcal{D}\bar{q}\mathcal{D}q\left[\mathrm{Det}\left\{\frac{\delta\bar{q}'}{\delta\bar{q}}\right\}\right]^{-1} \exp\left[i\int d^4x\mathcal{L} + \mathcal{O}(\eta^2)\right], \tag{A33}$$

where the inverse of the Jacobian comes from the transformation of the measure for the fermionic variable.

Next, we evaluate the Jacobian in the expression above. Since we are interested in the first-order derivative of the generating function, we expand the Jacobian in η and keep only terms linear in η:

$$\frac{\delta\bar{q}'_\beta(y)}{\delta\bar{q}_\alpha(x)} = \delta_{\alpha\beta}\delta^4(x-y) - \eta(y)\Gamma_{\alpha\beta}\delta^4(x-y) + \mathcal{O}(\eta^2). \tag{A34}$$

Using the identity

$$\mathrm{Det}\, M = \exp \mathrm{Tr} \ln M, \tag{A35}$$

we readily obtain the Jacobian as

$$\mathrm{Det}\left\{\frac{\delta\bar{q}'}{\delta\bar{q}}\right\} = \exp\left[-\mathrm{Tr}(\Gamma)\int d^4x\eta(x)\delta^4(x-x)\right]. \tag{A36}$$

It is found that if the trace of the matrix Γ is nonzero, the Jacobian yields a singular factor, while if it vanishes, we need careful treatment for evaluating this term. So, in the following discussion, we divide Γ into two types; one is the term proportional to the unit matrix, and the other is the traceless part.

First, we consider the case $\Gamma \propto \mathbb{1}$. Using Eqs. (A31), (A33), and (A36), we obtain the following equation:

$$\langle 0|\bar{q}\Gamma(i\not{\partial} - m_q)q|0\rangle_\theta = -i\mathrm{Tr}(\Gamma)\delta^4(0). \tag{A37}$$

Once we carry out the normal ordering for the composite operator $\bar{q}\Gamma(i\not{\partial} - m_q)q$, the singular factor in the right-hand side vanishes. Thus we conclude that, after normal ordering,

$$\langle 0|\bar{q}\Gamma(i\not{\partial} - m_q)q|0\rangle_\theta = 0, \tag{A38}$$

when $\Gamma \propto \mathbb{1}$. This equation implies that we may use the equations of motion for quark condensates in this case.

Next, we shall turn to the traceless part. In this case, the Jacobian in Eq. (A36) is written in terms of the anomaly function defined as

$$\mathcal{A}(x) \equiv 2\mathrm{Tr}(\Gamma)\delta^4(x-x). \tag{A39}$$

With this function, Eq. (A36) leads to

$$\mathrm{Det}^{-1}\left\{\frac{\delta\bar{q}'}{\delta\bar{q}}\right\} = \exp\left[+\frac{1}{2}\int d^4x\eta(x)\mathcal{A}(x)\right]. \tag{A40}$$

The usual analysis for the chiral anomaly tells us that the function $\mathcal{A}(x)$ in Eq. (A39) does not vanish only for the case $\Gamma = \gamma_5$. Thus, if $\Gamma \neq \gamma_5$, Eq. (A38) is satisfied. When $\Gamma = \gamma_5$, on the other hand, the function $\mathcal{A}(x)$ is evaluated as

$$\mathcal{A}(x) = \frac{\alpha_s}{4\pi}G^A_{\mu\nu}\tilde{G}^{A\mu\nu}. \tag{A41}$$

From Eqs. (A31), (A33), and (A40), we eventually find that

$$\langle 0|\bar{q}\gamma_5(i\not{\partial} - m_q)q|0\rangle_\theta = -\frac{i\alpha_s}{8\pi}\langle 0|G^A_{\mu\nu}\tilde{G}^{A\mu\nu}|0\rangle_\theta. \tag{A42}$$

This expression is simplified via the axial current anomaly equation:

$$\partial^\mu(\bar{q}\gamma_\mu\gamma_5 q) = 2im_q\bar{q}\gamma_5 q + \frac{\alpha_s}{4\pi}G^A_{\mu\nu}\tilde{G}^{A\mu\nu}. \tag{A43}$$

Then, Eq. (A42) leads to

$$\langle 0|\bar{q}\gamma_5 i\not{\partial}q|0\rangle_\theta = \frac{1}{2i}\langle 0|\partial^\mu(\bar{q}\gamma_\mu\gamma_5 q)|0\rangle_\theta = 0. \tag{A44}$$

Therefore, we are not able to use the classical equations of motion for quark condensates in this case.

As a result, we find that

$$\langle 0|\bar{q}\Gamma i\not{\partial}q|0\rangle_\theta = \begin{cases} \langle 0|\bar{q}\Gamma m_q q|0\rangle_\theta & (\text{for } \Gamma = \mathbb{1}, \gamma_\mu, \gamma_\mu\gamma_5, \sigma_{\mu\nu}) \\ 0 & (\text{for } \Gamma = \gamma_5). \end{cases} \tag{A45}$$

Also, its conjugate leads to

$$-\langle 0|\bar{q}i\overleftarrow{\not{\partial}}\Gamma q|0\rangle_\theta = \begin{cases} \langle 0|\bar{q}m_q\Gamma q|0\rangle_\theta & (\text{for } \Gamma = \mathbb{1}, \gamma_\mu, \gamma_\mu\gamma_5, \sigma_{\mu\nu}) \\ 0 & (\text{for } \Gamma = \gamma_5). \end{cases} \tag{A46}$$

Before concluding the section, we add a comment on the condensate of the total derivative terms. As we have already conducted in Eq. (A44), the Lorentz invariance of vacuum implies that condensates of the divergence of quark bilinear always vanish, i.e.,

$$\langle 0|\partial^\mu(\bar{q}\Gamma_\mu q)|0\rangle = \partial^\mu\langle 0|(\bar{q}\Gamma_\mu q)|0\rangle = 0, \tag{A47}$$

with Γ_μ a constant matrix which transforms as a vector under the Lorentz transformation, such as γ_μ, $\gamma_\mu\gamma_5$, or so

on. On the other hand, the total derivative of the quark bilinear is written as

$$\partial^\mu(\bar{q}\Gamma_\mu q) = (\partial^\mu\bar{q})\Gamma_\mu q + \bar{q}\Gamma_\mu(\partial^\mu q) = \bar{q}\,\overleftarrow{D^\mu}\,\Gamma_\mu q + \bar{q}\Gamma_\mu D^\mu q. \quad \text{(A48)}$$

Thus we find

$$\langle 0|\bar{q}\,\overleftarrow{D^\mu}\,\Gamma_\mu q|0\rangle = -\langle\bar{q}\Gamma_\mu D^\mu q|0\rangle. \quad \text{(A49)}$$

3. WILSON LINE IN FOCK-SCHWINGER GAUGE

Quark fields $q(x)$ are always accompanied by an appropriate Wilson-line operator in order to compensate the different gauge transformation property of the quark fields at different space-time points. In the Fock-Schwinger gauge, however, one may always choose a particular path which makes the Wilson-line operator equal to identity [32]. We show this statement in the following. The Wilson line is written as

$$U_P(x,0) = P\left\{\exp\left[ig_s\int_0^1 ds\,\frac{dx'^\mu(s)}{ds}G^A_\mu(x'(s))T^A\right]\right\}, \quad \text{(A50)}$$

where

$$x'(0) = 0, \qquad x'(1) = x, \quad \text{(A51)}$$

and P denotes path ordering. This operator depends on the choice of the integration path. Here we take a path such that

$$x'(s) = sx. \quad \text{(A52)}$$

Then,

$$U_P(x,0) = P\left\{\exp\left[ig_s\int_0^1 dsx^\mu G^A_\mu(sx)T^A\right]\right\}. \quad \text{(A53)}$$

In the Fock-Schwinger field, the gluon field is expanded as

$$G_\mu(x) = \frac{1}{2\cdot 0!}x^\nu G_{\nu\mu}(0) + \frac{1}{3\cdot 1!}x^\alpha x^\nu(D_\alpha G_{\nu\mu}(0)) + \frac{1}{4\cdot 2!}x^\alpha x^\beta x^\nu(D_\alpha D_\beta G_{\nu\mu}(0)) + \cdots. \quad \text{(A54)}$$

Inserting this expression into Eq. (A53), we readily find that all terms in the exponential vanish due to the antisymmetric property of the gluon field strength tensor. Therefore,

$$U_P(x,0) = 1. \quad \text{(A55)}$$

Abstract: We revisit proton decay via the color-triplet Higgs multiplets in the minimal supersymmetric grand unified model with heavy sfermions. Although the model has been believed to be excluded due to the too short lifetime of proton, we have found that it is possible to evade the experimental constraints on the proton decay rate if the supersymmetric particles have masses much heavier than the electroweak scale. With such heavy sfermions, the 126 GeV Higgs boson is naturally explained, while they do not spoil the gauge coupling unification and the existence of dark matter candidates. Since the resultant proton lifetime lies in the regions which may be reached in the future experiments, proton decay searches may give us a chance to verify the scenario as well as the supersymmetric grand unified models.

1 Introduction

The discovery of the Higgs boson [1, 2] has opened the way for physics beyond the Standard Model (SM). It is certainly a striking hint for understanding the high-energy physics, as elementary scalar particles may play an important role in realizing our complicated world with apparent broken symmetries. The theories with supersymmetry (SUSY) naturally include such scalar particles; the Higgs boson might be a superpartner of chiral fermions, called higgsinos. Besides, there exists a set of scalar particles for each SM fermion, as well as adjoint fermions for the SM gauge bosons. Then, astonishingly enough, we find that with these extra particles the gauge coupling constants of the SM are to be unified at a certain high-energy scale with great accuracy [3–7]. This observation motivates us to study the supersymmetric grand unified theories (SUSY GUTs) [8, 9].

The SUSY GUTs predict an exciting phenomenon: proton decay. It is induced by the exchanges of the color-triplet Higgs multiplets and the X-bosons, and their effects are described in terms of the dimension-five and -six effective operators, respectively. In the minimal SUSY SU(5) GUT [8, 9], which is a simple supersymmetric extension of the original SU(5) GUT [10], the former process yields the dominant decay modes, such as $p \to K^+\bar{\nu}$. The lifetime of the channel is estimated as $\tau(p \to K^+\bar{\nu}) \lesssim 10^{30}$ yrs [11, 12], with the SUSY particles, in particular those of the third generation, assumed to have masses of around the electroweak scale. On the other hand, the Super-Kamiokande experiment gives stringent limits on the channels: $\tau(p \to K^+\bar{\nu}) > 4.0 \times 10^{33}$ yrs [13]. This contradiction makes it widely believed that the minimal SUSY SU(5) GUT has been already excluded and, therefore, needs some extensions in order to suppress the dimension-five proton decay.

JHEP07(2013)038

As is often the case with SUSY models, the SUSY GUTs are usually discussed within the context of the low-scale supersymmetry. Recently, experiments at the Large Hadron Collider (LHC) provide limits on the SUSY models. The ATLAS and CMS Collaborations have been searching for the SUSY particles and imposed severe constraints on their masses, especially those of squarks and gluino [14–16]. The mass bounds have began to exceed 1 TeV and, thus, the low-energy SUSY models are confronted with difficulties. Moreover, the observed mass of the Higgs boson around 126 GeV [1, 2] might also indicate the SUSY scale is considerably higher than the electroweak scale; in the minimal SUSY Standard Model (MSSM), the mass of the lightest Higgs boson is below the Z-boson mass at tree level, so sufficient mass difference between stops and top quark is required in order to raise the Higgs boson mass through the radiative corrections [17–21].

In fact, the SUSY models with heavy SUSY particles have a lot of attractive features [22–28]. First of all, since the flavor changing neutral current (FCNC) processes and/or the electric dipole moments induced by SUSY particles are suppressed by their masses, the SUSY flavor and CP problems [29] are relaxed when the masses are considerably heavy. As mentioned to above, the heavy sfermions yield sufficient radiative corrections to lift the Higgs mass up to 126 GeV [30–33]. They do not spoil the gauge coupling unification since the sfermions form complete SU(5) multiplets. Actually, it turns out that the unification is improved in the sense that the required threshold corrections at the GUT scale tend to be reduced [34]. As for the cosmology, the gravitino problem is avoided because of the high-scale SUSY breaking, and the thermal leptogenesis scenario well works with high reheating temperature [35]. Further, this high-scale SUSY scenario naturally accommodates dark matter (DM) candidates, which might be detected in future dark matter experiments directly [36–39] and indirectly [32, 40, 41]. Thus, with the recent LHC results considered, the high-scale SUSY scenario is even promising from a phenomenological point of view.

Interestingly, this scenario also provides an alternative solution to the problem regarding the dimension-five proton decay in the minimal SUSY GUT. The dimension-five operators generated via the color-triplet Higgs exchange contain squarks and/or sleptons in their external lines. These fields are to be integrated out below the SUSY scale through the wino or higgsino exchanging processes, and then the four-Fermi operators, suppressed by the sfermion masses, are induced. Hence, their effects are expected to be extremely reduced when the SUSY scale is much higher than the electroweak scale.

In this paper, we study such possibilities within the context of the high-scale SUSY scenario. We will find that the minimal SUSY SU(5) GUT actually evades the constraints from the proton decay experiments with the SUSY braking scales which naturally explain the 126 GeV Higgs boson and the existence of dark matter in the Universe. The resultant proton lifetime lies in the regions which may be reached in the future proton decay experiments. Therefore, although the high-scale SUSY scenario is hard to be probed in the collider experiments, the proton decay searches may give us a chance to verify the scenario as well as the existence of supersymmetry and the grand unification.

This paper is organized as follows: In section 2, a high-scale SUSY model which we discuss in this work and its phenomenology are briefly explained. In the next section, we

JHEP07(2013)038

give a set of formulae for evaluating the proton decay rate via the dimension-five operators. Then, we show the resultant proton lifetime in the model, and compare it with current experimental limits in section 4. Section 5 is devoted to conclusions and discussion.

2 High-scale SUSY

To begin with, we describe a high-scale SUSY model which we deal with in the following discussion. Assume that there exists a SUSY breaking hidden sector where the SUSY breaking is triggered by a chiral superfield Z which is not a gauge singlet. Then, with a generic form of Kähler potential, all the scalar bosons except the lightest Higgs boson acquire masses of

$$M_S \sim \frac{F_Z}{M_*}\,, \tag{2.1}$$

with F_Z and M_* the F-component vacuum expectation value (VEV) of the field Z and the mediation scale of the SUSY breaking, respectively.The gravitino mass is $m_{3/2} = F_Z/\sqrt{3}M_{\rm Pl}$, and it is the same order as the scalar masses when M_* is around the Planck scale, $M_{\rm Pl}$. The soft masses for the two doublet Higgses and the μ-term are fine-tuned in order to realize the electroweak symmetry breaking at the proper scale. The gaugino masses, on the other hand, are not generated by the dimension-five operators like

$$\int d^2\theta\ Z{\rm Tr}[W^\alpha W_\alpha]\,, \tag{2.2}$$

since the symmetry under which the superfield Z is charged prohibits such an operator. Here, W_α denotes the gauge field-strength chiral superfield. Instead, they are induced by the anomaly mediation mechanism [42, 43]:

$$M_a = \frac{b_a g_a^2}{16\pi^2} m_{3/2}\,, \tag{2.3}$$

where M_1, M_2, and M_3 are the masses of bino, wino, and gluino, respectively, and b_a are the one-loop beta-function coefficients of the gauge coupling constants g_a ($a = 1,\ 2$, and 3 for ${\rm U}(1)_Y$, ${\rm SU}(2)_L$, and ${\rm SU}(3)_C$, respectively). This expression tells us that the gaugino masses are suppressed by one-loop factors compared with the gravitino mass. Similarly, since we assume that the superfield which breaks supersymmetry is not a gauge-singlet, the A-terms are generated with the suppression by the loop factors. Finally, the higgsino mass, μ_H, is somewhat model-dependent; it might lie around the same order of gaugino masses when some additional symmetries exist, or be as large as gravitino masses if it is generated by the Kähler potential. Thus we regard it as a free parameter in the following discussion.

In this scenario, the lightest SUSY particle (LSP) is either wino, which turns out to be the lightest gaugino, or the lighter higgsino. Then, it is found that in any case the LSP may explain the dark matter in the Universe. Indeed, the thermal relic abundance of wino and higgsino DM with a mass of 2.7–3.0 TeV [44] and 1 TeV [45], respectively, accounts for the observed density of DM. With relatively small masses, the non-thermal production of them also might be consistent with the observation [46, 47]. The wino or higgsino DM in this model implies sfermion masses lie around 10^2–10^3 TeV.

JHEP07(2013)038

From now on, we assume the sfermions are nearly degenerate in mass, and their masses are collectively denoted by M_S. The mass is supposed to be $M_S \simeq 10^2$–10^3 TeV, and either wino or higgsino is assumed to be the LSP. Models with such a mass spectrum and their phenomenology have been enthusiastically studied in the previous literature [48–55].

As mentioned to in the Introduction, the mass spectrum does not spoil the gauge coupling unification [23, 24], since the sfermions are embedded in the complete multiplets of SU(5). In fact, the unification may be improved [34]; a renormalization group analysis reveals that all of the GUT scale particles, especially the color-triplet Higgs multiplets, possibly lie around the GUT scale $\simeq 10^{16}$ GeV, contrary to the case of the low-energy SUSY. It indicates that the threshold corrections to the gauge coupling constants at the GUT scale are reduced in the high-scale SUSY scenario. Thus, the SUSY GUTs are still well-motivated.

3 Proton decay in the minimal SUSY SU(5) GUT

In this section, we review the proton decay in the minimal SUSY SU(5) GUT. In this model, the MSSM matter fields are embedded in a $\bar{\mathbf{5}} \oplus \mathbf{10}$ representation. The $\mathrm{SU}(2)_L$ singlet down-type quarks $\bar{D}$ and doublet leptons L are incorporated into the $\bar{\mathbf{5}}$ fields, Φ, while the $\mathrm{SU}(2)_L$ singlet up-type quarks, $\bar{U}$, doublet quarks, Q, and singlet leptons, $\bar{E}$, are formed into the $\mathbf{10}$ representations, Ψ. Here all the superfields are expressed in terms of the left-handed chiral superfields. The explicit form of the multiplets is

$$\Phi = \begin{pmatrix} \bar{D}_1 \\ \bar{D}_2 \\ \bar{D}_3 \\ E \\ -N \end{pmatrix}, \qquad \Psi = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 & \bar{U}_3 & -\bar{U}_2 & U^1 & D^1 \\ -\bar{U}_3 & 0 & \bar{U}_1 & U^2 & D^2 \\ \bar{U}_2 & -\bar{U}_1 & 0 & U^3 & D^3 \\ -U^1 & -U^2 & -U^3 & 0 & \bar{E} \\ -D^1 & -D^2 & -D^3 & -\bar{E} & 0 \end{pmatrix}, \tag{3.1}$$

with

$$L = \begin{pmatrix} N \\ E \end{pmatrix}, \qquad Q^\alpha = \begin{pmatrix} U^\alpha \\ D^\alpha \end{pmatrix}. \tag{3.2}$$

Here, $\alpha = 1, 2, 3$ denotes the color index. The MSSM Higgs superfields, on the other hand, are embedded into a pair of $\mathbf{5}$ and $\bar{\mathbf{5}}$ superfields accompanied with the new Higgs superfields H_C^α and $\bar{H}_{C\alpha}$ called the color-triplet Higgs multiplets:

$$H = \begin{pmatrix} H_C^1 \\ H_C^2 \\ H_C^3 \\ H_u^+ \\ H_u^0 \end{pmatrix}, \qquad \bar{H} = \begin{pmatrix} \bar{H}_{C1} \\ \bar{H}_{C2} \\ \bar{H}_{C3} \\ H_d^- \\ -H_d^0 \end{pmatrix}, \tag{3.3}$$

where the last two components are corresponding to the MSSM Higgs superfields,

$$H_u = \begin{pmatrix} H_u^+ \\ H_u^0 \end{pmatrix}, \qquad H_d = \begin{pmatrix} H_d^0 \\ H_d^- \end{pmatrix}. \tag{3.4}$$

JHEP07(2013)038

Exchanges of the color-triplet Higgs multiplets induce the baryon-number violating interactions. They are coupled with the ordinary matter fields by the Yukawa coupling terms in the superpotential:[1]

$$W_{\rm Yukawa} = \frac{1}{4} h^{ij} \epsilon_{abcde} \Psi_i^{ab} \Psi_j^{cd} H^e - \sqrt{2} f^{ij} \Psi_i^{ab} \Phi_{ja} \bar{H}_b \,, \tag{3.5}$$

where $i, j = 1, 2, 3$ and $a, b, c, \ldots = 1$–5 represent the generations and the SU(5) indices, respectively. The Yukawa couplings h^{ij} and f^{ij} in eq. (3.5) have redundant degrees of freedom, most of which are eliminated by the field re-definition of Ψ and Φ [56]. We parametrize the couplings according to ref. [57] as

$$\begin{aligned} h^{ij} &= f_{u_i} e^{i\varphi_i} \delta_{ij} \,, \\ f^{ij} &= V_{ij}^* f_{d_j} \,, \end{aligned} \tag{3.6}$$

with V_{ij} the Cabibbo-Kobayashi-Maskawa (CKM) matrix. The phase factors φ_i are subject to a constraint

$$\varphi_1 + \varphi_2 + \varphi_3 = 0 \,, \tag{3.7}$$

and thus two of them are independent parameters. The Yukawa coupling terms in eq. (3.5) are written with the component fields as follows:

$$\begin{aligned} W_{\rm Yukawa} = {} & f_{u_i} e^{i\varphi_i} \epsilon_{rs} \overline{U}_{i\alpha} Q_i^{\alpha r} H_u^s - V_{ij}^* f_{d_j} \epsilon_{rs} Q_i^{\alpha r} \overline{D}_{j\alpha} H_d^s - f_{d_j} \epsilon_{rs} V_{ij}^* \overline{E}_i L_j^r H_d^s \\ & - \frac{1}{2} f_{u_i} e^{i\varphi_i} \epsilon_{\alpha\beta\gamma} \epsilon_{rs} Q_i^{\alpha r} Q_i^{\beta s} H_C^\gamma + V_{ij}^* f_{d_j} \epsilon_{rs} Q_i^{\alpha r} L_j^s \overline{H}_{C\alpha} \\ & + f_{u_i} e^{i\varphi_i} \overline{U}_{i\alpha} \overline{E}_i H_C^\alpha - V_{ij}^* f_{d_j} \epsilon^{\alpha\beta\gamma} \overline{U}_{i\alpha} \overline{D}_{j\beta} \overline{H}_{C\gamma} \,. \end{aligned} \tag{3.8}$$

Here, r, s are the $\mathrm{SU}(2)_L$ indices. In the following discussion, we also use the flavor basis for the matter fields. The relations between the flavor and gauge eigenstates are given as

$$\begin{aligned} Q_i &= \begin{pmatrix} U_i' \\ V_{ij} D_j' \end{pmatrix} , & L_i &= \begin{pmatrix} N_i' \\ E_i' \end{pmatrix} , \\ \bar{U}_i &= e^{-i\varphi_i} \bar{U}_i' , & \bar{D}_i &= \bar{D}_i' , & \bar{E}_i &= V_{ij} \bar{E}_j' \,, \end{aligned} \tag{3.9}$$

where primes represent the flavor eigenstates.

The Yukawa interactions of color-triplet Higgs multiplets give rise to the dimension-five baryon-number violating operators. The processes in which the operators are induced are illustrated by the diagrams in figure 1. After the color-triplet Higgs multiplets are decoupled, we obtain the effective superpotential as

$$\begin{aligned} W_5 = {} & + \frac{1}{2M_{H_C}} f_{u_i} f_{d_l} V_{kl}^* e^{i\varphi_i} \epsilon_{\alpha\beta\gamma} \epsilon_{rs} \epsilon_{tu} Q_i^{\alpha r} Q_i^{\beta s} Q_k^{\gamma t} L_l^u \\ & + \frac{1}{M_{H_C}} f_{u_i} e^{i\varphi_i} f_{d_l} V_{kl}^* \epsilon^{\alpha\beta\gamma} \overline{U}_{i\alpha} \overline{E}_i \overline{U}_{k\beta} \overline{D}_{l\gamma} \,, \end{aligned} \tag{3.10}$$

[1] In this paper we evaluate the proton decay rate with the SU(5) symmetric Yukawa couplings which are evaluated with up-type and down-type quark masses and the Cabibbo-Kobayashi-Maskawa matrix, though the ratios of charged lepton and down-type quark masses are not necessarily consistent with them. We have checked that, even if the lepton masses are used for f_{d_i}, our consequence presented below is not changed significantly.

JHEP07(2013)038

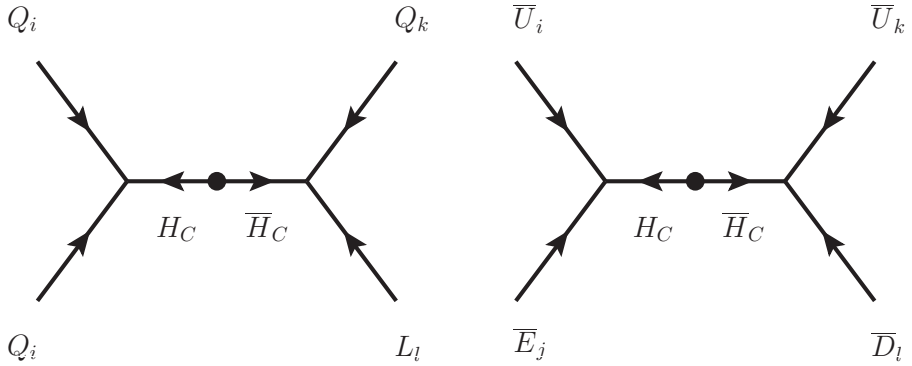

Figure 1. Supergraphs which illustrate color-triplet Higgs exchanging processes where dimension-five effective operators for proton decay are induced. Bullets indicate color-triplet Higgs mass term.

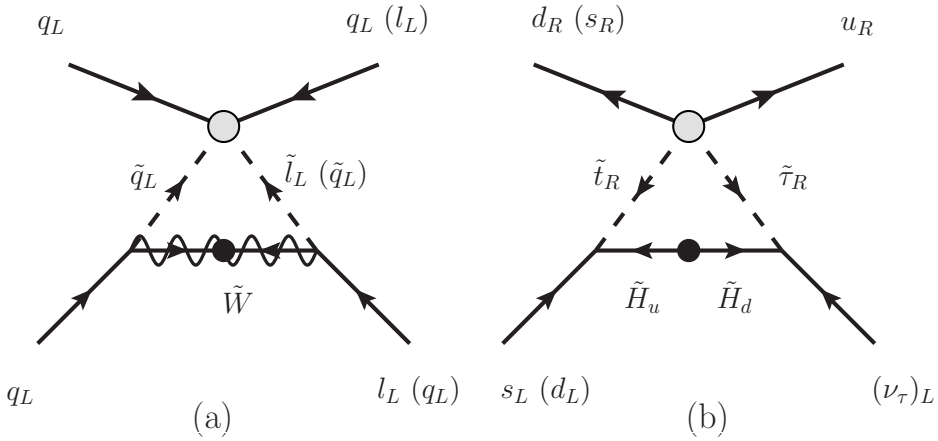

Figure 2. One-loop diagrams which yield the baryon-number violating four-Fermi operators. Diagrams (a) and (b) are generated by charged wino and higgsino exchanging processes, respectively. Gray dots indicate dimension-five effective interactions, while black dots represent wino or higgsino mass terms.

which yields the dimension-five effective operators,

$$\mathcal{L}_5 = \int d^2\theta W_5 \quad + \quad \text{h.c.}\,. \tag{3.11}$$

The effective operators contain sfermions in their external lines. Below the SUSY breaking scale, M_S, these sfermions turn into the SM fermions via the charged wino and higgsino exchanging processes shown in figure 2. In this figure, the gray and black dots indicate the dimension-five effective interactions and the mass terms for wino or higgsino, respectively. The first operator in eq. (3.10) contributes to the diagram (a), while the second one induces the diagram (b). Although the contribution of the diagram (b) is suppressed by the CKM matrix elements as it is generated in the flavor changing process, it is found to be sizable because of the large Yukawa couplings of the third generation fermions [11, 58]. The contributions of flavor-conserving neutral gauginos and higgsino

JHEP07(2013)038

exchange are in general suppressed by the Yukawa couplings of the first generation, thus negligible. Among them, the gluino contribution might be sizable because of the large coupling. It turns out, however, that the gluino contribution vanishes in the limit where squarks are degenerate in mass, and we consider such a case in the following calculation. When sfermion mass matrices have large flavor mixing, the contributions may also be significant, though we do not take into account such a situation for simplicity.

After the electroweak symmetry breaking, the charged wino and higgsino are mixed with each other. In the following calculation, however, we neglect the effect since we mainly consider the case where $M_2, \mu_H \gg m_W$ with m_W the mass of W-boson. When the masses of wino and higgsino are nearly degenerate, the mixing effects might be significant. It is straight-forward to modify the formulae obtained below in such a case.

Evolving the four-Fermi operators from the SUSY breaking scale to the hadron scale ($\sim 1\,\mathrm{GeV}$) according to the renormalization group equations (RGEs), we finally obtain the effective operators for proton decay as

$$\begin{aligned}\mathcal{L}_6 =& \frac{\alpha_2^2}{M_{H_C} m_W^2 \sin 2\beta}\Bigg[2F(M_2, M_S^2) \sum_{i,j=2,3} \overline{m}_{u_i}\overline{m}_{d_j} V_{u_i d} V_{u_i s} V_{ud_j}^* e^{i\varphi_i} \\ &\times A_R^{(i,j)} \epsilon_{\alpha\beta\gamma}\left\{(u_L^\alpha d_L^\beta)(\nu_{Lj} s_L^\gamma) + (u_L^\alpha s_L^\beta)(\nu_{Lj} d_L^\gamma)\right\} \\ &- \frac{\overline{m}_t^2 \overline{m}_\tau V_{tb}^* e^{i\varphi_1}}{m_W^2 \sin 2\beta} F(\mu_H, M_S^2) \overline{A}_R \epsilon_{\alpha\beta\gamma} \\ &\times \left\{\overline{m}_d V_{ud} V_{ts} (u_R^\alpha d_R^\beta)(\nu_\tau s_L^\gamma) + \overline{m}_s V_{us} V_{td} (u_R^\alpha s_R^\beta)(\nu_\tau d_L^\gamma)\right\}\Bigg] \\ &+ \text{h.c.}, \end{aligned} \tag{3.12}$$

where we use the two-component spinor notation for the SM fermion fields; all of the quarks are written in the flavor basis though primes are omitted for simplicity; M_S is the mass of sfermions with all the sfermions assumed to be degenerate in mass; $\overline{m}_q$ are the masses of quarks defined in the $\overline{\mathrm{DR}}$ scheme at the scale of $\mu = 2\,\mathrm{GeV}$; u_2, d_2, u_3, and d_3 denote c, s, t, and b quarks, respectively; $\alpha_2 \equiv g_2^2/4\pi$ with g_2 the $\mathrm{SU}(2)_L$ gauge coupling constant at the electroweak scale; $\tan\beta \equiv \langle H_u^0\rangle/\langle H_d^0\rangle$; $A_R^{(i,j)}$ and $\overline{A}_R$ in eq. (3.12) represent the renormalization factors. These factors include the renormalization effects for both the couplings and the effective operators. The estimation of these factors is carried out in appendix A.

The loop function $F(M, M_S^2)$ is given as

$$F(M, M_S^2) = M\left[\frac{1}{M_S^2 - M^2} - \frac{M^2}{(M_S^2 - M^2)^2}\ln\left(\frac{M_S^2}{M^2}\right)\right], \tag{3.13}$$

where M is either the wino mass, M_2, or the higgsino mass, μ_H. In the limit of $M \ll M_S$, the function leads to

$$F(M, M_S^2) \to \frac{M}{M_S^2}, \qquad (M_S \gg M)\,, \tag{3.14}$$

while in the limit of $M \to M_S$, it follows that

$$F(M, M_S^2) \to \frac{1}{2M_S}, \qquad (M \to M_S)\ . \tag{3.15}$$

JHEP07(2013)038

Note that the function is proportional to M, when $M \lesssim M_S$. For this reason, the contribution of the diagrams in figure 2 is enhanced when the masses of the exchanged particles are large. In particular, in the case of $\mu_H \gg M_2$, the higgsino exchange contribution (the diagram (b) in figure 2) dominates the wino exchange one. We also find from the behavior of the loop function that the transition amplitude is considerably suppressed when the sfermions have sufficiently large masses. Thus, we expect that the experimental constraints on the proton decay rate may be avoided in the high-scale SUSY scenario.

The effective operators in eq. (3.12) are written in terms of partons. In order to derive the decay amplitude for proton, we need to obtain the matrix elements of the quarks appearing in the operators between the proton state $|p\rangle$ and the kaon state $|K^+\rangle$. With the matrix elements, we finally obtain the partial decay widths, $\Gamma(p \to K^+\bar{\nu}_\mu)$ and $\Gamma(p \to K^+\bar{\nu}_\tau)$, and the sum of them well approximates the total decay rate of the $p \to K^+\bar{\nu}$ channel. Explicit formulae for the decay widths as well as the determination of the matrix elements are presented in appendix. B.

Before concluding this section, we briefly comment on the proton decay via the SU(5) gauge boson exchange. The SU(5) gauge bosons, called X-bosons, give rise to the dimension-six operators which contribute to proton decay by the $p \to \pi^0 e^+$ channel. In ref. [34], it is pointed out that the GUT scale in the high-scale SUSY tends to be slightly lower than that in the low-energy SUSY. Thus, the proton decay rate in this channel is expected to be enhanced. It turns out, however, that the resultant lifetime is generally long enough [59] to evade the current experimental bound, $\tau(p \to \pi^0 e^+) > 1.29 \times 10^{34}$ yrs [60]. Thus, we ignore the contribution in the following calculation.

4 Results

Now we show numerical results of the proton decay lifetime in the high-scale SUSY scenario. We will see below that the resultant lifetime is well above the current experimental limits in a wide range of parameter region.

First, we consider the case where the higgsino mass is of the order of the sfermion masses, M_S. In this case, the higgsino exchange contribution (the diagram (b) in figure 2) dominates the wino exchange one, as mentioned to in the previous section. For this reason, the lifetime has little dependence on the additional phases, φ_i in eq. (3.6), as well as the wino mass. Thus, it is possible to make a robust prediction for the proton decay lifetime. As the right-handed stop and stau run in the loop in the higgsino exchanging diagram, M_S should be regarded as their masses, which we assume to be degenerate for brevity. For $M_S = \mu_H$, the proton lifetime τ_p is approximately given as[2]

$$\tau_p \simeq 4 \times 10^{35} \times \sin^4 2\beta \left(\frac{0.1}{\overline{A}_R}\right)^2 \left(\frac{M_S}{10^2\ \mathrm{TeV}}\right)^2 \left(\frac{M_{H_C}}{10^{16}\ \mathrm{GeV}}\right)^2 \ \mathrm{yrs}\,, \tag{4.1}$$

and found to be well above the current experimental limits, $\tau(p \to K^+\bar{\nu}) > 4.0 \times 10^{33}$ yrs [13], with the SUSY scale being much higher than the electroweak scale.

[2]The renormalization factor reduces the proton decay rate for larger M_S when $M_S = \mu_H = (10^2$–$10^5)$ TeV, as described in figure 8 in appendix. A.

JHEP07(2013)038

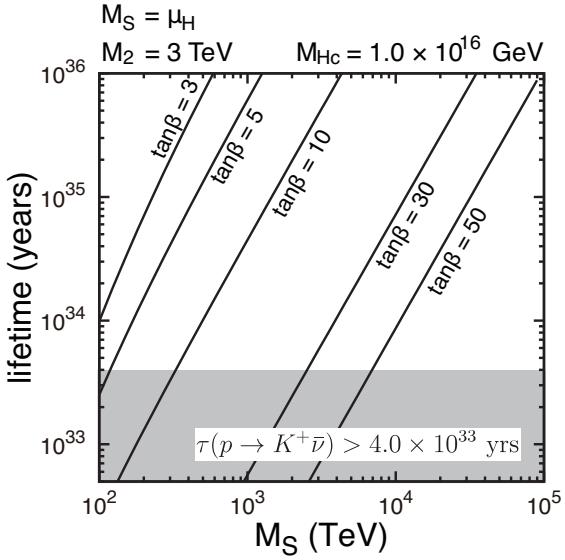

Figure 3. Lifetime of $p \to K^+\bar{\nu}$ mode as functions of $M_S = \mu_H$. Wino mass is set to be 3 TeV and $M_{H_C} = 1.0 \times 10^{16}$ GeV. Solid lines correspond to $\tan\beta = 3, 5, 10, 30$, and 50 from left-top to right-bottom, respectively. Shaded region is excluded by the current experimental bound, $\tau(p \to K^+\bar{\nu}) > 4.0 \times 10^{33}$ yrs [13].

Let us investigate it in detail. To begin with, we consider the mass of the color-triplet Higgs multiplets, M_{H_C}. As mentioned to in section 2, through the RGE analysis discussed in refs. [57, 61] with requiring the gauge coupling unification, one finds that M_{H_C} may be around the GUT scale in the case of high-scale SUSY [34]. The prediction is, however, quite sensitive to the mass spectrum below the GUT scale, especially to the masses of higgsinos and gauginos. Thus, in the following discussion, we just fix M_{H_C} to be around the GUT scale. One easily obtains proton lifetimes corresponding to other values of M_{H_C} by using the power law given in eq. (4.1).

In figure 3, we present the lifetime of the $p \to K^+\bar{\nu}$ mode as functions of $M_S = \mu_H$. Here, the wino mass is set to be 3 TeV, while the result scarcely depends on the mass as long as $M_2 \ll M_S$. The color-triplet Higgs mass is fixed to $M_{H_C} = 1.0 \times 10^{16}$ GeV. The solid lines are for $\tan\beta = 3, 5, 10, 30$, and 50 from left-top to right-bottom, respectively. The shaded region is excluded by the current experimental bound, $\tau(p \to K^+\bar{\nu}) > 4.0 \times 10^{33}$ yrs [13]. The figure illustrates the behavior presented in eq. (4.1). Moreover, it is found that the proton decay lifetime in the high-scale SUSY scenario may evade the experimental constraints, especially for small $\tan\beta$ and high SUSY breaking scales. We also show a similar plot for a relatively small value of M_{H_C} in figure 4, where the mass is taken to be 1.0×10^{15} GeV. The wino mass is again set to be $M_2 = 3$ TeV, and the solid lines correspond to $\tan\beta = 3, 5, 10$, and 30 from left-top to right-bottom, respectively. We see that the relation between the results presented in figures 3 and 4 is well explained by the simple power law in eq. (4.1), though the renormalization factors may also be changed with different values of M_{H_C}. For this reason, we just fix $M_{H_C} = 1.0 \times 10^{16}$ GeV in the following analysis. One easily read other results with different values of M_{H_C} by using the relation given in eq. (4.1).

JHEP07(2013)038

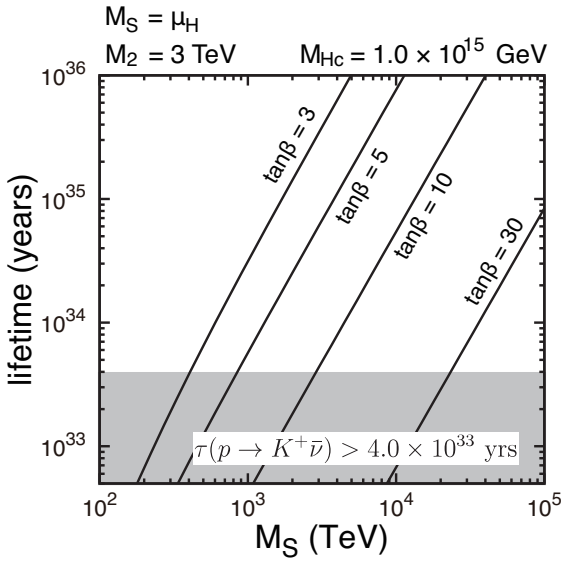

Figure 4. Lifetime of $p \to K^+\bar{\nu}$ mode as functions of $M_S = \mu_H$. Wino mass is set to be 3 TeV and $M_{H_C} = 1.0 \times 10^{15}$ GeV. Solid lines correspond to $\tan\beta = 3, 5, 10$, and 30 from left-top to right-bottom, respectively. Shaded region is excluded by the current experimental bound, $\tau(p \to K^+\bar{\nu}) > 4.0 \times 10^{33}$ yrs [13].

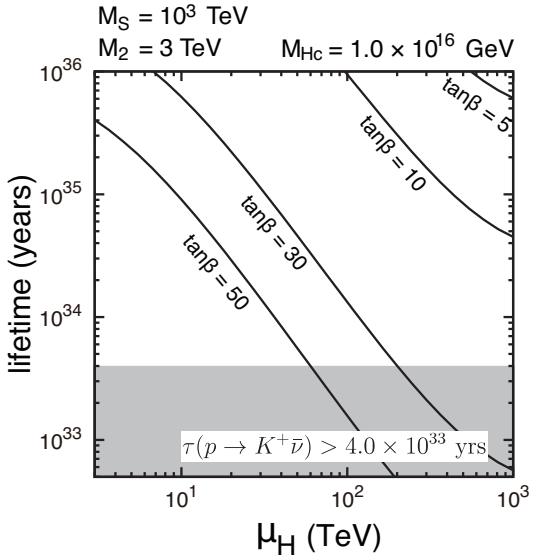

Figure 5. Lifetime of $p \to K^+\bar{\nu}$ mode as functions of μ_H. Wino, sfermion and color-triplet Higgs masses are set to be $M_2 = 3$ TeV, $M_S = 10^3$ TeV, and $M_{H_C} = 1.0 \times 10^{16}$ GeV, respectively. Solid lines correspond to $\tan\beta = 5, 10, 30$, and 50 from right-top to left-bottom, respectively. Shaded region is excluded by the current experimental bound, $\tau(p \to K^+\bar{\nu}) > 4.0 \times 10^{33}$ yrs [13].

Next, we consider the case where the higgsinos are lighter than the sfermions. In this case, the lifetime depends on the new phases appearing in eq. (3.6). Here, we take the phases so that they yield the maximal amplitude for the proton decay rate, i.e., we require that each term in eqs. (B.5) and (B.6) be constructive. This requirement together with

JHEP07(2013)038

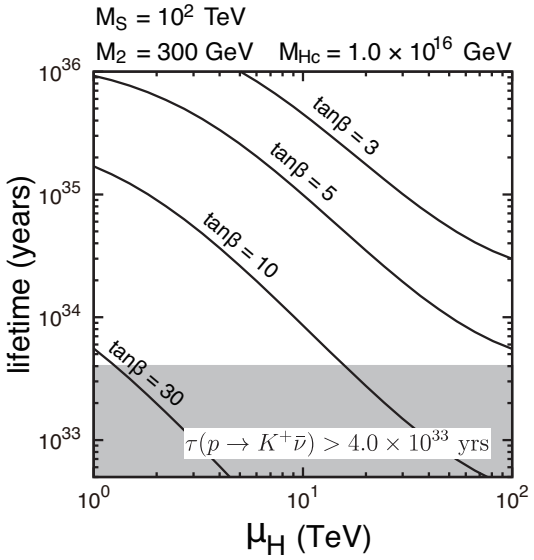

Figure 6. Lifetime of $p \to K^+\bar{\nu}$ mode as functions of μ_H. Wino, sfermion, and color-triplet Higgs masses are set to be $M_2 = 300\,\mathrm{GeV}$, $M_S = 10^2\,\mathrm{TeV}$, and $M_{H_C} = 1.0 \times 10^{16}\,\mathrm{GeV}$, respectively. Solid lines correspond to $\tan\beta = 3, 5, 10$, and 30 from right-top to left-bottom, respectively. Shaded region is excluded by the current experimental bound, $\tau(p \to K^+\bar{\nu}) > 4.0 \times 10^{33}$ yrs [13].

the constraint (3.7) uniquely determines all of the phases φ_i. Since the choice of phases gives the maximal proton decay rate, we are to obtain the most stringent limit on the parameters. In addition, we assume that both the higgsino and wino mass parameters are real and positive. However, as long as one chooses the phases constructively, the results would not change since it is possible to include the extra phases of the higgsino and wino masses into the redefinition of the phases φ_i.

In figure 5, we plot the proton lifetime as functions of the higgsino mass. Here, the wino, sfermion,[3] and color-triplet Higgs masses are set to be $M_2 = 3\,\mathrm{TeV}$, $M_S = 10^3\,\mathrm{TeV}$, and $M_{H_C} = 1.0 \times 10^{16}\,\mathrm{GeV}$, respectively. The solid lines correspond to $\tan\beta = 5, 10, 30$, and 50 from right-top to left-bottom, respectively. Again the shaded region is excluded by the current experimental bound, $\tau(p \to K^+\bar{\nu}) > 4.0 \times 10^{33}$ yrs [13]. It is found that the lifetime considerably depends on the mass of higgsino as well as the value of $\tan\beta$. It illustrates that the higgsino contribution is dominant in a wide range of parameter region. Indeed, the contribution gets more significant as the higgsino mass is raised up. We also show a similar plot in the case of $M_2 = 300\,\mathrm{GeV}$ and $M_S = 100\,\mathrm{TeV}$ in figure 6. In this case, large $\tan\beta$ region is excluded even if the higgsino mass is around 1 TeV, while with a rather small value of $\tan\beta$ the proton lifetime easily exceeds the experimental limit. Anyway, we have found that in the high-scale SUSY scenario, the minimal SUSY SU(5) GUT is still alive without any conspiracy of suppressing the dimension-five operators.

[3]To be concrete, we regard M_S as the stop mass, and all of the other sfermion masses are assumed to be degenerate with M_S. Generally speaking, stops are lighter than other sfermions, especially those of the first and second generations. So, even though one relaxes the degeneration assumption, one ends up obtaining a smaller proton decay rate.

JHEP07(2013)038

5 Conclusions and discussion

In this work, we have evaluated the proton decay lifetime via the dimension-five operators in the high-scale SUSY scenario. It is found that the higgsino exchanging diagram gives rise to the dominant contribution in a wide range of parameter region. After all, we have revealed that the proton lifetime may evade the current experimental limit and, thus, the minimal SUSY SU(5) GUT is not excluded in the high-scale SUSY scenario.

In the $\mu_H \simeq M_S$ case, after M_{H_C} being fixed, the proton lifetime depends only on M_S and $\tan\beta$. In fact, these two parameters are also crucial for the prediction of the Higgs boson mass in the high-scale SUSY scenario. Therefore, since now we know that the mass of Higgs boson is 126 GeV, it is possible to relate the M_S and $\tan\beta$ in the present scenario [30–33]. Further, if the mass spectrum is somehow fixed, we are able to constraint M_{H_C} by requiring the gauge coupling unification [34, 57, 61]. Precise analyses in this direction enable us to predict proton decay rate in this scenario, and future experiments may examine the prediction. Such kind of model-dependent study is carried out on another occasion.

While the dimension-five proton decay is suppressed by the heavy sfermion masses, the dimension-six one through the X-boson exchange does not suffer from such a suppression. As referred to above, the GUT scale in the high-scale SUSY is slightly lower than the ordinary one. Since the dimension-six proton decay lifetime scales as $\propto M_X^4$ with M_X the mass of X-boson, it may be significantly enhanced even by a small change in the GUT scale. In such a case, the $p \to \pi^0 e^+$ mode may dominate the $p \to K^+\bar{\nu}$ mode, and both of the modes might be searched in future experiments. For instance, the expected sensitivities of the Hyper-Kamiokande with ten years exposure [13] are 1.3×10^{35} and 2.5×10^{34} years at 90 % confidence level for the $p \to e^+\pi^0$ and $p \to \bar{\nu}K^+$ modes,[4] respectively, which enable us to explore a wide range of parameter region in high-scale SUSY models.

After all, the minimal SUSY SU(5) GUT is still quite promising, and the proton decay experiments may reveal the existence of supersymmetry as well as the grand unification.

Note added: while this work was being finalized, we noticed the authors in refs. [55, 63] discussed the dimension-five proton decay in a similar context. In ref. [55], they have just shown dimensional analysis to constraint the dimension-five operators, while in ref. [63], the proton lifetime is examined in supergravity unified models.

[4] Recent improvements in the analysis of the $K^+ \to \pi^+\pi^0$ decay channel may provide a better sensitivity for the $p \to \bar{\nu}K^+$ mode: 3.2×10^{34} years at 90 % confidence level [62].

JHEP07(2013)038

A Renormalization factors

Here we present the explicit expressions for the renormalization factors defined in eq. (3.12). First, we write the renormalization factors $A_R^{(i,j)}$ and $\overline{A}_R$ as the products of the long- and short-distance renormalization factors:

$$A_R^{(i,j)} \equiv A_L A_S^{(i,j)} ,$$
$$\overline{A}_R \equiv \overline{A}_L \overline{A}_S , \tag{A.1}$$

where A_L and $\overline{A}_L$ represent the long-distance QCD renormalization factors between the electroweak scale ($\mu = m_Z$ with m_Z the Z-boson mass) and the scale of $\mu = 2\,\mathrm{GeV}$, while $A_S^{(i,j)}$ and $\overline{A}_S$ correspond to the short-distance renormalization effects between the electroweak and GUT scales. All of the effects are to be computed at one-loop level.

A.1 Long-range factors

First, we discuss the long-distance renormalization factors. The factors consist of two effects; one is the running of the quark masses from $\mu = 2\,\mathrm{GeV}$ to $\mu = m_Z$, and the other is the renormalization effect of the four-Fermi operators in eq. (3.12) from $\mu = m_Z$ to $\mu = 2\,\mathrm{GeV}$. We neglect the QED corrections since the electromagnetic coupling is much smaller than the strong coupling.

Before analyzing the renormalization effects, we first discuss the input parameters for quark masses. In ref. [64], the values of the light quark masses m_q ($q = u, d, s$) are given in the $\overline{\mathrm{MS}}$ scheme at $\mu \simeq 2\,\mathrm{GeV}$, while those for c- and b-quarks are presented in the $\overline{\mathrm{MS}}$ at $\mu = m_c$ and m_b, respectively. Since we define $\overline{m}_q$ in eq. (3.12) in the $\overline{\mathrm{DR}}$ scheme, we convert the input parameters into those in the $\overline{\mathrm{DR}}$ scheme. We use the one-loop relation [65]:

$$\overline{m}_q(\mu) = m_q(\mu)\left(1 - \frac{\alpha_s(\mu)}{3\pi}\right) , \tag{A.2}$$

where $\alpha_s \equiv g_s^2/4\pi$ with g_s the strong coupling constant. For c- and b-quarks, we evolve the masses to $\mu = 2\,\mathrm{GeV}$ by using the RGEs. For top quark, on the other hand, the pole mass is displayed in ref. [64]. The relation between the pole mass and the $\overline{\mathrm{DR}}$ mass is given by [65]

$$m_t = \overline{m}_t(\mu)\left[1 + \frac{\alpha_s(\mu)}{3\pi}\left(6\log\frac{\mu}{\overline{m}_t} + 5\right)\right] . \tag{A.3}$$

Now we consider the QCD renormalization effects. The RGEs for the Wilson coefficients of the effective operators in eq. (3.12) at one-loop [66] are given as[5]

$$\mu\frac{\partial}{\partial\mu}C = -\frac{4g_s^2}{16\pi^2}C . \tag{A.4}$$

[5]Two-loop effects are also calculated in ref. [67], though their contribution is found to be small.

JHEP07(2013)038

By using the equation, as well as the RGEs for the quark masses, we readily obtain the long-range renormalization factors A_L and $\overline{A}_L$:

$$A_L = \frac{\overline{m}_{u_i}\overline{m}_{d_i}(m_Z)\cdot C(2\text{ GeV})}{\overline{m}_{u_i}\overline{m}_{d_i}(2\text{ GeV})\cdot C(m_Z)} = \left(\frac{\alpha_s(2\text{ GeV})}{\alpha_s(m_b)}\right)^{-\frac{18}{25}}\left(\frac{\alpha_s(m_b)}{\alpha_s(m_Z)}\right)^{-\frac{18}{23}},$$
$$\overline{A}_L = \frac{\overline{m}_t^2\overline{m}_{d_i}(m_Z)\cdot C(2\text{ GeV})}{\overline{m}_t^2\overline{m}_{d_i}(2\text{ GeV})\cdot C(m_Z)} = \left(\frac{\alpha_s(2\text{ GeV})}{\alpha_s(m_b)}\right)^{-\frac{6}{5}}\left(\frac{\alpha_s(m_b)}{\alpha_s(m_Z)}\right)^{-\frac{30}{23}}. \tag{A.5}$$

Numerically, we have

$$A_L = 0.53, \qquad \overline{A}_L = 0.34, \tag{A.6}$$

at one-loop level.

A.2 Short-range factors

Next, we evaluate the short-distance renormalization factors. They are composed of three factors. First, the effective operators given at the GUT scale receive the renormalization effects as they are taken down to the electroweak scale. Second, the Yukawa couplings in the color-triplet Higgs exchanging process are determined through the running of the couplings from the electroweak scale to the GUT scale. Third, the interaction vertices in the one-loop diagrams in figure 2 are obtained by evolving the $SU(2)_L$ gauge coupling and the Yukawa couplings according to the RGEs from the electroweak scale to the SUSY breaking scale, $\mu = M_S$.

Let us begin with the running of the Yukawa couplings. Initial values for the Yukawa coupling constants are given by

$$y_{u_i}(m_Z) = \frac{g_2}{\sqrt{2}m_W}\overline{m}_{u_i}(m_Z),$$
$$y_{d_i}(m_Z) = \frac{g_2}{\sqrt{2}m_W}\overline{m}_{d_i}(m_Z),$$
$$y_{e_i}(m_Z) = \frac{g_2}{\sqrt{2}m_W}\overline{m}_{e_i}(m_Z). \tag{A.7}$$

In the SM, the Yukawa couplings flow according to the following RGEs at one-loop level:

$$\mu\frac{\partial}{\partial\mu}y_{u_i} = \frac{1}{16\pi^2}y_{u_i}\left[\frac{3}{2}(y_{u_i}^2 - y_{d_i}^2) + Y_2 - \frac{17}{20}g_1^2 - \frac{9}{4}g_2^2 - 8g_3^2\right],$$
$$\mu\frac{\partial}{\partial\mu}y_{d_i} = \frac{1}{16\pi^2}y_{d_i}\left[\frac{3}{2}(y_{d_i}^2 - y_{u_i}^2) + Y_2 - \frac{1}{4}g_1^2 - \frac{9}{4}g_2^2 - 8g_3^2\right],$$
$$\mu\frac{\partial}{\partial\mu}y_{e_i} = \frac{1}{16\pi^2}y_{e_i}\left[\frac{3}{2}y_{e_i}^2 + Y_2 - \frac{9}{4}g_1^2 - \frac{9}{4}g_2^2\right], \tag{A.8}$$

where Y_2 is given as

$$Y_2 = \sum_i (3y_{u_i}^2 + 3y_{d_i}^2 + y_{e_i}^2), \tag{A.9}$$

and we neglect the off-diagonal components for simplicity. The equations are also applicable when the renormalization scale exceeds the gaugino masses. Above the higgsino mass,

JHEP07(2013)038

eq. (A.8) is valid except that Y_2 is modified to

$$Y_2 = \sum_i (3y_{u_i}^2 + 3y_{d_i}^2 + y_{e_i}^2) + \frac{3}{10}g_1^2 + \frac{3}{2}g_2^2 \,. \tag{A.10}$$

Here we assume the ordinary supersymmetric relation for the gaugino-Higgs-higgsino couplings. The couplings may deviate the relation when the SUSY breaking scale is much higher than the gaugino and higgsino masses, but it is found that the deviation is usually not so significant [23, 24].

At the SUSY breaking scale, the Yukawa couplings y_f are matched with the supersymmetric ones, $\overline{y}_f$, as follows:

$$\begin{aligned}
\overline{y}_{u_i}(M_S) &= \frac{1}{\sin\beta} y_{u_i}(M_S)\,, \\
\overline{y}_{d_i}(M_S) &= \frac{1}{\cos\beta} y_{d_i}(M_S)\,, \\
\overline{y}_{e_i}(M_S) &= \frac{1}{\cos\beta} y_{e_i}(M_S)\,.
\end{aligned} \tag{A.11}$$

Above $\mu = M_S$, the RGEs for the Yukawa couplings are given as

$$\begin{aligned}
\mu\frac{\partial}{\partial\mu}\overline{y}_{u_i} &= \frac{1}{16\pi^2}\overline{y}_{u_i}\left[3\sum_j \overline{y}_{u_j}^2 + 3\overline{y}_{u_i}^2 + \overline{y}_{d_i}^2 - \frac{13}{15}g_1^2 - 3g_2^2 - \frac{16}{3}g_3^2\right], \\
\mu\frac{\partial}{\partial\mu}\overline{y}_{d_i} &= \frac{1}{16\pi^2}\overline{y}_{d_i}\left[\sum_j (3\overline{y}_{d_j}^2 + \overline{y}_{e_j}^2) + 3\overline{y}_{d_i}^2 + \overline{y}_{u_i}^2 - \frac{7}{15}g_1^2 - 3g_2^2 - \frac{16}{3}g_3^2\right], \\
\mu\frac{\partial}{\partial\mu}\overline{y}_{e_i} &= \frac{1}{16\pi^2}\overline{y}_{e_i}\left[\sum_j (3\overline{y}_{d_j}^2 + \overline{y}_{e_j}^2) + 3\overline{y}_{e_i}^2 - \frac{9}{5}g_1^2 - 3g_2^2\right].
\end{aligned} \tag{A.12}$$

Then, at the GUT scale, the Yukawa couplings f_{u_i} and f_{d_i} in eq. (3.6) are defined by

$$\begin{aligned}
f_{u_i} &\equiv \overline{y}_{u_i}(M_{H_C})\,, \\
f_{d_i} &\equiv \overline{y}_{d_i}(M_{H_C})\,.
\end{aligned} \tag{A.13}$$

For the gauge couplings, the one-loop gauge coupling beta function coefficients are given in the SM as

$$b_a = (41/10, -19/6, -7)\,, \tag{A.14}$$

for $\mathrm{U}(1)_Y$, $\mathrm{SU}(2)_L$, and $\mathrm{SU}(3)_C$, respectively. Above the gaugino threshold, the coefficients are converted to[6]

$$b_a = (41/10, -11/6, -5)\,, \tag{A.15}$$

and after the higgsinos showing up, they lead to

$$b_a = (9/2, -7/6, -5)\,. \tag{A.16}$$

[6]When evaluating the renormalization factors, we take the gluino mass equal to wino mass for simplicity.

JHEP07(2013)038

Finally, in the MSSM, they are given as

$$b_a = (33/5, 1, -3) \ . \tag{A.17}$$

The short-distance renormalization factors for the four-Fermi operators in eq. (3.12) are presented in ref. [66]. For the effective operators generated by the wino exchanging diagram, the renormalization factor for the Wilson coefficient is

$$C(\mu) = \left(\frac{\alpha_3(\mu)}{\alpha_3(\mu_0)}\right)^{-\frac{2}{b_3}} \left(\frac{\alpha_2(\mu)}{\alpha_2(\mu_0)}\right)^{-\frac{15}{2b_2}} \left(\frac{\alpha_1(\mu)}{\alpha_1(\mu_0)}\right)^{-\frac{1}{10b_1}} C(\mu_0) \,, \tag{A.18}$$

while for those induced by the higgsino exchange, we have

$$\overline{C}(\mu) = \left(\frac{\alpha_3(\mu)}{\alpha_3(\mu_0)}\right)^{-\frac{2}{b_3}} \left(\frac{\alpha_2(\mu)}{\alpha_2(\mu_0)}\right)^{-\frac{9}{4b_2}} \left(\frac{\alpha_1(\mu)}{\alpha_1(\mu_0)}\right)^{-\frac{11}{20b_1}} \overline{C}(\mu_0) \ . \tag{A.19}$$

In the case of $\mu > M_S$, the theory is to be regarded as supersymmetric, and the renormalization factors are obtained as the product of the wave function renormalizations of the fields in the effective operators [68]. The wino contribution to the effective operators in eq. (3.12) is induced by the effective operators with a form like

$$C_{ij} \int d^2\theta \epsilon_{\alpha\beta\gamma}\epsilon_{rs}\epsilon_{tu} Q_i^{\alpha r} Q_i^{\beta s} Q_1^{rt} L_j^u \,, \tag{A.20}$$

with $i, j = 2, 3$, while the higgsino contribution is generated by

$$\overline{C} \int d^2\theta \epsilon^{\alpha\beta\gamma} \overline{U}_{3\alpha} \overline{E}_3 \overline{U}_{1\beta} \overline{D}_{l\gamma} \,, \tag{A.21}$$

with $l = 1, 2$. Then, the REGs for the Wilson coefficients of the operators are

$$\mu\frac{\partial}{\partial\mu} C_{ij} = \frac{1}{16\pi^2}\left[2(\overline{y}_{u_i}^2 + \overline{y}_{d_i}^2) + \overline{y}_{e_j}^2 - 8g_3^2 - 6g_2^2 - \frac{2}{5}g_1^2\right] C_{ij} \,, \tag{A.22}$$

and

$$\mu\frac{\partial}{\partial\mu} \overline{C} = \frac{1}{16\pi^2}\left[2(\overline{y}_t^2 + \overline{y}_\tau^2) - 8g_3^2 - \frac{12}{5}g_1^2\right] \overline{C} \ . \tag{A.23}$$

Note that in this case it is important to take the Yukawa interactions into account since the effective operators contain the third generation chiral superfields.

With the RGEs presented above, we finally compute the short-distance renormalization factors as follows:

$$\begin{aligned} A_S^{(i,j)} &= \frac{m_W^2 \sin 2\beta f_{u_i} f_{d_j}}{4\pi\ \overline{m}_{u_i}\overline{m}_{d_j}(m_Z)} \frac{\alpha_2(M_S)}{\alpha_2^2(m_Z)} \cdot \frac{C(m_Z)}{C(M_S)} \frac{C_{ij}(M_S)}{C_{ij}(M_{H_C})} \,, \\ \overline{A}_S &= \frac{m_W^4 \sin^2 2\beta f_t \overline{y}_t(M_S)\overline{y}_\tau(M_S) f_{d_i}}{(4\pi)^2 \alpha_2^2(m_Z)\overline{m}_t^2 \overline{m}_\tau \overline{m}_{d_i}(m_Z)} \cdot \frac{\overline{C}(m_Z)}{\overline{C}(M_{H_C})} \ . \end{aligned} \tag{A.24}$$

With the results obtained above, we compute the renormalization factors. We present $A_R^{(i,j)}$ and $\overline{A}_R$ in figures 7 and 8, respectively, as functions of M_S. In both figures, we take $M_S = \mu_H$, $M_2 = 3\,\text{TeV}$, and $M_{H_C} = 1.0 \times 10^{16}\,\text{GeV}$. In the left graph in figure 7,

JHEP07(2013)038

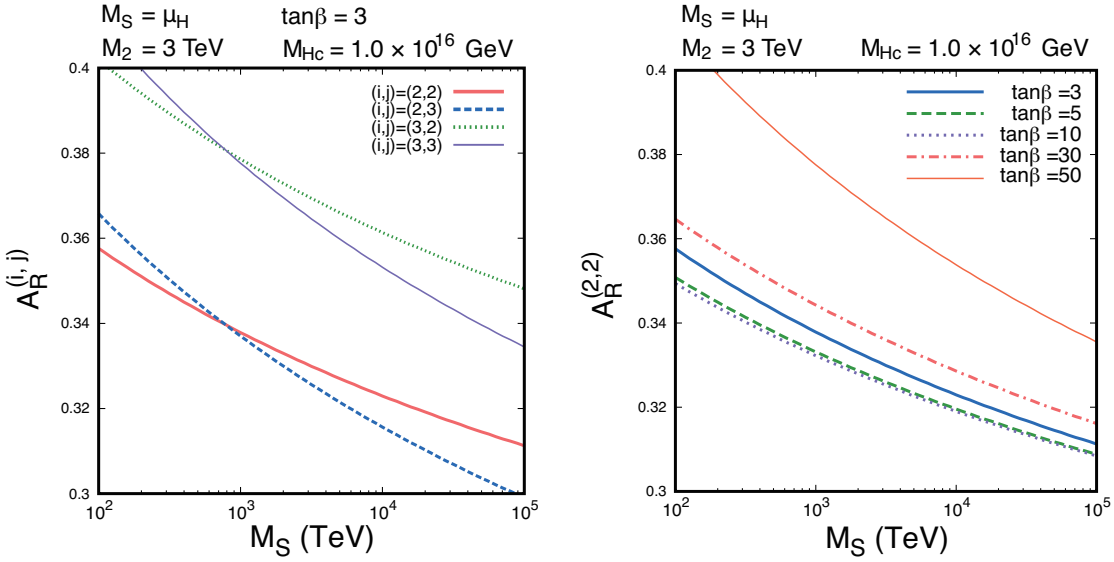

Figure 7. Left: $A_R^{(i,j)}$ with $(i,j) = (2,2),\ (2,3),\ (3,2),\ (3,3)$ as functions of M_S. Here we set $\tan\beta = 3$, $M_S = \mu_H$, $M_2 = 3\,\text{TeV}$, and $M_{H_C} = 1.0 \times 10^{16}\,\text{GeV}$. Right: $A_R^{(2,2)}$ as functions of M_S. Same parameters as in the left graph are used except for $\tan\beta$. Each line corresponds to different values of $\tan\beta$ ($\tan\beta = 3, 5, 10, 30, 50$).

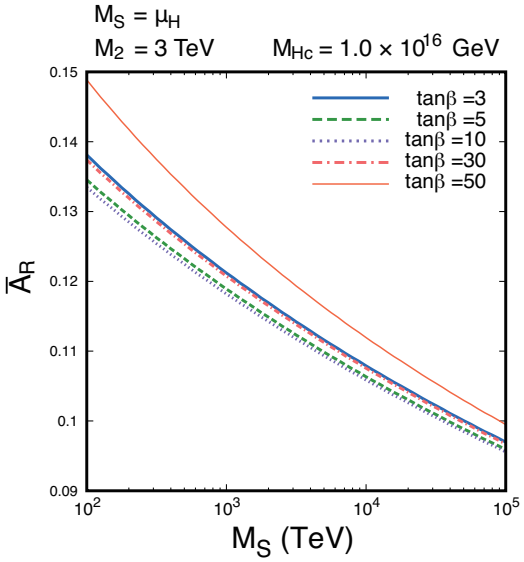

Figure 8. $\overline{A}_R$ as functions of M_S. Here we set $M_S = \mu_H$, $M_2 = 3\,\text{TeV}$, and $M_{H_C} = 1.0 \times 10^{16}\,\text{GeV}$. Each line shows different values of $\tan\beta$.

each $A_R^{(i,j)}$ is presented with $\tan\beta$ fixed to be $\tan\beta = 3$, while in the right graph the behavior of $A_R^{(2,2)}$ is shown for different values of $\tan\beta$ ($\tan\beta = 3, 5, 10, 30, 50$). Similarly, each line in figure 8 corresponds to $\overline{A}_R$ evaluated with various $\tan\beta$'s. It is found that the renormalization factors decrees as the SUSY scale increases, while their dependence on $\tan\beta$ is somewhat complicated. In addition, the left panel in figure 7 illustrates that the effects of the third generation Yukawa couplings are significant.

JHEP07(2013)038

B Formulae for proton decay rate

In this section, we display the formulae for the partial decay widths of $p \to K^+\bar{\nu}$ channels as well as the hadronic matrix elements which we need to evaluate the decay widths. Let us start with the matrix elements. We divide the derivation into two steps.[7] First, we express them in terms of the low-energy constants α_p and β_p by using the chiral perturbation techniques [71–73]:

$$\begin{aligned}
\langle K^+|\epsilon_{\alpha\beta\gamma}(u_L^\alpha d_L^\beta)s_L^\gamma|p\rangle &= \frac{\beta_p}{\sqrt{2}f_\pi}\left(1+\frac{D+3F}{3}\frac{m_p}{M_B}\right)P_L u_p\,,\\
\langle K^+|\epsilon_{\alpha\beta\gamma}(u_L^\alpha s_L^\beta)d_L^\gamma|p\rangle &= \frac{\beta_p}{\sqrt{2}f_\pi}\left(\frac{2D}{3}\frac{m_p}{M_B}\right)P_L u_p\,,\\
\langle K^+|\epsilon_{\alpha\beta\gamma}(u_R^\alpha d_R^\beta)s_L^\gamma|p\rangle &= \frac{\alpha_p}{\sqrt{2}f_\pi}\left(1+\frac{D+3F}{3}\frac{m_p}{M_B}\right)P_L u_p\,,\\
\langle K^+|\epsilon_{\alpha\beta\gamma}(u_R^\alpha s_R^\beta)d_L^\gamma|p\rangle &= \frac{\alpha_p}{\sqrt{2}f_\pi}\left(\frac{2D}{3}\frac{m_p}{M_B}\right)P_L u_p\,,
\end{aligned} \tag{B.1}$$

where $f_\pi \simeq 92.2\,\mathrm{MeV}$ [64] is the pion decay constant and the baryon-meson couplings D and F are given as $D \simeq 0.80$ and $F \simeq 0.47$, respectively. m_p denotes the proton mass, while M_B represents the baryon mass parameter in the chiral Lagrangian, which we choose as $M_B \simeq (m_{\Sigma^0}+m_{\Lambda^0})/2$ with m_{Σ^0} and m_{Λ^0} the masses of Σ^0 and Λ^0, respectively. u_p is the four-component spinor wave function of proton, and P_L is the projection operator defined by $P_L \equiv (1-\gamma_5)/2$. The low-energy constants α_p and β_p are defined as

$$\begin{aligned}
\langle 0|\epsilon_{\alpha\beta\gamma}(u_R^\alpha d_R^\beta)u_L^\gamma|p\rangle &= \alpha_p P_L u_p\,,\\
\langle 0|\epsilon_{\alpha\beta\gamma}(u_L^\alpha d_L^\beta)u_L^\gamma|p\rangle &= \beta_p P_L u_p\,,
\end{aligned} \tag{B.2}$$

with $|0\rangle$ the vacuum state. Second, we determine the constants α_p and β_p. We extract them from the results of lattice simulations [74]:

$$\begin{aligned}
\alpha_p &= -0.0112 \pm 0.0012_{(\mathrm{stat})} \pm 0.0022_{(\mathrm{syst})}\ \mathrm{GeV}^3\,,\\
\beta_p &= 0.0120 \pm 0.0013_{(\mathrm{stat})} \pm 0.0023_{(\mathrm{syst})}\ \mathrm{GeV}^3\,,
\end{aligned} \tag{B.3}$$

where they are evaluated at $\mu = 2\,\mathrm{GeV}$.

With the matrix elements and the effective operators in eq. (3.12), it is straightforward to derive the partial decay widths of the $p \to K^+\bar{\nu}_\mu$ and $p \to K^+\bar{\nu}_\tau$ channels. The result is

$$\Gamma(p \to K^+\bar{\nu}_i) = \frac{m_p \alpha_2^4 |C_i|^2}{64\pi f_\pi^2 M_{H_C}^2 m_W^4 \sin^2 2\beta}\left(1-\frac{m_K^2}{m_p^2}\right)^2\,, \tag{B.4}$$

[7] Calculation of the matrix elements is also conducted by using the direct method [69], in which the three-point correlation functions relevant for proton decay are directly computed on the lattice. Preliminary for the recent progress is reported in ref. [70].

JHEP07(2013)038

with $(i = \mu, \tau)$ and

$$C_\mu = 2\beta_p F(M_2, M_S^2)\left\{1 + (D+F)\frac{m_p}{M_B}\right\}\overline{m}_s V_{us}^* \sum_{i=2,3} \overline{m}_{u_i} V_{u_i d} V_{u_i s} e^{i\varphi_i} A_R^{(i,2)}\,, \tag{B.5}$$

$$\begin{aligned} C_\tau = {} & 2\beta_p F(M_2, M_S^2)\left\{1 + (D+F)\frac{m_p}{M_B}\right\}\overline{m}_b V_{ub}^* \sum_{i=2,3} \overline{m}_{u_i} V_{u_i d} V_{u_i s} e^{i\varphi_i} A_R^{(i,3)} \\ & - \alpha_p \frac{\overline{m}_t^2 \overline{m}_\tau V_{tb}^* e^{i\varphi_1}}{m_W^2 \sin 2\beta} F(\mu_H, M_S^2)\overline{A}_R \times \\ & \times \left\{\overline{m}_d V_{ud} V_{ts}\left(1 + \frac{D+3F}{3}\frac{m_p}{M_B}\right) + \overline{m}_s V_{us} V_{td}\frac{2D}{3}\frac{m_p}{M_B}\right\}. \end{aligned} \tag{B.6}$$

Higgs boson mixes with an $SU(2)$ septet representation

Junji Hisano[1,2,*] and Koji Tsumura[1,†]

(Received 28 January 2013; published 12 March 2013)

We study the possibility of the Higgs boson, which consists of an $SU(2)$ doublet and a septet. The vacuum expectation value of a septet with hypercharge $Y = 2$ is known to preserve the electroweak rho parameter unity at the tree level. Therefore, the septet can give a significant contribution to the electroweak symmetry breaking. Because of the mixing with the septet, the gauge coupling of the standard-model-like Higgs boson is larger than that in the standard model. We show the sizable vacuum expectation value of the Higgs septet can be allowed under the constraint from the electroweak precision data. The signal strengths of the Higgs boson for the diphoton and a pair of weak gauge boson decay channels at the LHC are enhanced, while those for the fermionic decay modes are suppressed. The mass of additional neutral Higgs boson is also bounded by the current LHC data for the standard model Higgs boson. We discuss the phenomenology of the multiply charged Higgs bosons, which come from the septet.

I. INTRODUCTION

The Higgs boson has been discovered at the LHC [1,2]. However, detailed information such as interaction strengths with each particle has not yet been tested very precisely. The most evident signal excess compared with the background at both experiments (ATLAS [3] and CMS [4]) has been observed in the diphoton decay channel of the Higgs boson. So far, the reported rates of this channel are larger than the value predicted in the standard model (SM). The second best excess was discovered by the $ZZ(\to 4\ell)$ decay mode. We have also seen the small excess in the WW decay channel. The fermionic decay modes of the Higgs boson have not yet been established directly.

The Higgs sector of the SM is still uncertain, which can be extended in various ways. One of the promising extensions is supersymmetry, which is motivated by the stability of the Higgs boson mass under the quantum corrections. In this model, the Higgs sector is required to have an even number of the doublet. Another interesting extension is the Higgs triplet model [5], which consists of the SM Higgs doublet and a Higgs triplet with $Y = 1$. In this model, Majorana neutrino masses are generated from the small vacuum expectation value (VEV) of the triplet. Since there are many extensions of the SM, we need to discriminate them from each other at further precision measurement of the Higgs boson.

The Veltman's rho parameter [6] has been measured very precisely. It would be a good guiding principle to construct beyond the SM. For an arbitrary number of $SU(2)$ scalar multiplets, which have an isospin j_ϕ, a hypercharge Y_ϕ, and a VEV v_ϕ, the rho parameter at tree level is calculated as

$$\rho = \frac{\Sigma_\phi [j_\phi(j_\phi + 1) - Y_\phi^2] v_\phi^2}{\Sigma_\phi 2 Y_\phi^2 v_\phi^2}. \quad (1)$$

The precision measurement suggests that ρ is very close to unity. In the SM, the Higgs doublet ($j_\phi = \frac{1}{2}$ and $Y_\phi = \frac{1}{2}$) predicts $\rho = 1$. The multiple doublet extensions of the SM, e.g., the minimal supersymmetric standard model, also predict $\rho = 1$ at tree level. It is known that the next minimal representation, which satisfies $\rho = 1$, is a septet with $Y_\phi = 2$, and the next next minimal one is a 26-plet with $Y_\phi = \frac{15}{2}$. In the usual Higgs representation, the VEV is bounded to be small. For instance, in the Higgs triplet model which consists of a doublet and a triplet Higgs field, the VEV of the triplet is constrained to be less than 3 GeV (2σ level) from $\rho_0 = 1.0004^{+0.0003}_{-0.0004}$ [7], where $\rho_0 = \rho/\rho_{\rm SM}$. If we allow the cancellation among various contributions, the rho parameter can remain unity [8].

In this paper, we construct a framework of the low energy effective theory, which contains a Higgs doublet and a Higgs septet with sizable VEVs. The electroweak sector of the model is extended due to the presence of the septet while keeping the rho parameter unity at tree level. The model is consistent with the electroweak precision data based on the S and T parameter analysis. The gauge coupling of the SM-like Higgs boson can be largely deviated from the SM value due to the mixing with the septet component. The signal strengths of the Higgs boson for the diphoton and for the weak gauge boson pair decays can be enhanced, while those for fermionic decay channels are suppressed. Additional Higgs bosons appear in the weak scale and may be discovered at the LHC. In particular, the singly charged Higgs boson can be produced by the $W^\pm Z$ fusion mechanism.

This paper is organized as follows. In Sec. II, we present a model which consists of a Higgs doublet and a Higgs

septet. The electroweak precision constraints and the signal strengths of the Higgs bosons at the LHC are studied in Sec. III. The characteristic signatures of the extra (septetlike) Higgs boson are discussed. Conclusions and discussion are given in Sec. IV.

II. THE MODEL

A scalar septet field (χ) with $Y = 2$ is introduced to the SM in addition to the SM Higgs doublet (Φ) with $Y = 1/2$. The Higgs potential is given by

$$\mathcal{V} = -\mu_2^2\Phi^\dagger\Phi + M_7^2\chi^\dagger\chi + \lambda(\Phi^\dagger\Phi)^2 - \frac{1}{\Lambda^3}\{(\chi^*\Phi^5\Phi^*) + \text{H.c.}\} + \sum_{A=1}^{4}\lambda_A(\chi^\dagger\chi\chi^\dagger\chi)_A + \sum_{B=1}^{2}\kappa_B(\Phi^\dagger\Phi\chi^\dagger\chi)_B, \quad (2)$$

where

$$(\Phi^\dagger\Phi\chi^\dagger\chi)_1 = \Phi^{*i}\Phi_i\chi^{*abcdef}\chi_{abcdef}, \quad (3)$$

$$(\Phi^\dagger\Phi\chi^\dagger\chi)_2 = \Phi^{*i}\Phi_j\chi^{*jabcde}\chi_{iabcde}, \quad (4)$$

$$(\chi^\dagger\chi\chi^\dagger\chi)_1 = \chi^{*ijklmn}\chi_{ijklmn}\chi^{*abcdef}\chi_{abcdef}, \quad (5)$$

$$(\chi^\dagger\chi\chi^\dagger\chi)_2 = \chi^{*ijklmn}\chi_{ijklmf}\chi^{*abcdef}\chi_{abcden}, \quad (6)$$

$$(\chi^\dagger\chi\chi^\dagger\chi)_3 = \chi^{*ijklmn}\chi_{ijklef}\chi^{*abcdef}\chi_{abcdmn}, \quad (7)$$

$$(\chi^\dagger\chi\chi^\dagger\chi)_4 = \chi^{*ijklmn}\chi_{ijkdef}\chi^{*abcdef}\chi_{abclmn}, \quad (8)$$

and

$$(\chi^*\Phi^5\Phi^*) = \chi^{*abcdef}\Phi_a\Phi_b\Phi_c\Phi_d\Phi_e\Phi^{*g}\epsilon_{fg} \quad (9)$$

with $\Phi_1 = \omega_2^+$ and $\Phi_2 = (v_2 + h_2 + iz_2)/\sqrt{2}$. We here introduce the symmetric tensor notation of the septet field as $\chi_{111111} = \chi_3$, $\chi_{111112} = \chi_2/\sqrt{6}$, $\chi_{111122} = \chi_1/\sqrt{15}$, $\chi_{111222} = \chi_0/\sqrt{20}$, $\chi_{112222} = \chi_{-1}/\sqrt{15}$, $\chi_{122222} = \chi_{-2}/\sqrt{6}$, and $\chi_{222222} = \chi_{-3}$ with $\chi_{-2} = (v_7 + h_7 + iz_7)/\sqrt{2}$. Although the Higgs septet can break the electroweak symmetry properly, the Higgs doublet is required for the mass generation of SM fermions. Without a nonrenormalizable term with mass dimension seven, $\chi^*\Phi^5\Phi^*$, the Higgs potential is conserved under an accidental global $U(1)$ transformations of the doublet and the septet, separately. Therefore, a breaking term of the global symmetry is added in order to avoid an exact massless Nambu-Goldstone boson.

As an example, the dimension-seven operator can be generated from the one-loop contribution given in Fig. 1 by introducing two scalar quintuplets $\Sigma_{I,II}(Y = 1)$ and a scalar triplet $\Delta(Y = 0)$, which are odd under the extra discrete symmetry. The renormalizable Lagrangian related to this one-loop diagram is given by

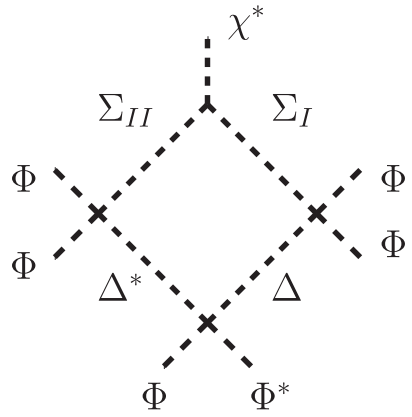

FIG. 1. Radiative generation of dimension-seven operator $\chi^*\Phi^5\Phi^*$ from the renormalizable UV theory.

$$\mathcal{L}_{U(1)} = \mu\chi_{abcdef}\Sigma_I^{*abci}\Sigma_{II}^{*defj}\epsilon_{ij} + \Phi_i\Phi_j(c_I\Sigma_I^{*ijkl} + c_{II}\Sigma_{II}^{*ijkl})\Delta_{kl} + f\Phi_a\Phi^{*b}\Delta^{*ac}\Delta_{bc} + \text{H.c.}, \quad (10)$$

where μ is a soft breaking mass parameter of the global $U(1)$ symmetry and $c_{I,II}$ and f are the coupling constants. In the following discussion, we take into account the dimension-seven operator instead of specifying the UV completion of the model without limiting the generality of the low energy effective theory.[1]

If $M_7^2 < 0$, the Higgs septet and the Higgs doublet develop the VEVs independently. In this case, there are possibilities of the charge-breaking vacua. In addition, the stability of the vacuum is unclear even in the charge-conserving vacuum. In this paper, we consider the case with $M_7^2 > 0$, where the VEV of the Higgs septet is induced through the higher dimensional operator,

$$v_7 \simeq \frac{\sqrt{3}}{24}\frac{v_2^6}{\Lambda^3 M_7^2}. \quad (11)$$

The VEVs of the Higgs doublet and septet are automatically aligned so that the charge-conserving vacuum is realized. Furthermore, we assume that λ_{1-4} and $\kappa_{1,2}$ in the Higgs potential are sufficiently small for simplicity. In this case, we can parametrize the model by only two parameters with the SM-like Higgs boson mass as shown later. Let us remind you that the septet quartic coupling constants generically produce mass splittings among the septetlike scalar bosons, and the latter coupling constants generate mixings between the doublet and the septet. In the following discussion, we mostly neglect the effect of λ_{1-4} and $\kappa_{1,2}$, but a few important implications will be mentioned in the relevant parts.

[1]Phenomenology of the UV theories including dark matter will be studied [9].

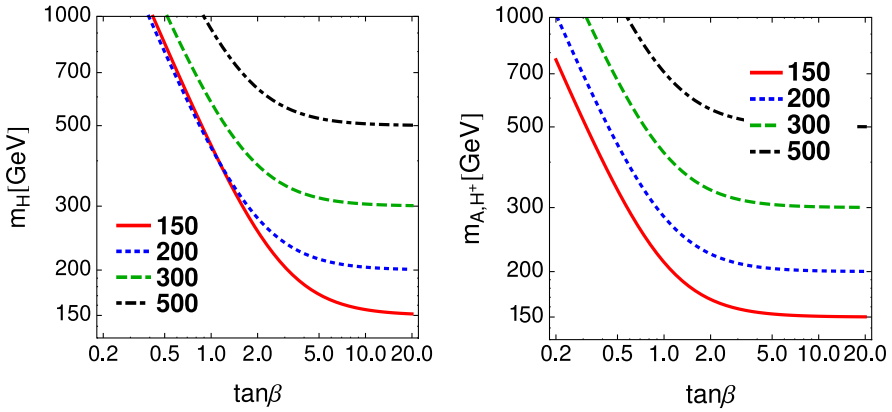

FIG. 2 (color online). Masses for H (left), A, and $H_1^\pm$ (right) are given as functions of $\tan\beta$. The solid, dotted, dashed, and dot-dashed curves correspond to $M_7 = 150$, 200, 300, and 500 GeV, respectively.

The mass matrices for the scalar sector are diagonalized by

$$\begin{pmatrix} h_7 \\ h_2 \end{pmatrix} = \begin{pmatrix} c_\alpha & -s_\alpha \\ s_\alpha & c_\alpha \end{pmatrix} \begin{pmatrix} H \\ h \end{pmatrix}, \tag{12}$$

$$\begin{pmatrix} z_7 \\ z_2 \end{pmatrix} = \begin{pmatrix} c_\beta & -s_\beta \\ s_\beta & c_\beta \end{pmatrix} \begin{pmatrix} z \\ A \end{pmatrix}, \tag{13}$$

$$\begin{pmatrix} \chi_{-1} \\ \chi_{-3}^* \\ \omega_2^+ \end{pmatrix} = \begin{pmatrix} \frac{\sqrt{10}}{4} & \frac{\sqrt{6}}{4} & 0 \\ -\frac{\sqrt{6}}{4} & \frac{\sqrt{10}}{4} & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} c_\beta & 0 & -s_\beta \\ 0 & 1 & 0 \\ s_\beta & 0 & c_\beta \end{pmatrix} \begin{pmatrix} \omega^+ \\ H_2^+ \\ H_1^+ \end{pmatrix}, \tag{14}$$

where z and $\omega^\pm$ are the electroweak Nambu-Goldstone bosons, the ratio of VEVs is $\tan\beta = v_2/(4v_7)$, and the CP even scalar boson mixing is α. Note that the doublet VEV is dominated in the large $\tan\beta$ limit. Mass eigenvalues are calculated as

$$m_h^2 = \left(1 + \frac{3}{2}\frac{1}{t_\beta t_\alpha}\right) M_7^2, \tag{15}$$

$$m_H^2 = \left(1 - \frac{3}{2}\frac{t_\alpha}{t_\beta}\right) M_7^2, \tag{16}$$

$$m_A^2 = m_{H_1^\pm}^2 = M_7^2/s_\beta^2, \tag{17}$$

$$m_{H_2^\pm}^2 = m_{H^{2\pm}}^2 = m_{H^{3\pm}}^2 = m_{H^{4\pm}}^2 = m_{H^{5\pm}}^2 = M_7^2, \tag{18}$$

where $\chi_3 = H^{5+}$, $\chi_2 = H^{4+}$, $\chi_1 = H^{3+}$, and $\chi_0 = H^{2+}$. There are four input parameters. We here choose $v = (\sqrt{2}G_F)^{-1/2}$, $m_h = 126$ GeV, M_7, and $\tan\beta$. The electroweak interactions of these scalar bosons are determined straightforwardly.

In Fig. 2, masses for H (left), A, and $H_1^\pm$ (right) are shown as functions of $\tan\beta$. The solid, dotted, dashed, and dot-dashed curves denote the cases for $M_7 = 150$, 200, 300, and 500 GeV, respectively. They coincide with the M_7 value at the large $\tan\beta$ region. Mass splittings can be large in the small $\tan\beta$ region, and $m_H > m_A$ is satisfied. We can see from Eq. (11) that the UV completion of the dimension-seven operator spoils rapidly for $\tan\beta \ll 1$. As for the reference, the values of m_H and m_A are listed in Table I.

Let us discuss the modification of the Higgs coupling constant. The correction factors for the gauge interaction of the CP even Higgs bosons are given by

$$C_V^h = s_\beta c_\alpha - 4 c_\beta s_\alpha, \tag{19}$$

$$C_V^H = s_\beta s_\alpha + 4 c_\beta c_\alpha. \tag{20}$$

The factors are normalized by the SM Higgs boson coupling constant, i.e., $C_V^\phi \equiv \lambda_{\phi VV}/\lambda_{H_{\rm SM}VV}$. Similar correction factors for the Yukawa interaction are also given by

$$C_F^h = c_\alpha/s_\beta, \tag{21}$$

$$C_F^H = s_\alpha/s_\beta. \tag{22}$$

These expressions are the same as in the so-called type-I two Higgs doublet model [10].

In Fig. 3, we show the modification factors C_V^ϕ and C_F^ϕ of the CP even Higgs boson ($\phi = h$, H) for $M_7 = 150$ GeV (top left), $M_7 = 200$ GeV (top right), $M_7 = 300$ GeV

TABLE I. Masses of the heavy CP even and CP odd Higgs bosons are listed for $M_7 = 150$, 200, 300, and 500 GeV.

(m_H, m_A) [GeV]	$\tan\beta = 3$	$\tan\beta = 5$	$\tan\beta = 10$	$\tan\beta = 20$
$M_7 = 150$ GeV	(204., 158.)	(171., 153.)	(156., 151.)	(151., 150.)
$M_7 = 200$ GeV	(238., 211.)	(214., 204.)	(204., 201.)	(202., 200.)
$M_7 = 300$ GeV	(343., 316.)	(316., 306.)	(304., 301.)	(302., 301.)
$M_7 = 500$ GeV	(563., 527.)	(523., 510.)	(506., 502.)	(503., 501.)

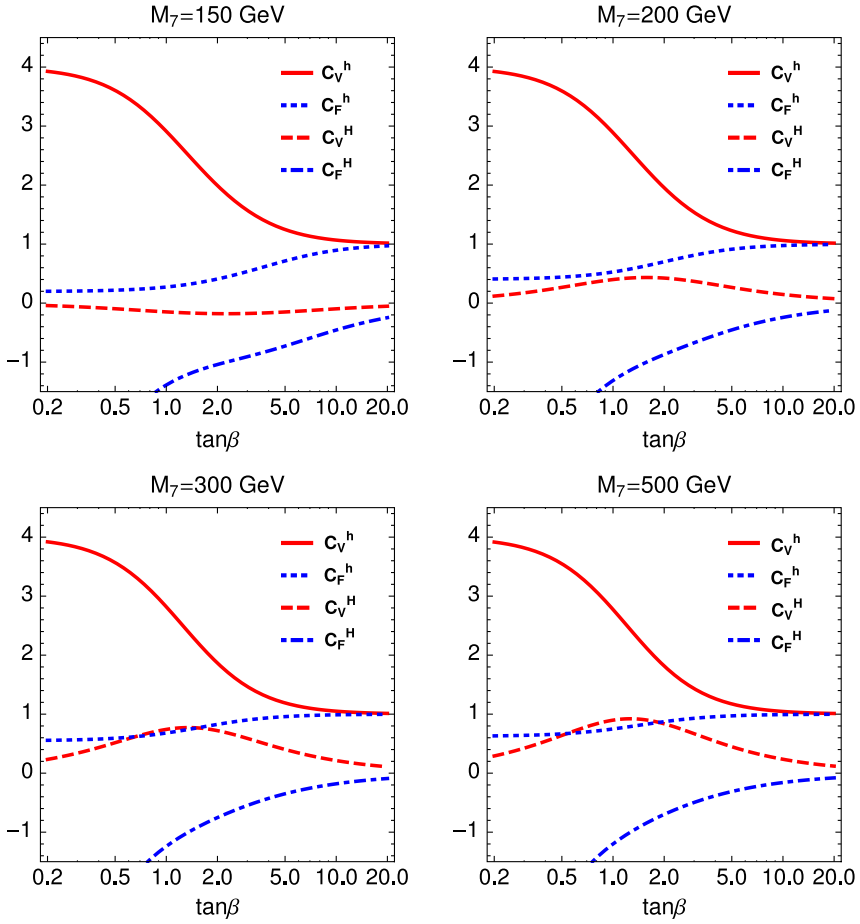

FIG. 3 (color online). Correction factors for the gauge and the Yukawa coupling constants of the CP even Higgs bosons are presented as functions of $\tan\beta$ for $M_7 = 150$ GeV (top left), $M_7 = 200$ GeV (top right), $M_7 = 300$ GeV (bottom left), and $M_7 = 500$ GeV (bottom right). The solid, dotted, dashed, and dot-dashed curves express C_V^h, C_F^h, C_V^H, and C_F^H, respectively.

(bottom left), and $M_7 = 500$ GeV (bottom right). The solid, dotted, dashed, and dot-dashed curves represent C_V^h, C_F^h, C_V^H, and C_F^H, respectively. Since the doublet VEV is dominated in the large $\tan\beta$ region, the coupling strengths of h become SM-like, while those of H vanish. The maximal value of C_V^h is four, which is determined by the hypercharges of the septet and the doublet. The gauge interaction of the SM-like Higgs boson is greater than one for all plots because of the mixing with the septet component. The prediction $C_V^h > 1$ can also be obtained in the Georgi-Machacek model, which has been studied with the Higgs boson signal at the LHC [11,12].

III. PHENOMENOLOGY

In this section, we investigate the current experimental constraint from the electroweak precision data and also from the Higgs boson searches at the LHC. The LHC signatures of the model are also studied.

We begin with the constraint from the electroweak sector. In this model, the oblique corrections [13] from the scalar bosons are calculated as

$$S = \frac{1}{4\pi}[(C_V^h)^2 G^{hZ\prime} + (C_V^H)^2 G^{HZ\prime} + 30c_\beta^2 G^{H_2^\pm W\prime} + 30s_\beta^2 F^{H_1^\pm H_2^{\pm\prime}} - \frac{1}{3}\ln m_{H_1^\pm}^2 - 15\ln m_{H_2^\pm}^2 + (4s_\alpha s_\beta - c_\alpha c_\beta)F^{hA\prime} + (4c_\alpha s_\beta + s_\alpha c_\beta)F^{HA\prime}], \quad (23)$$

$$T = \frac{\sqrt{2}G_F}{\alpha_{\rm EM}(4\pi)^2}[(C_V^h)^2\Delta G^h + (C_V^H)^2\Delta G^H - 15c_\beta^2\Delta G^{H_2^\pm}], \quad (24)$$

where the loop functions $G^{xy\prime}$, $F^{xy\prime}$, and ΔG^x are given in the Appendix.

In Fig. 4, the deviations of the S parameter (left) and T parameter (right) are plotted for $M_7 = 150$ GeV (solid line), $M_7 = 200$ GeV (dotted line), $M_7 = 300$ GeV (dashed line), and $M_7 = 500$ GeV (dot-dashed line) as functions of $\tan\beta$. The current experimental bounds on oblique parameters are $\Delta S = 0.04 \pm 0.09$ and $\Delta T = 0.07 \pm 0.08$ with the 88% correlation by fixing $\Delta U = 0$ [7]. In the small $\tan\beta$ region, relatively larger negative (positive) contributions to the S (T) parameter are

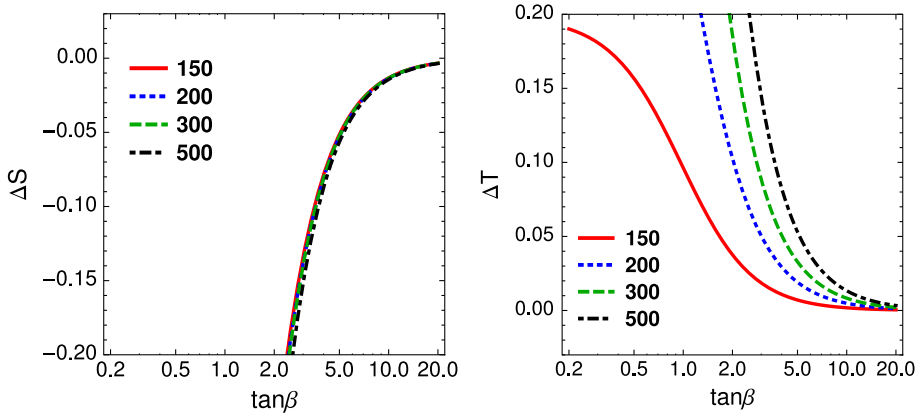

FIG. 4 (color online). Oblique corrections are evaluated as functions of $\tan\beta$. The solid, dotted, dashed, and dot-dashed curves represent the cases for $M_7 = 150$, 200, 300, and 500 GeV, respectively.

found. For $\Delta T = 0$, ΔS is constrained to be larger than $-0.08(-0.11)$ at 68(90)% confidence level. From the S parameter only, $\tan\beta \gtrsim 5$ is obtained. Because we are fixing the value of $\tan\beta$, these effects are nondecoupling for higher M_7. In fact, the largest contribution to the T parameter is seen for $M_7 = 500$ GeV. As for the reference, the values of ΔS and ΔT are listed in Table II.

Let us turn to the LHC phenomenology. At the LHC, we have found the Higgs boson around 126 GeV using $\gamma\gamma$ and $ZZ(\to 4\ell)$ decay channels. Since the coupling constants of the SM-like Higgs boson are corrected, these signal strengths can be changed. Roughly speaking, 90% of the Higgs bosons come from the gluon fusion mechanism at the LHC with $\sqrt{s} = 7$ TeV and/or $\sqrt{s} = 8$ TeV without selection cuts. Assuming the dominance of the gluon fusion production cross section, the signal strengths are evaluated as

$$\mu^h_{VV} \simeq (C^h_F)^2 \frac{1}{(C^h_F)^2(\mathcal{B}_{bb} + \mathcal{B}_{cc} + \mathcal{B}_{\tau\tau} + \mathcal{B}_{gg}) + (C^h_V)^2(\mathcal{B}_{WW} + \mathcal{B}_{ZZ})} (C^h_V)^2, \tag{25}$$

$$\mu^h_{f\bar{f}} \simeq (C^h_F)^2 \frac{1}{(C^h_F)^2(\mathcal{B}_{bb} + \mathcal{B}_{cc} + \mathcal{B}_{\tau\tau} + \mathcal{B}_{gg}) + (C^h_V)^2(\mathcal{B}_{WW} + \mathcal{B}_{ZZ})} (C^h_F)^2, \tag{26}$$

$$\mu^h_{\gamma\gamma} \simeq (C^h_F)^2 \frac{1}{(C^h_F)^2(\mathcal{B}_{bb} + \mathcal{B}_{cc} + \mathcal{B}_{\tau\tau} + \mathcal{B}_{gg}) + (C^h_V)^2(\mathcal{B}_{WW} + \mathcal{B}_{ZZ})} R, \tag{27}$$

where

$$R = \left| \frac{C^h_F N_c Q_t^2 A_{1/2}(\tau_t) + C^h_V A_1(\tau_W)}{N_c Q_t^2 A_{1/2}(\tau_t) + A_1(\tau_W)} \right|^2, \tag{28}$$

$$A_{1/2}(\tau) = 2[\tau + (\tau - 1) f(\tau)]\tau^{-2}, \tag{29}$$

$$A_1(\tau) = -[2\tau^2 + 3\tau + 3(2\tau - 1) f(\tau)]\tau^{-2}, \tag{30}$$

with $\tau_x = m_h^2/(4m_x^2)$ and

$$f(\tau) = \begin{cases} \arcsin^2\sqrt{\tau} & \tau \le 1, \\ -\frac{1}{4}\left[\ln\frac{1+\sqrt{1-\tau^{-1}}}{1-\sqrt{1-\tau^{-1}}} - i\pi\right]^2 & \tau > 1. \end{cases} \tag{31}$$

The recommended values of the branching ratios of the SM Higgs boson are listed in Table III [14]. Because we are neglecting the interactions between the doublet and the septet in the Higgs potential, the (multiply) charged Higgs boson loop contributions are omitted.[2]

In Fig. 5, the signal strengths of the SM-like Higgs boson at the LHC are shown as functions of $\tan\beta$ for $M_7 = 150$ GeV (top left), $M_7 = 200$ GeV (top right), $M_7 = 300$ GeV (bottom left), and $M_7 = 500$ GeV (bottom right). The solid, dotted, and dashed curves denote the signal strengths for $\gamma\gamma$, $VV^*(V = W, Z)$, and $f\bar{f}$ decays, respectively, of the SM-like Higgs boson h. As we have seen in Fig. 3, the production cross section of the Higgs boson via gluon fusion is suppressed by $(C^h_F)^2$. On the other hand, the $b\bar{b}$ decay channel, which is the main decay mode of the SM Higgs boson, is suppressed in the present model. Furthermore, the effective gauge coupling of the SM-like Higgs boson is larger than that of the SM

[2]Detailed studies of the extended scalar sector are beyond the scope of this paper. It will be shown in elsewhere [9].

TABLE II. Oblique corrections to S and T parameters are listed for $M_7 = 150$, 200, 300, and 500 GeV.

$(\Delta S, \Delta T)$	$\tan\beta = 3$	$\tan\beta = 5$	$\tan\beta = 10$	$\tan\beta = 20$
$M_7 = 150$ GeV	$(-0.13, 0.019)$	$(-0.05, 0.007)$	$(-0.013, 0.002)$	$(-0.003, 0.)$
$M_7 = 200$ GeV	$(-0.14, 0.050)$	$(-0.05, 0.019)$	$(-0.014, 0.005)$	$(-0.003, 0.001)$
$M_7 = 300$ GeV	$(-0.14, 0.088)$	$(-0.05, 0.033)$	$(-0.013, 0.008)$	$(-0.003, 0.002)$

Higgs boson. Therefore, the net contributions to μ^h_{VV} can be enhanced. The diphoton decay mode is more enhanced than the VV mode due to the enhanced gauge interaction and the suppressed Yukawa interaction in the loop. For $M_7 = 150$ GeV, $\mu^h_{\gamma\gamma}$ can be close to 1.2 with $\tan\beta \simeq 5$, which is allowed by electroweak precision data. In this case, μ^h_{VV} is close to unity, which is favored by the current experimental data. For larger M_7, $\mu^h_{\gamma\gamma}$ can be larger than 1.5 in the small $\tan\beta$ region, which is, however, excluded by electroweak precision data.

It is too early to discuss the precise values of the signal strengths. Qualitatively, the larger signal strengths for the bosonic decay modes and the smaller signal strengths for the fermionic decay modes are predicted. You might consider that the enhancement of the diphoton decay rate is not sufficient to explain the observations at the LHC. However, in the Higgs septet there are many multiply charged Higgs

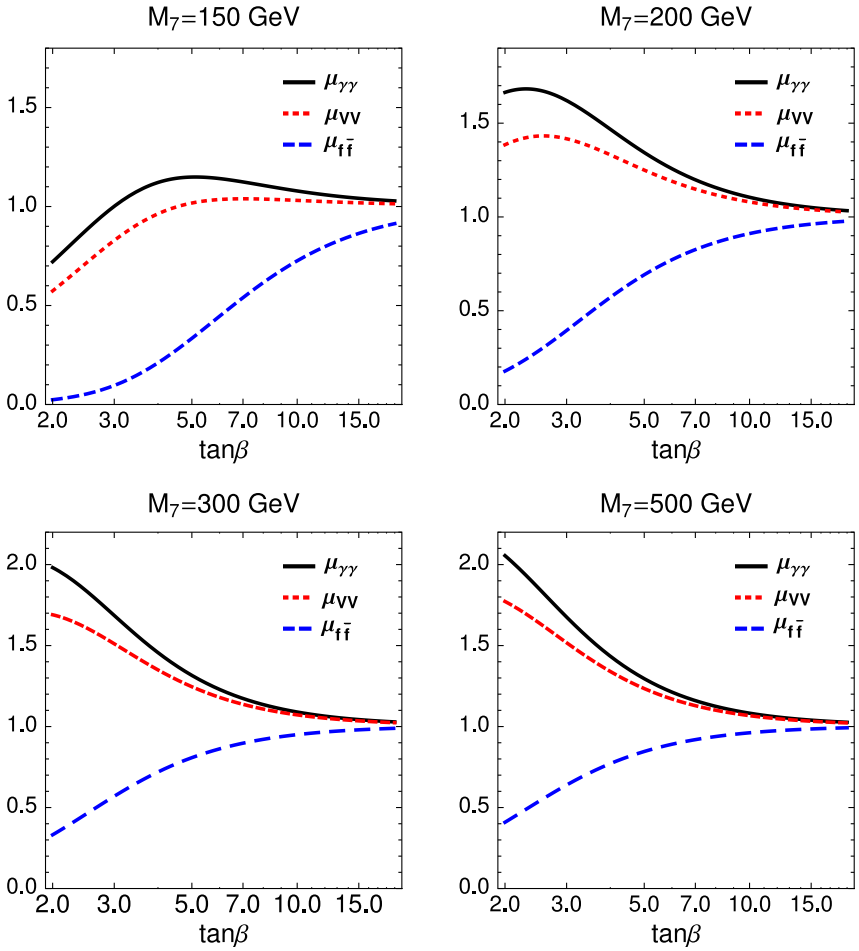

FIG. 5 (color online). Signal strengths for each Higgs boson decay mode at the LHC are shown as functions of $\tan\beta$. The mass scale M_7 is chosen as 150 (top left), 200 (top right), 300 (bottom left), and 500 GeV (bottom right).

bosons, which may further enhance the diphoton signal if there are interactions between the doublet and the septet.

The current LHC bound for the heavier SM Higgs boson can be rescaled to constrain the mass of H using C_F^H and C_V^H factors. For the heavier CP even Higgs boson, the strongest bound comes from the signal strength of weak gauge boson decay modes. By using the recommended values of the SM Higgs decay branching ratios, the signal strength is evaluated in Table IV, where only the decay modes into the SM particles are included. The decays of $H \to AZ^*$ and $H \to H_1^\pm W^{\mp *}$ give a negligible contribution due to the small mass splittings. From the LHC data [4,15], the signal strength is constrained to be less than 0.1–0.3 for $m_H = 150$–500 GeV. For $M_7 \simeq 200$ GeV, $\tan\beta \gtrsim 5$ is allowed by current experimental data. For smaller M_7, $\tan\beta$ is required to be small in order to avoid the constraint from the nondiscovery of such a boson.

The smoking gun of the septet contribution would be the presence of the $ZW^\mp H^\pm$ vertex. This kind of interaction is prohibited in the multi-Higgs doublet models, which give $\rho = 1$ at tree level. The higher dimensional representation can generate this vertex; however, the size of the coupling strength is suppressed by the small VEV due to the strong constraint from the rho parameter. Since the VEV of the Higgs septet with $Y = 2$ can be sizable, a relatively large $ZW^\mp H^\pm$ vertex is allowed. In this model, we have

$$\mathcal{L}_v = +\frac{\sqrt{15}}{2} g g_Z v c_\beta Z_\mu (H_2^- W^{+\mu} + H_2^+ W^{-\mu}). \quad (32)$$

Note that if the term proportional to κ_i exists in the Higgs potential, $H_1^\pm$ also couples with $ZW^\mp$ via the mixing with $H_2^\pm$. If the charged Higgs boson $H_2^\pm$ is sufficiently light and $\tan\beta \lesssim 10$, $H_2^\pm$ can be produced by $W^\pm Z$ fusion at the LHC [16]. The precision measurement of this coupling is possible at the International Linear Collider by using the recoil method via $e^+e^- \to Z^* \to W^\mp H_2^\pm$ [17].

The presence of the multiply charged Higgs bosons is also an interesting feature of the model. Because of the relatively large VEV of the septet, the doubly charged Higgs boson in this model mostly decays into the same-signed weak gauge bosons and is produced via the $W^\pm W^\pm \to H^{2\pm}$ process. Such a process has been studied [18] in the context of the Higgs triplet model and the Georgi-Machacek model. The multiply charged Higgs boson with an electric charge higher than two has a long decay chain, which provides multiple weak boson final states.

IV. CONCLUSIONS

We have studied the model that consists of the Higgs doublet with $Y = 1/2$ and the Higgs septet with $Y = 2$. The VEVs of the doublet and the septet preserve the electroweak rho parameter unity at tree level without any cancellation. The presence of the Higgs septet can give substantial contributions to the electroweak symmetry breaking. A nonrenormalizable operator is introduced in order to break the accidental global symmetry. A UV completion of the operator is also presented. From the viewpoint of the UV completion, it would be difficult to introduce much higher dimensional representations with a sizable VEV such as a 26-plet with $Y = \frac{15}{2}$. Therefore, the Higgs septet would only be a realistic possibility besides doublets.

In this model, the gauge coupling constant of the SM-like Higgs boson (h) is predicted to be larger than that in the SM. We have shown that the modified electroweak interactions due to the sizable VEV of the Higgs septet are consistent with the electroweak precision data. The signal strengths of the SM-like Higgs boson at the LHC for the diphoton and for the weak boson pair decay modes are enhanced, while those for the fermionic decay channels are suppressed. The mass of the additional CP even neutral Higgs boson (H) is constrained by the current LHC data depending on the ratio of the VEVs. The VEV of the Higgs septet induces a sizable $W^\mp Z H^\pm$ vertex ($H^\pm$ is the charged Higgs boson in the Higgs septet), which is forbidden in the multi-Higgs doublet extension of the SM and is highly suppressed by the VEV, e.g., in the Higgs triplet model. One of the interesting signatures of the model would be the $W^\pm Z$ fusion production of the charged Higgs boson at the LHC.

The electroweak sector of the model has been discussed in this paper. We mention the implications of the model. As we have slightly noted, the diphoton decay rate of the SM-like Higgs boson can be enhanced by the effects of the multiply charged Higgs boson loops. Such an effect generally requires larger coupling constants in the Higgs potential. Therefore, the mass degeneracy among the septetlike scalar bosons would be resolved. These mass splitting may give sizable contributions to the electroweak precision parameters as in the two Higgs doublet models [19]. The potential parameters are further bounded by perturbative unitarity and the vacuum stability. If the singly charged Higgs boson is light, it may be constrained by

flavor data. The Higgs sector with the Higgs septet potentially has rich phenomena. It would be worth investigating further [9].

Abstract: We calculate all gauge invariant Barr-Zee type contributions to fermionic electric dipole moments (EDMs) in the two-Higgs doublet models (2HDM) with softly broken Z_2 symmetry. We start by studying the tensor structure of $h \to VV'$ part in the Barr-Zee diagrams, and we calculate the effective couplings in a gauge invariant way by using the pinch technique. Then we calculate all Barr-Zee diagrams relevant for electron and neutron EDMs. We make bounds on the parameter space in type-I, type-II, type-X, and type-Y 2HDMs. The electron and neutron EDMs are complementary to each other in discrimination of the 2HDMs. Type-II and type-X 2HDMs are strongly constrained by recent ACME experiment's result, and future experiments of electron and neutron EDMs may search $\mathcal{O}(10)$ TeV physics.

JHEP01(2014)106

1 Introduction

The standard model (SM) has been worked very well for a long time, and its last missing piece, the Higgs boson, was finally discovered by the Large Hadron Collider (LHC) experiment at CERN [1, 2]. This is a triumph of the SM and a great step to understand physics at the electroweak scale. However, there are many unsolved problems within the SM, for example, the observed dark matter particles and baryon asymmetry in the Universe. From theoretical viewpoint, the gauge hierarchy problem is still in question. Hence, there have been many attempts to solve such problems in frameworks beyond the SM.

In a bottom-up approach towards new physics beyond the SM, an attractive option is to study the two-Higgs doublet models (2HDMs). They are simple and may be low-energy effective theories of various new physics models. Since 2HDMs generally have dangerous flavor changing neutral currents (FCNCs), we particularly consider 2HDMs with softly broken Z_2 symmetry which suppresses the FCNCs. If two Higgs fields do not distinguish the generations of quarks and leptons, the models are classified, with respect to the Yukawa interactions, into four types: type-I, type-II, type-X, and type-Y. One of the important feature of 2HDMs is that there is a new CP violation source in the Higgs potential.

In general, the powerful tool to seek new physics including 2HDMs is of course the LHC which may directly probe physics up to a few TeV. Another possibility is provided by low energy precision measurements, such as in flavor physics. The remarkable feature is that these measurements have a potential to investigate new physics beyond the LHC reach by orders of magnitude. In particular, the electric dipole moments (EDMs) are interesting because the EDMs are highly sensitive to CP violation in physics beyond the SM. While the SM predictions of EDMs are much lower than the current experimental bounds, assuming the strong CP problem is solved by some mechanism, such as the Peccei-Quinn symmetry [3, 4], new physics around TeV scale would give large values within the reach of the future EDM measurements [5–7]. In addition, the electroweak baryogenesis (EWBG) [8–11], which needs a new CP violation source, may lead to larger values of EDMs than the SM predictions.

The EDM measurements, therefore, are concrete tests on 2HDMs containing a new CP phase. In the models, the one-loop contributions to the fermionic EDMs are too small to observed since those contributions are proportional to the third power of small Yukawa couplings. Some two-loop diagrams, called the Barr-Zee diagrams [12], which we show in figure 1, may give sizable contributions to the EDMs, since they are suppressed by only one power of small Yukawa couplings. These diagrams contain one-loop effective vertices, $h\gamma\gamma$, $h\gamma Z$, and $H^{\mp}W^{\pm}\gamma$. The Type-II case was evaluated in refs. [13, 14], but the results in the previous works are not gauge invariant. We improve this point by using the pinch technique [15–17] and make the Barr-Zee diagrams gauge invariant. We also study EDMs in the other three types as well as the type-II.

We organize this paper as follows. In section 2, we briefly review the 2HDMs with softly-broken Z_2 symmetry. In section 3, we study the tensor structure of the effective vertices which are needed to evaluate the Barr-Zee diagrams, and show the gauge invariant tensor structure. After that, we calculate the effective vertices explicitly and show that the diagrams which include the gauge bosons are not gauge invariant. This implies that we

JHEP01(2014)106

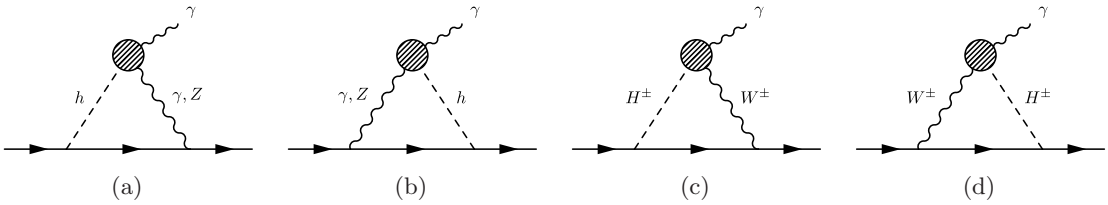

Figure 1. Barr-Zee diagrams, which contribute to fermionic EDMs at two-loop level.

need some non-Barr-Zee diagrams to make the effective vertices gauge invariant. We show it by using the pinch technique. The formulae of the gauge invariant Barr-Zee diagrams are given in section 4, and their numerical evaluation is presented in section 5. There we discuss the complementarity between the electron and neutron EDM measurements in discrimination of 2HDMs, and also prospects of future experiments. Section 6 is devoted to conclusions and discussion. Notations and details of the calculation are given in the appendices.

2 Models

We briefly review the models discussed in this paper. We have two Higgs doublets, H_1 and H_2, and they have the vacuum expectation values (VEVs). The Higgs doublets are parametrized as follows,

$$H_i = \begin{pmatrix} \pi_i^+ \\ \frac{1}{\sqrt{2}}\left(v_i + \sigma_i - i\pi_i^3\right) \end{pmatrix}, \qquad (i = 1, 2)\,. \tag{2.1}$$

In order to avoid the dangerous FCNC problems, we introduce the Z_2 symmetry. The Z_2 symmetry is assumed to be softly broken so that the domain-wall formation in the early universe is suppressed. Under this symmetry, the Higgs doublets are translated into $H_1 \to +H_1$ and $H_2 \to -H_2$, and the Higgs potential is given as

$$\begin{aligned} V = {} & m_1^2 H_1^\dagger H_1 + m_2^2 H_2^\dagger H_2 - \left(\left(\mathrm{Re}m_3^2 + i\mathrm{Im}m_3^2\right) H_1^\dagger H_2 + (h.c.)\right) \\ & + \frac{1}{2}\lambda_1 \left(H_1^\dagger H_1\right)^2 + \frac{1}{2}\lambda_2 \left(H_2^\dagger H_2\right)^2 + \lambda_3 \left(H_1^\dagger H_1\right)\left(H_2^\dagger H_2\right) + \lambda_4 \left(H_1^\dagger H_2\right)\left(H_2^\dagger H_1\right) \\ & + \left(\lambda_5 e^{i2\phi}\left(H_1^\dagger H_2\right)^2 + (h.c.)\right). \end{aligned} \tag{2.2}$$

The third and last terms in this potential contain complex parameters. While one of them can be eliminated by redefinition of Higgs fields, another phase is physical so that CP symmetry is broken. In this paper we take the Higgs VEVs, v_1 and v_2, real using the gauge symmetry and also redefinition of a Higgs field. In this basis, two phases in the potential are related to each others by the stationary condition of the potential, $V' = 0$. In this paper we choose ϕ as an input parameter for CP violation.

We also use the following variables for convenience in this paper,

$$\cos\beta = \frac{v_1}{v}\,, \quad \sin\beta = \frac{v_2}{v}\,, \tag{2.3}$$

$$M^2 \equiv \frac{v_1^2 + v_2^2}{v_1 v_2}\mathrm{Re}m_3^2\,, \tag{2.4}$$

ℓ	H_2	H_1	H_1	H_2

Table 1. Summary of the Higgs fields which couple to quarks and leptons in four types.

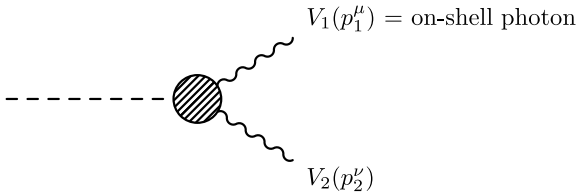

Figure 2. Effective Higgs boson-vector boson-vector boson vertices.

and where

$$v = \sqrt{v_1^2 + v_2^2} = \left(\sqrt{2}G_F\right)^{-1/2} \simeq 246\,\text{GeV}\,. \tag{2.5}$$

G_F is the Fermi constant. It is easy to find the charged Higgs boson mass,

$$m_{H^\pm}^2 = M^2 - \frac{1}{2}v^2(\lambda_4 + \lambda_5\cos(2\phi)). \tag{2.6}$$

On the other hand, since CP symmetry is broken in the Higgs potential, we need to diagonalize a 3 by 3 matrix to find the neutral Higgs masses.

The Yukawa interaction in this model is given by

$$\mathcal{L}_{\text{Yukawa}} = -\overline{q}_L\widetilde{H}_2 y_u u_R - \overline{q}_L H_i y_d d_R - \overline{\ell}_L H_j y_e e_R + h.c.\,, \tag{2.7}$$

where $\widetilde{H}_2 = \epsilon H_2^*$, and $i, j = 1$ or 2, depending on the type of 2HDMs. While up-type quarks couple to only to H_2, leptons and down-type quarks couple to either H_1 or H_2 due to the Z_2 symmetry. We summarize which Higgs fields couple to fermions in table 1.

The detail information of the models, such as mass eigenvalues, mixings, and interactions of the Higgs bosons, are given in appendix A.

3 Effective vertices

In this section we calculate effective vertices relevant for the Barr-Zee diagrams in a gauge invariant way. To make our point clear, we start by exploring the relevant form of the effective vertices shown in figure 2. Then we calculate effective $h\gamma\gamma$, $hZ\gamma$ and $H^\mp W^\pm\gamma$ vertices . We also calculate the pinch terms to make the vertices gauge invariant.

3.1 Tensor structure of the effective vertices

We study the tensor structure of the effective vertices shown in figure 2. This part has two Lorentz indices, and does not contain γ-matrices. Then it is generally written as

$$\Gamma^{\mu\nu} = A_0 g^{\mu\nu} + A_1 p_1^\mu p_1^\nu + A_2 p_2^\mu p_2^\nu + A_{12} p_1^\mu p_2^\nu + A_{21} p_2^\mu p_1^\nu + i\Gamma_5\epsilon^{\mu\nu\rho\sigma}p_{1\rho}p_{2\sigma}, \tag{3.1}$$

JHEP01(2014)106

where p_1^μ and p_2^ν are the momenta of V_1 and V_2, respectively, and their direction is outgoing. We consider the case that V_1 is on-shell photon, and thus the terms proportional to p_1^μ are dropped. In addition, the gauge symmetry of photon requires $\Gamma^{\mu\nu}p_{1\mu} = 0$. Then, the effective vertex for h-V_1-V_2 in the case that V_1 is on-shell photon is defined with only two form factors as

$$\Gamma^{\mu\nu}(p_1,p_2) = \Gamma(p_1,p_2)\,(-(p_1p_2)g^{\mu\nu} + p_2^\mu p_1^\nu) + i\Gamma^5(p_1,p_2)\epsilon^{\mu\nu\rho\sigma}p_{1\rho}p_{2\sigma}\,. \tag{3.2}$$

Note that this tensor structure is led from the gauge symmetry of on-shell photon. Then all the effective vertices must be this form. We emphasize this point because sometimes this point seems overlooked, for example the tensor structure in eq. (9) in ref. [13] is different from eq. (3.2).

However, in the actual calculation, we would find terms proportional to $p_2^\mu p_2^\nu$ and $g^{\mu\nu}$, which should vanish and do not appear in eq. (3.2), namely we would find the effective vertices become

$$\widetilde{\Gamma}^{\mu\nu}(p_1,p_2) = \Gamma^{\mu\nu}(p_1,p_2) + \Gamma^P(p_1,p_2)g^{\mu\nu} + \Gamma^D(p_1,p_2)p_2^\mu p_2^\nu\,, \tag{3.3}$$

where $\Gamma^{\mu\nu}(p_1,p_2)$ is defined in eq. (3.2). These extra terms, Γ^P and Γ^D, are apparently against the gauge invariance, but, nevertheless, they would appear. See, for example, eq. (9) in ref. [13]. As we will see the following sections, we find they disappear *if* we take on-shell conditions for all the external legs. However, we should keep them off-shell except for a single photon because we use the effective vertices to calculate the Barr-Zee diagrams. Hence we need to consider how to deal with these gauge variant terms.

Fortunately, it is found that the $p_2^\mu p_2^\nu$ term does not contribute to the EDMs at two-loop level. If $\Gamma^{\mu\nu}(p_1,p_2)$ contains terms proportional to $p_2^\mu p_2^\nu$, the diagrams shown in figure 1 contain the following structures,

$$\overline{u}(p+q)\not{\ell}\frac{1}{\not{p}+\not{q}-\not{\ell}-m_f}u(p)\,, \tag{3.4}$$

$$\overline{u}(p+q)\frac{1}{\not{p}+\not{\ell}-m_f}\not{\ell}u(p)\,, \tag{3.5}$$

where eq. (3.4) (eq. (3.5)) comes from figures 1(a) and 1(c) (figures 1(b) and 1(d)). If we omit $\mathcal{O}(y_f^2)$ terms, we can ignore the mass term in the fermion propagator and the mass of the external fermions. Then, by using the equation of motion of the external fermions,

$$\overline{u}(p+q)(\not{\ell}-\not{p}-\not{q})\frac{1}{\not{p}+\not{q}-\not{\ell}}u(p)\,, \tag{3.6}$$

$$\overline{u}(p+q)\frac{1}{\not{p}+\not{\ell}}(\not{\ell}+\not{p})u(p)\,. \tag{3.7}$$

Now it is apparent that these terms do not contain $\sigma^{\mu\nu}\gamma^5$ structure because all the γ-matrices are canceled out. Therefore the terms which are proportional to $p_2^\mu p_2^\nu$ in the effective vertices do not contribute to the EDMs. Then we can safely drop the Γ^D term from eq. (3.3).

On the other hand, the Γ^P term in eq. (3.3) remains as long as we take off-shell conditions. This is nothing strange because the gauge invariance is promised for S-matrix, not for effective coupling. Then the gauge invariance will recover once we calculate non-Barr-Zee diagrams as well as the Barr-Zee diagrams, namely a full two-loop order calculation

JHEP01(2014)106

manifestly gives the gauge invariant results. However, it is very tough work to accomplish it. Instead of the full two-loop order calculation, we make the effective vertex gauge invariant by borrowing some terms from non-Barr-Zee diagrams. This technique is known as the pinch technique, and the borrowed terms are called pinch terms [15–17]. As we will see in the fallowing section, we find that Γ^P term in eq. (3.3) is completely compensate with the pinch terms.

Hereafter we calculate both $-(p_1p_2)g^{\mu\nu} + p_2^\mu p_1^\nu$ and $g_{\mu\nu}$ terms, and demonstrate the latter term completely vanishes thanks to the pinch terms.

3.2 Effective $h\gamma\gamma$ and $hZ\gamma$ vertices — W boson loop —

Now we move on to calculate the effective vertices for $h\gamma\gamma$ and $hZ\gamma$, which appear in figures 1(a) and 1(b). In the following, p_1 is the momentum of the external (on-shell) photon where $p_1^2 = 0$, and p_2 is the momentum of the virtual gauge boson in the Barr-Zee diagram. Note that the diagrams which contain both W and $H^\pm$ in the loop are absent in the 2HDM because $g_{\gamma W^\pm H^\mp} = g_{ZW^\pm H^\mp} = 0$, where $H^\pm$ is a physical charged scalar not a NG boson.

In this subsection, we focus on W boson loops of the $h\gamma\gamma$ and $hZ\gamma$ effective vertices because we find these are not gauge invariant as long as we keep off-shell conditions. We work in 't Hooft-Feynman gauge and find the $h\gamma\gamma$ and $hZ\gamma$ effective vertices are given by

$$\begin{aligned}\Gamma^{\mu\nu}_{hG\gamma}(p_1,p_2) = &+\frac{e}{(4\pi)^2}\frac{1}{m_W^2}g_{WWh}g_{WWG}\\ &\times\left[\Gamma^A_{hG\gamma}\left(p_2^\mu p_1^\nu - p_2p_1g^{\mu\nu}\right) + \Gamma^P_{hG\gamma}\left(p_2^2 - m_G^2\right)g^{\mu\nu} + \Gamma^B_{hG\gamma}p_2^\mu p_2^\nu\right.\\ &\left.+\,\Gamma^C_{hG\gamma}\left[(p_1+p_2)^2 - m_h^2\right]g^{\mu\nu}\right],\end{aligned} \tag{3.8}$$

where

$$\Gamma^A_{hG\gamma} = 4\left(-4J_1\left(m_W^2\right) + 6J_2\left(m_W^2\right) + \frac{m_G^2}{m_W^2}\left(J_1\left(m_W^2\right) - J_2\left(m_W^2\right)\right) + \left(1 - \frac{1}{2}\frac{m_G^2}{m_W^2}\right)\frac{m_h^2}{m_W^2}J_2\left(m_W^2\right)\right), \tag{3.9}$$

$$\Gamma^P_{hG\gamma} = +3J_1\left(m_W^2\right), \tag{3.10}$$

$$\begin{aligned}\Gamma^B_{hG\gamma} = &-3J_1\left(m_W^2\right) + \frac{m_G^2}{m_W^2}\left(J_1\left(m_W^2\right) - J_2\left(m_W^2\right)\right) + \frac{1}{2}\frac{m_G^2}{p_2^2}\left(1 - 2J_1\left(m_W^2\right)\right)\\ &+\frac{m_G^2}{m_W^2}\frac{(p_1+p_2)^2}{p_2^2}J_2\left(m_W^2\right),\end{aligned} \tag{3.11}$$

$$\Gamma^C_{hG\gamma} = -\left(1 - \frac{m_G^2}{m_W^2}\right)J_1\left(m_W^2\right), \tag{3.12}$$

where G stands for Z or γ, and where

$$J_1\left(m^2\right) = \int_0^1 dx\int_0^{1-x} dy\frac{1}{1 - \frac{p_2^2}{m^2}x(1-x) - \frac{(p_1+p_2)^2 - p_2^2}{m^2}xy}, \tag{3.13}$$

$$J_2\left(m^2\right) = \int_0^1 dx\int_0^{1-x} dy\frac{xy}{1 - \frac{p_2^2}{m^2}x(1-x) - \frac{(p_1+p_2)^2 - p_2^2}{m^2}xy}. \tag{3.14}$$

JHEP01(2014)106

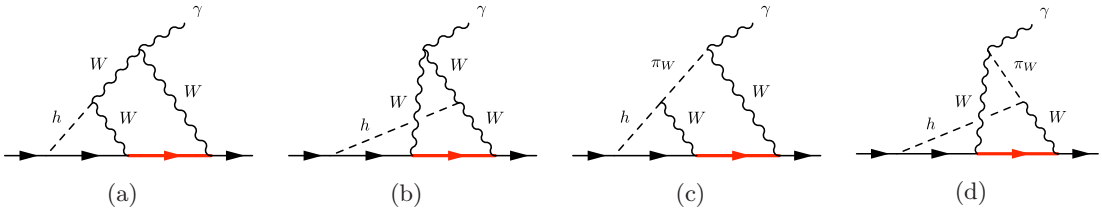

Figure 3. Diagrams containing the pinch terms for the effective $h\gamma\gamma$ and $hZ\gamma$ vertices. We pinch the fermion lines shown with red color. The dashed lines attached to the fermion lines are the physical scalars, and those not attached are would-be NG bosons.

The explicit forms of couplings, such as g_{WWh} and g_{WWG}, are given in appendix A. This result is consistent with previous works, for example in eq. (9) in ref. [13].

Although the gauge invariance requires $\Gamma^P = \Gamma^B = \Gamma^C = 0$ as we discussed in section 3, it is not satisfied in eq. (3.8). So we should consider the gauge invariance for the EDM calculation carefully. As discussed in ref. [13], the Γ^C term does not contribute to the EDMs. Because this term is proportional to inverse of neutral Higgs propagator, it can reduce neutral Higgs propagator in Barr-Zee diagram. Then we can apply the vertex relation[1] $\sum_h g^A_{\ell\ell h} g_{WWh} = 0$, where $g^A_{\ell\ell h}$ is axial-scalar coupling of external fermion ℓ with neutral Higgs bosons h and $\sum_h$ is summation for three neutral Higgs bosons. The Γ^B terms do not contribute to the EDMs neither, because these terms do not keep $\sigma^{\mu\nu}\gamma^5$ structure as we discussed in section 3.1. Then only the Γ^P terms are problematic. Actually the Γ^P terms vanish once we consider the pinch contributions as will be shown.

There are many two-loop diagrams which contribute to the EDMs, as well as the Barr-Zee diagrams. Once we calculate all the diagrams, the result must be gauge invariant. Therefore the gauge variant terms we discussed above should be canceled out by contributions from non-Barr-Zee diagrams. In order to see this cancellation, we do not need to calculate all the diagrams, but only *the pinch contributions*. The gauge invariance of eq. (3.8) would be recovered by borrowing some terms from non-Barr-Zee diagrams.

For this purpose, we calculate the diagrams shown in figure 3. These diagrams contain derivative couplings which are contracted with the gamma matrices by the Lorentz index. Then, these terms cancel out internal fermion propagators. We pick up the terms in which the fermion lines with red color in figure 3 are canceled out, and they are just the pinch contributions which make Barr-Zee contributions gauge invariant. These terms are schematically shown in figure 4. In 't Hooft-Feynman gauge,[2] we find

$$\text{Fig. 3}|_{\text{pinch}} = \sum_h \int_\ell i\tilde{\Gamma}^{\mu\nu}_{hG\gamma}(-q,\ell)\frac{i}{(q-\ell)^2-m_h^2}\frac{-ig_{\nu\rho}}{\ell^2-m_G^2}(-i\gamma^\rho g_{G\ell\ell})\frac{i}{\not{p}+\not{q}-\not{\ell}-m_f}(-ig_{\ell\ell h}), \tag{3.15}$$

where

$$\tilde{\Gamma}^{\mu\nu}_{hG\gamma}(p_1,p_2) = -g^{\mu\nu}3\frac{e}{(4\pi)^2}\frac{g_{WWh}}{m_W^2}g_{WWG}(p_2^2-m_G^2)J_1(m_W^2). \tag{3.16}$$

[1] We show this vertex relation in appendix A.3.4.

[2] In other gauge, we would need other diagrams as well as shown in figure 3.

JHEP01(2014)106

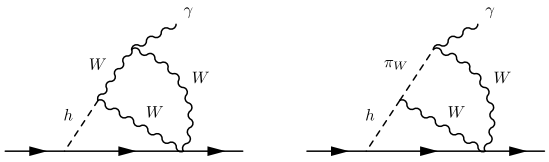

Figure 4. Diagrams (a) and (b) are the diagrams after pinched away the red lines. Figures 3(a) and 3(b) and figures 3(c) and 3(d) become diagrams (a) and (b), respectively.

Here, J_1 is given in eq. (3.13), $g_{G\ell\ell}$ and $g_{\ell\ell h}$ are couplings of external fermion ℓ with gauge and Higgs bosons, respectively, and $\int_\ell = \int d^4\ell/(2\pi)^4$. Since figure 1(a) with effective $hG\gamma$ vertices is calculated as

$$\text{Fig. 1(a)} = \sum_h \int_\ell i\Gamma^{\mu\nu}_{hG\gamma}(-q,\ell)\frac{-ig_{\nu\rho}}{\ell^2-m_G^2}\frac{i}{(\ell-q)^2-m_h^2}(-i\gamma^\rho g_{\ell\ell G})\frac{i}{\not p+\not q-\not\ell-m_f}(-ig_{\ell\ell h}), \tag{3.17}$$

we find eq. (3.16) is nothing but parts of the effective vertices by comparing eq. (3.17) to eq. (3.15), and cancels the second term in eq. (3.8) (Γ^P) which is gauge variant term. In other words, the pinch term certainly cancels the gauge variant term and make the effective coupling gauge invariant.

After adding the pinch terms, we finally find the gauge invariant W loop contributions to the effective $h\gamma\gamma$ and $hZ\gamma$ vertices for the Barr-Zee diagrams,

$$\Gamma^{\mu\nu}_{hG\gamma}(p_1,p_2) = \frac{e}{(4\pi)^2}\frac{1}{m_W^2}g_{WWh}g_{WWG}\Gamma^A_{hG\gamma}\left(-(p_1p_2)g^{\mu\nu}+p_2^\mu p_1^\nu\right), \tag{3.18}$$

where $\Gamma^A_{hG\gamma}$ is given in eq. (3.9).

3.3 Effective $h\gamma\gamma$ and $hZ\gamma$ vertices — fermion, $H^\pm$ loop —

For the Barr-Zee diagram calculation, we need other contributions to effective $h\gamma\gamma$ and $hZ\gamma$ vertices. We calculate the fermion loop contribution to the effective $h\gamma\gamma$ and $hZ\gamma$ vertices. We denote the fermion as f. Note that they are independent from the gauge fixing terms. Hence Γ^P and Γ^D in eq. (3.3) are zero. We find Γ and Γ_5 defined in eq. (3.2) are

$$\Gamma_{hG\gamma}(p_1,p_2) = +\frac{N_c}{(4\pi)^2}2eQ_f g^V_{ffh}\left(g^L_{Gff}+g^R_{Gff}\right)\frac{2}{m_f}\left(J_1\left(m_f^2\right)-4J_2\left(m_f^2\right)\right), \tag{3.19}$$

$$\Gamma^5_{hG\gamma}(p_1,p_2) = +\frac{N_c}{(4\pi)^2}2eQ_f\left(ig^A_{ffh}\right)\left(g^L_{Gff}+g^R_{Gff}\right)\frac{2}{m_f}J_1\left(m_f^2\right), \tag{3.20}$$

where N_c is the color factor, for example $N_c = 3$ for the top quark loop, Q_f is the QED charge of the fermion in the loop, for example $Q_f = 2/3$ for the top quark loop.

The diagrams with the charged Higgs boson loop are also independent from the gauge fixing terms. Thus Γ^P and Γ^D in eq. (3.3) are zero. We find Γ and Γ_5 defined in eq. (3.2) are

$$\Gamma_{hG\gamma}(p_1,p_2) = -4\frac{1}{(4\pi)^2}eg_{hH^+H^-}g_{GH^+H^-}\frac{2}{m_H^2}J_2\left(m_H^2\right), \tag{3.21}$$

$$\Gamma^5_{hG\gamma}(p_1,p_2) = 0. \tag{3.22}$$

JHEP01(2014)106

3.4 Effective $H^{\mp}W^{\pm}\gamma$ vertices — W, $H^{\pm}$ loop —

The effective vertices for $H^{\mp}W^{\pm}\gamma$, shown in figures 1(c) and 1(d), are also necessary to calculate the all the Barr-Zee diagrams. Note that these Barr-Zee contributions have not been studied in the literature yet, and we first calculate them. To find a gauge invariant set for the Barr-Zee diagrams, we need to take into account for the pinch contributions. Calculations are tedious and long, so the details are given in appendix C. After summing up all terms which are relevant for the EDM calculations, we find the following gauge invariant effective vertex:

$$\Gamma^{\mu\nu}_{H^-W^+\gamma}(p_1,p_2) = +\frac{1}{(4\pi)^2}\left(p_{2\mu}p_{1\nu}-p_2p_1g_{\mu\nu}\right) \tag{3.23}$$
$$\times\left(+\sum_h eg_{W^+H^-h}g_{WWh}\int_0^1 dz\int_0^{1-z}dy\,\frac{-2yz-4z+4-\frac{m_H^2-m_h^2}{m_W^2}2yz}{m_W^2(1-z)+m_h^2z-p_2^2z(1-z)-2p_1p_2yz}\right.$$
$$\left.-\sum_h eg_{W^+H^-h}g_{HHh}\int_0^1 dz\int_0^{1-z}dy\,\frac{4yz}{m_H^2(1-z)+m_h^2z-p_2^2z(1-z)-2p_1p_2yz}\right),$$

$$\Gamma^{\mu\nu}_{H^+W^-\gamma}(p_1,p_2) = \left(\Gamma^{\mu\nu}_{H^-W^+\gamma}(p_1,p_2)\right)^*. \tag{3.24}$$

Here we have already omitted the terms which do not contribute to the EDM calculations.[3]

There might also be fermion loops in the effective $H^{\mp}W^{\pm}\gamma$ vertices. It is found that the fermion loops in the effective $H^{\mp}W^{\pm}\gamma$ vertices do not contribute to the EDMs if we consider only the CP phase in the Higgs potential in 2HDMs. While another CP phase is present in the Cabibbo-Kobayashi-Maskawa (CKM) matrix, the contributions to the EDMs should be much suppressed due to the GIM mechanism. Then, we do not calculate the fermion loop contributions to the effective $H^{\mp}W^{\pm}\gamma$ vertices in this paper.

4 EDM from Barr-Zee diagram

In this section we calculate diagrams in figure 1. The EDM, d_ℓ, for fermion ℓ is defined through

$$\mathcal{H}_{\rm eff} = i\frac{d_\ell}{2}\overline{\psi}_\ell\sigma_{\mu\nu}\gamma_5\psi_\ell F^{\mu\nu}, \tag{4.1}$$

where

$$\sigma_{\mu\nu} = \frac{i}{2}[\gamma_\mu,\gamma_\nu]. \tag{4.2}$$

Once we get the gauge invariant effective vertex whose tensor structure is given in eq. (3.2), we find the neutral Higgs boson contributions to d_ℓ as

$$(d_\ell)^{\text{Fig. 1(a)}}_{+\text{Fig. 1(b)}} = \frac{1}{2}\sum_{G=Z,\gamma}\sum_h\left(g^L_{G\ell\ell}+g^R_{G\ell\ell}\right)\int_\ell\left(ig^A_{h\ell\ell}\Gamma_{hG\gamma}(0,\ell)+g^V_{h\ell\ell}\Gamma^5_{hG\gamma}(0,\ell)\right)\frac{1}{\ell^2-m_G^2}\frac{1}{\ell^2-m_h^2}. \tag{4.3}$$

where $g^{L(R)}_{G\ell\ell}$ is for couplings of left(right)-handed fermion ℓ with gauge boson G, and $g^{V(A)}_{\ell\ell h}$ is for (axial) scalar couplings with scalar boson h. Here we keep only the leading term for p and q, and ignore mass term in the fermion propagator, and we have used a relation, $\epsilon^{\mu\nu\alpha\beta}\gamma_\alpha\gamma_\beta = -i\gamma^5[\gamma^\mu,\gamma^\nu]$.

[3] These terms do not contribute to the on-shell $H^-\to W^-\gamma$ process neither.

JHEP01(2014)106

Note that we work in 't Hooft-Feynman gauge in eq. (4.3). If we work in other gauge, gauge boson propagators contain the terms that proportional to ℓ_ν and contract with the effective vertices. Since $\Gamma^{\mu\nu}(-q,\ell)\ell_\nu = 0$, the terms proportional to ℓ_ν in the gauge boson propagators always vanish. Therefore the Barr-Zee diagrams are gauge invariant *as long as* the effective vertices are gauge invariant.

In the similar manner, we find the charged Higgs boson contribution to the leptonic EDMs as

$$(d_\ell)^{\text{Fig. 1(c)}}_{+\text{Fig. 1(d)}} = \frac{1}{2\sqrt{2}}\frac{e}{s_W}\int_\ell \frac{1}{\ell^2 - m_W^2}\frac{1}{\ell^2 - m_H^2} i\text{Im}\left(g^R_{H^+\bar{\nu}e}\Gamma_{H^-W^+\gamma}(0,\ell)\right). \tag{4.4}$$

Here we have used the following relations,

$$g^L_{H^-\bar{e}\nu} = \left(g^R_{H^+\bar{\nu}e}\right)^*, \tag{4.5}$$

$$\Gamma_{H^+W^-\gamma}(0,\ell) = \left(\Gamma_{H^-W^+\gamma}(0,\ell)\right)^*. \tag{4.6}$$

The charged Higgs contributions to the up-type and down-type quark EDMs are derived by replacing $g^R_{H^+\bar{\nu}e}\Gamma_{H^-W^+\gamma}$ in eq. (4.4) by $g^R_{H^-\bar{d}u}\Gamma_{H^+W^-\gamma}$ and $g^R_{H^+\bar{u}d}\Gamma_{H^-W^+\gamma}$, respectively.

The chromo-EDMs (cEDMs) also contribute to the neutron EDM. Its definition is similar to eq. (4.1), replace $F_{\mu\nu}$ by $g_s G_{\mu\nu}$,

$$\mathcal{H}_{\text{eff}} = i\frac{d^c_q}{2}\bar{q}g_s\sigma_{\mu\nu}\gamma_5 G^{\mu\nu}q\,, \tag{4.7}$$

where g_s and $G_{\mu\nu}$ are the QCD coupling and the field strength of the gluon, respectively.

The formulae of EDMs include complicated functions. Here, we show the approximated expressions in the *decoupling limit* for qualitative discussion, while all plots are drawn by using the exact formulae. The exact formula are given in appendix B. In the decoupling limit all the non-SM particles are degenerated, heavier than the electroweak scale, and decoupled from the SM sector. We can take such a limit by $M \to \infty$ where M is defined in eq. (2.4).

Since the results depend on the Yukawa structure, we introduce the following notation to simplify our expressions:

$$\mathcal{G}^A_x = \begin{array}{c} \\ u/c/t \\ d/s/b \\ e/\mu/\tau \end{array} \begin{array}{c} \begin{array}{cccc} \text{Type-I} & \text{Type-II} & \text{Type-X} & \text{Type-Y} \end{array} \\ \begin{pmatrix} 1 & 1 & 1 & 1 \\ -1 & \tan^2\beta & -1 & \tan^2\beta \\ -1 & \tan^2\beta & \tan^2\beta & -1 \end{pmatrix} \end{array}, \tag{4.8}$$

$$\mathcal{S}_x = \begin{array}{c} \\ u/c/t \\ d/s/b \\ e/\mu/\tau \end{array} \begin{pmatrix} -1 \\ 1 \\ 1 \end{pmatrix}, \tag{4.9}$$

where index A represents type of the model, and index x is for flavor.

JHEP01(2014)106

It is found that the EDMs for fermion ℓ in the decoupling limit are approximated to be

$$\left(\frac{d_\ell}{e}\right)_W \simeq -X\mathcal{G}_\ell^A \times \left(e\left(15 + 2\ln\left(\frac{M}{\mathrm{TeV}}\right)\right)\left(g^L_{\gamma\ell\ell} + g^R_{\gamma\ell\ell}\right) + g_{ZWW}\left(6.5 + 0.71\ln\left(\frac{M}{\mathrm{TeV}}\right)\right)\left(g^L_{Z\ell\ell} + g^R_{Z\ell\ell}\right)\right), \tag{4.10}$$

$$\left(\frac{d_\ell}{e}\right)_{\mathrm{top}} \simeq +X\times\left(e\left(5.3\mathcal{G}_\ell^A + 7.6\right)\left(g^L_{\gamma\ell\ell} + g^R_{\gamma\ell\ell}\right) + e\left(1.4\mathcal{G}_\ell^A + 2.0\right)\left(g^L_{Z\ell\ell} + g^R_{Z\ell\ell}\right)\right), \tag{4.11}$$

$$\left(\frac{d_\ell}{e}\right)_{\mathrm{bottom}} \simeq +X \times \left(e\left(0.018\mathcal{G}_\ell^A + 0.022\mathcal{G}_b^A\right)\left(g^L_{\gamma\ell\ell} + g^R_{\gamma\ell\ell}\right) + e\left(0.0075\mathcal{G}_\ell^A + 0.0087\mathcal{G}_b^A\right)\left(g^L_{Z\ell\ell} + g^R_{Z\ell\ell}\right)\right), \tag{4.12}$$

$$\left(\frac{d_\ell}{e}\right)_{\mathrm{tau}} \simeq +X \times \left(e\left(0.024\mathcal{G}_\ell^A + 0.029\mathcal{G}_\tau^A\right)\left(g^L_{\gamma\ell\ell} + g^R_{\gamma\ell\ell}\right) + e\left(0.00034\mathcal{G}_\ell^A + 0.00038\mathcal{G}_\tau^A\right)\left(g^L_{Z\ell\ell} + g^R_{Z\ell\ell}\right)\right), \tag{4.13}$$

$$\left(\frac{d_\ell}{e}\right)_{H^\pm} \simeq +X\mathcal{G}_\ell^A \times \left(0.34e\left(g^L_{\gamma\ell\ell} + g^R_{\gamma\ell\ell}\right) + 0.34 g_{ZH^+H^-}\left(g^L_{Z\ell\ell} + g^R_{Z\ell\ell}\right)\right), \tag{4.14}$$

$$\left(\frac{d_\ell}{e}\right)_{HW\gamma} \simeq -X\mathcal{G}_\ell^A\mathcal{S}_\ell \times \left(0.23 + 0.20\ln\left(\frac{M}{\mathrm{TeV}}\right)\right), \tag{4.15}$$

$$(d_q^c)_{\mathrm{top}} \simeq +X \times g_s^2\left(4.0\mathcal{G}_q^A + 5.7\right), \tag{4.16}$$

$$(d_q^c)_{\mathrm{bottom}} \simeq +X \times g_s^2\left(0.053\mathcal{G}_q^A + 0.065\mathcal{G}_b^A\right), \tag{4.17}$$

where

$$X = \frac{1}{(4\pi)^4}\frac{m_\ell}{M^2}\cos^2\beta\lambda_5\sin 2\phi\,, \tag{4.18}$$

and we use $\overline{MS}$ mass of M_Z scale, $m_e = 0.511\,\mathrm{MeV}$, $m_\tau = 1.75\,\mathrm{GeV}$, $m_u = 1.40\,\mathrm{MeV}$, $m_t = 170.9\,\mathrm{GeV}$, $m_d = 2.92\,\mathrm{MeV}$ and $m_b = 2.94\,\mathrm{GeV}$. Notice that the EDMs and cEDMs are proportional to $\lambda_5\sin 2\phi = \mathrm{Im}[\lambda_5\exp(i2\phi)]$, namely the imaginary part of the coupling which is needed for CP violation.

It is found that the W loop contributions are dominant in large parameter region. Among the contributions from fermion loops, only the top quark contributions are relevant in the decoupling limit as long as $\tan\beta \lesssim 10$. In the similar manner, we can make approximation of cEDMs. The diagrams with charged Higgs boson in $h\gamma\gamma$, $hZ\gamma$, and $H^\mp W^\pm\gamma$ couplings are smaller than the other contributions. Note that the contributions from Z boson exchange diagrams are proportional to $\left(g^L_{Z\ell\ell} + g^R_{Z\ell\ell}\right)$. Although this factor is numerically small at electron EDM case, one must not ignore at quark EDM case. Actually, Z boson exchange diagrams occupy $30 - 50\%$ of all contribution at down quark EDM case.

In the decoupling limit the bottom quark and tau lepton contributions are small because of their small Yukawa couplings. In the non-decoupling region, however, these are not

JHEP01(2014)106

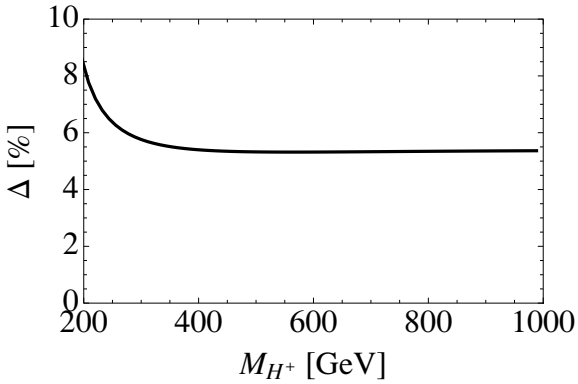

Figure 5. Numerical improvement of electron EDM by the pinch contributions in the type-II 2HDM. We take $\tan\beta = 10$, $\lambda_1 = \lambda_3 = \lambda_4 = \lambda_5 \sin 2\phi = 0.5$ and require the 126 GeV Higgs mass.

necessarily valid. Their leading contributions are given by diagrams in which heavy Higgs propagate, and their values are approximately $\mathcal{O}\left(X\mathcal{G}_\ell^A \mathcal{G}_{b/\tau}^A \left(m_{h_3}^2 - m_{h_2}^2\right)/M^2\right)$, where h_3 and h_2 is the heaviest and the next heaviest Higgs bosons, respectively. These contributions are enhanced by $\tan^2\beta$ when $\tan\beta \gg 1$. Thus, when $\tan\beta$ is large, the contribution may be sizable in the non decoupling region.

5 Numerical results

Now we evaluate the EDMs numerically. At first, in figure 5, we show the numerical improvement by the pinch contributions. Here we consider the electron EDM in the type-II 2HDM. The vertical axis in the figure 5 is difference of the gauge invariant EDM contribution and non-invariant one, Δ, defined as

$$\Delta = \frac{(d_e)_{\text{gauge non-inv.}} - (d_e)_{\text{gauge inv.}}}{(d_e)_{\text{gauge inv.}}}, \tag{5.1}$$

where the gauge non-invariant EDM contribution $(d_e)_{\text{gauge non-inv.}}$ is gotten by calculating only Barr-Zee diagrams [13, 14]. The horizontal axis is the mass of charged Higgs boson. We take $\tan\beta = 10$, $\lambda_1 = \lambda_3 = \lambda_4 = \lambda_5 \sin 2\phi = 0.5$ and require the mass of lightest neutral scalar to be 126 GeV, then λ_2 is uniquely determined. We find that the pinch contributions are 5%-8%. This is not big improvement from the numerical point of view. However, we would like to emphasize that our result is now gauge invariant, which must be satisfied when we discuss observables.

Next, we discuss dependence of the electron EDM on the types of 2HDMs. The contributions from each types of diagrams to the electron EDM for type-I and II cases in figures 6 and 7, respectively. Here we take $\tan\beta = 3$ or 50, and $\lambda_1 = \lambda_3 = \lambda_4 = \lambda_5 \sin 2\phi = 0.5$ as a benchmark. We also require the mass of lightest neutral Higgs to be 126 GeV.

It is found that in the type-I case the W boson contribution to $h \to \gamma\gamma$ is dominant and that all contributions to the electron EDM are proportional to $1/\tan^2\beta$ for $\tan\beta \gtrsim 1$. On the other hand, the electron EDM in the type-II case is qualitatively different from the type-I case. Even when $\tan\beta$ is large, the W boson and top quark contributions are

JHEP01(2014)106

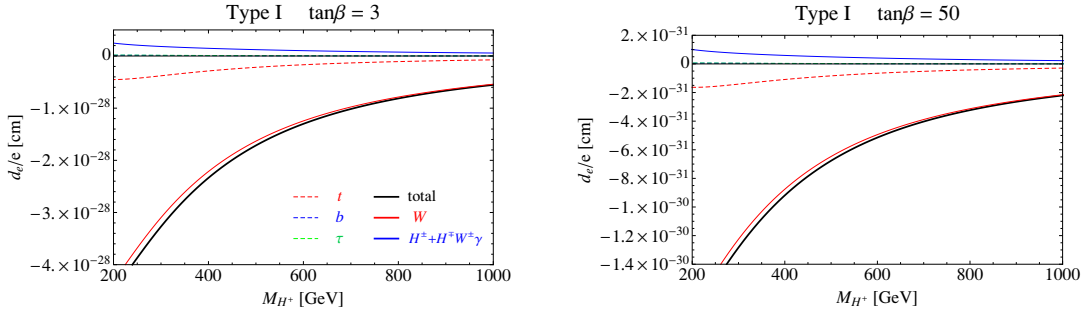

Figure 6. Anatomy of the type-I electron EDM. Various Barr-Zee contributions to the electron EDM are shown as functions of charged Higgs mass M_H^+. We take $\tan\beta = 3$ or 50, and $\lambda_1 = \lambda_3 = \lambda_4 = \lambda_5 \sin 2\phi = 0.5$. The mass of lightest neutral Higgs is 126 GeV. We see that W loop is the dominant contribution. The qualitative feature are independent from $\tan\beta$.

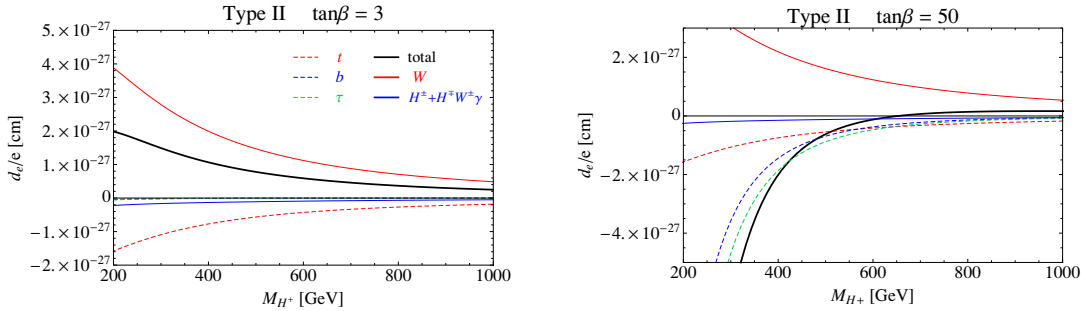

Figure 7. Anatomy of the type-II electron EDM. The input parameters are the same as in figure 6. In contrast of the type-I case, the qualitative feature depends on $\tan\beta$. For large $\tan\beta$, bottom quark and tau lepton contributions are sizable due to the $\tan\beta$ enhancement of their Yukawa couplings.

Table 2. Future prospects on electron EDM.

not suppressed and the bottom quark and tau lepton contributions also become dominant due to the non-decoupling effect. Since the signs of the bottom quark and tau lepton contributions are opposite to that of the W boson, the accidental cancellation occurs in some parameter region. Thus, the $\tan\beta$ dependence is non-trivial in the type-II case.

In figures 8, the electron EDM is shown in four types of 2HDMs as functions of $\tan\beta$ and charged Higgs boson mass. We take $\lambda_1 = \lambda_3 = \lambda_4 = \lambda_5 \sin 2\phi = 0.5$ and $\lambda_2 = 0.25$. The regions filled with red color in the figures show the excluded regions by the latest upper bound on electron EDM, which is derived by the ACME experiment,

$$|d_e| < 8.7 \times 10^{-29} e \text{ cm} \ \ (90\% \text{ CL } [3]) \,. \tag{5.2}$$

The blue dashed lines are the future prospects given in table 2.

JHEP01(2014)106

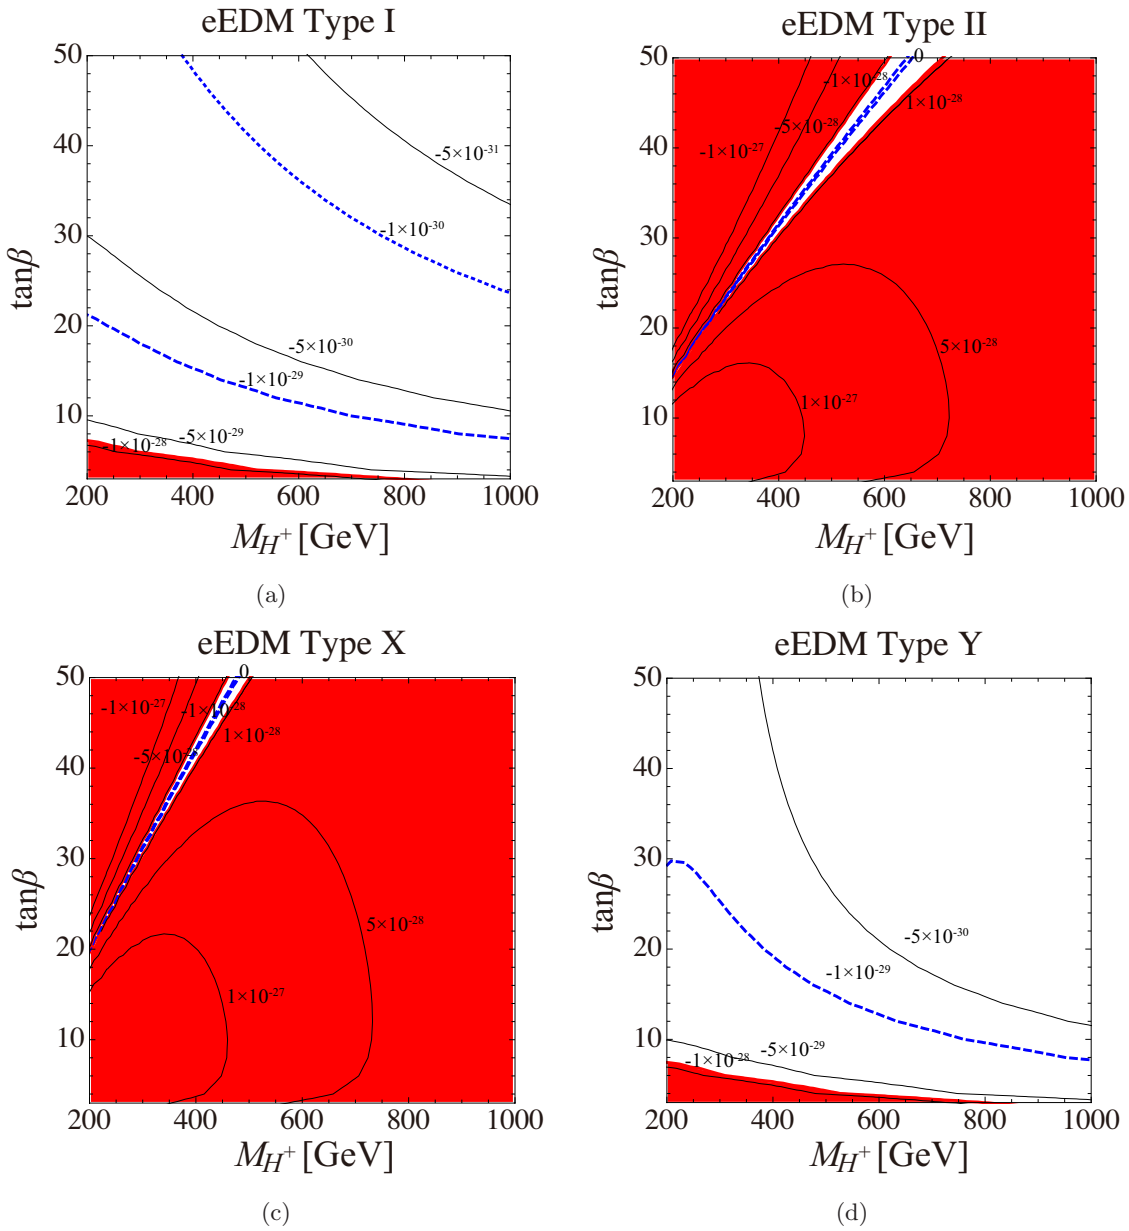

Figure 8. Electron EDM on charged Higgs boson mass and $\tan\beta$ plane in four types of 2HDMs. We take $\lambda_1 = \lambda_3 = \lambda_4 = \lambda_5 \sin 2\phi = 0.5$ and $\lambda_2 = 0.25$. The regions filled with red color show the current bound [3]. The blue dashed lines are the future prospects given in table 2.

The electron EDM in the type-X and Y models has similar behavior to the type-II and I ones, respectively, because leptons couple to H_2 in type-I and Y models, and to H_1 in type-II and X models. We find that type-II and type-X 2HDMs are strongly constrained by the recent ACME experimental result, except for regions where the cancellation among diagrams occurs, as shown in figure 8. Furthermore, the future experiments could cover wide parameter regions with charged Higgs mass smaller than 1 TeV even in type-I and Y cases.

Table 3. Future prospects for neutron EDM.

Next let us consider the neutron EDM. Even when the Peccei-Quinn mechanism [21] is operative, the neutron EDM is generated by higher-dimensional CP-violating operators in QCD, such as quark EDMs and also cEDMs with mass dimension up to 5. The neutron EDM is evaluated from the up and down quarks EDM and cEDM with the QCD sum rules [22–24]. The evaluation still $\mathcal{O}(1)$ uncertainties from the excited state contribution to the correlation function [22], and also from input parameters [23]. In this paper we use the result in ref. [24] since it gives more conservative prediction for the neutron EDM,

$$d_n = 0.79 d_d - 0.20 d_u + e\,(0.59 d_d^c + 0.30 d_u^c)\,. \tag{5.3}$$

Here, the Peccei-Quinn mechanism is assumed.

Before going to evaluate the neutron EDM, we discuss behaviors of the quark EDMs and cEDMs in the 2HDMs. We plot the contributions from each types of diagrams to the down and up quark EDMs and cEDMs in the type-I case in figures 9 and 10. The input parameters are the same as in figure 6. We see that the W boson and top quark contributions give the dominant contributions to the EDMs and cEDMs, respectively, and the $\tan\beta$ dependence is $1/\tan^2\beta$, as expected from eq. (4.18). It is found that the sizes of cEDMs and EDMs are comparable to each others so that both contributions have to be included in evaluation of the neutron EDM.

In figures 11 and 12, the contributions from each types of diagrams to the down and up quark EDMs and cEDMs in the type-II case are also shown. The EDMs and cEDMs have qualitatively different behaviors from the type-I case. We find that the largest contribution to the neutron EDM comes from down quark cEDM. The top quark loop dominates in the down quark cEDM (and also the up quark cEDM) for small $\tan\beta$, while the bottom quark one quickly dominates it when $\tan\beta$ is large. The later comes from the non-decoupling effect. Thus, the neutron EDM would be enhanced when $\tan\beta$ is large. It is also found that the down quark EDM has similar behavior to the electron EDM in the type-II case, though it is smaller than the down quark cEDM in the neutron EDM.

Here, we ignore the QCD corrections to the quark EDMs and cEDMs. The QCD corrections may change them up to $\mathcal{O}(10)\%$ [25, 26], while the neutron EDM evaluation from the quark EDMs and cEDMs may have larger uncertainties. See ref. [26] for evaluation for the QCD corrections to the Barr-Zee diagrams.

Now we show the neutron EDM in four types of 2HDMs in figure 13. The regions filled with red color in figure 13 show the excluded region by the current neutron EDM data,

$$\lvert d_n \rvert < 2.9 \times 10^{-26} e \text{ cm } (90\% \text{ CL } [4]). \tag{5.4}$$

The blue dashed lines are the future prospects given in table 3.

JHEP01(2014)106

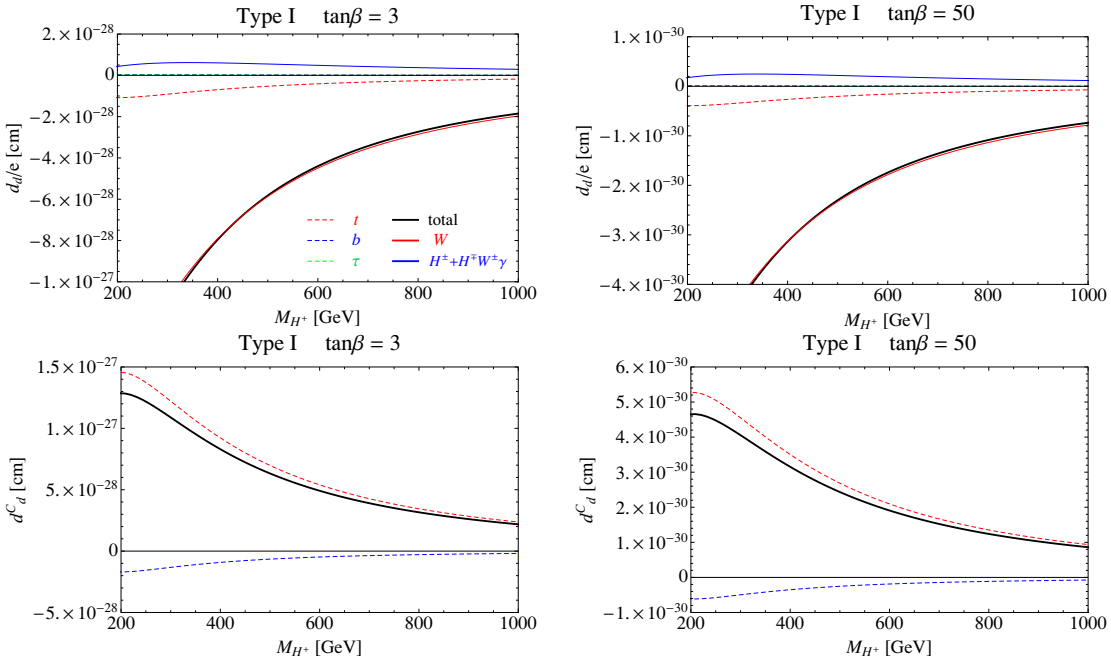

Figure 9. Anatomy of the type-I down quark EDM and cEDM. Various Barr-Zee contributions to the EDM and cEDM are shown as functions of charged Higgs mass M_H^+. We take $\tan\beta = 3$ and 50. Other input parameters are the same as in figure 6. We see that W and top give dominant contributions to EDM and cEDM, respectively.

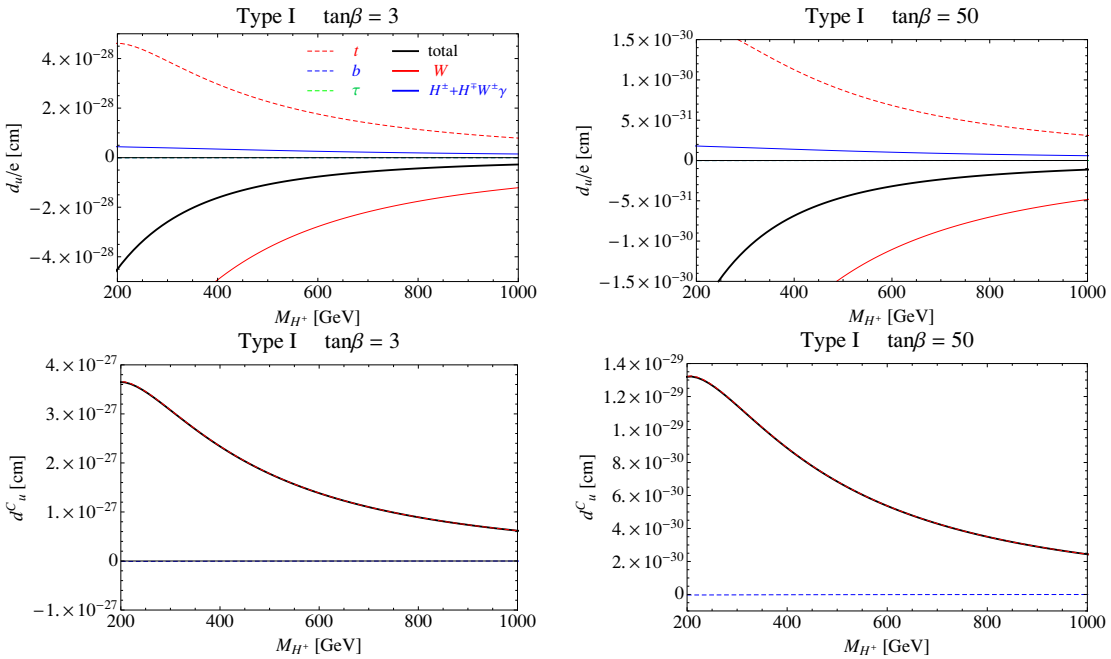

Figure 10. Anatomy of the type-I up quark EDM and cEDM. We taketan $\beta = 3$ and 50. Other input parameters are the same as in figure 6. We see that W and top give dominant contributions.

JHEP01(2014)106

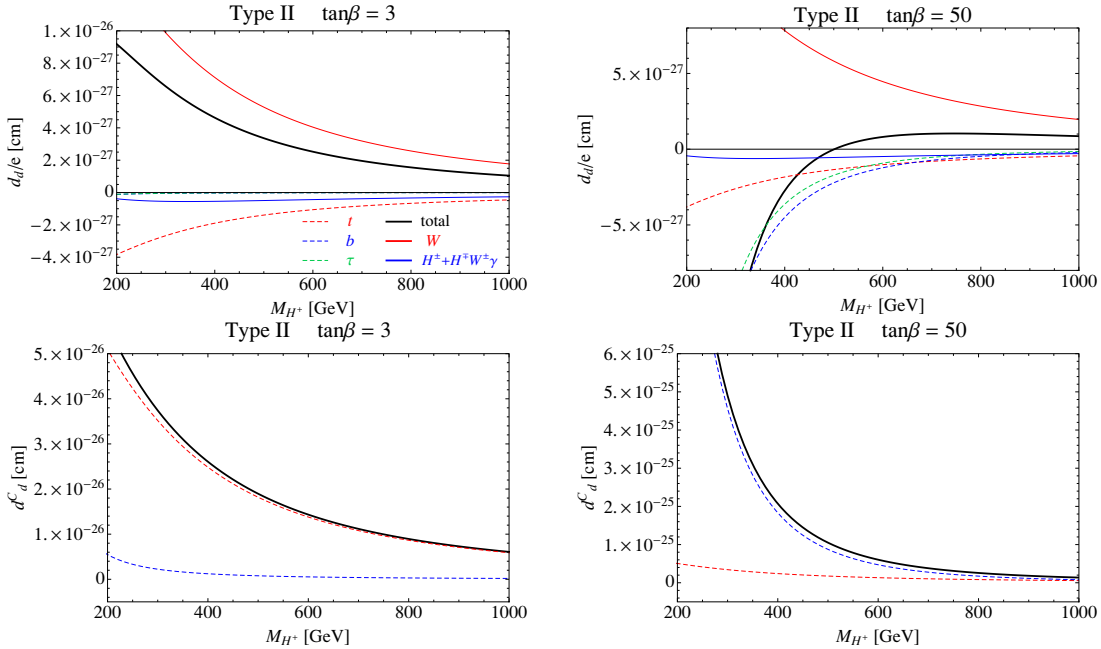

Figure 11. Anatomy of the type-II down quark EDM and cEDM. We take $\tan\beta = 3$ and 50. Other input parameters are the same as in figure 6. In contrast of the type-I case, the qualitative feature depends on $\tan\beta$. For large $\tan\beta$, the bottom quark and tau lepton contributions are sizable due to the $\tan\beta$ enhancement of their Yukawa couplings.

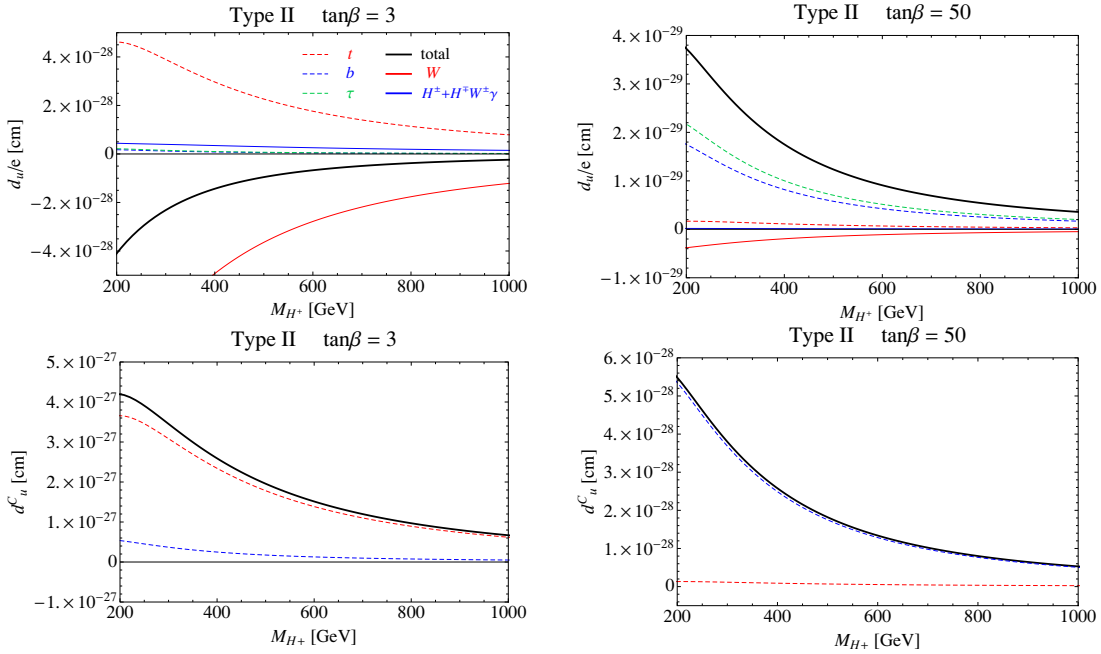

Figure 12. Anatomy of the type-II up quark EDM and cEDM. We take $\tan\beta = 3$ and 50. Other input parameters are the same as in figure 6. In contrast of the type-I case, the qualitative feature depends on $\tan\beta$. For large $\tan\beta$, bottom and tau contributions are sizable due to the $\tan\beta$ enhancement of their Yukawa couplings.

JHEP01(2014)106

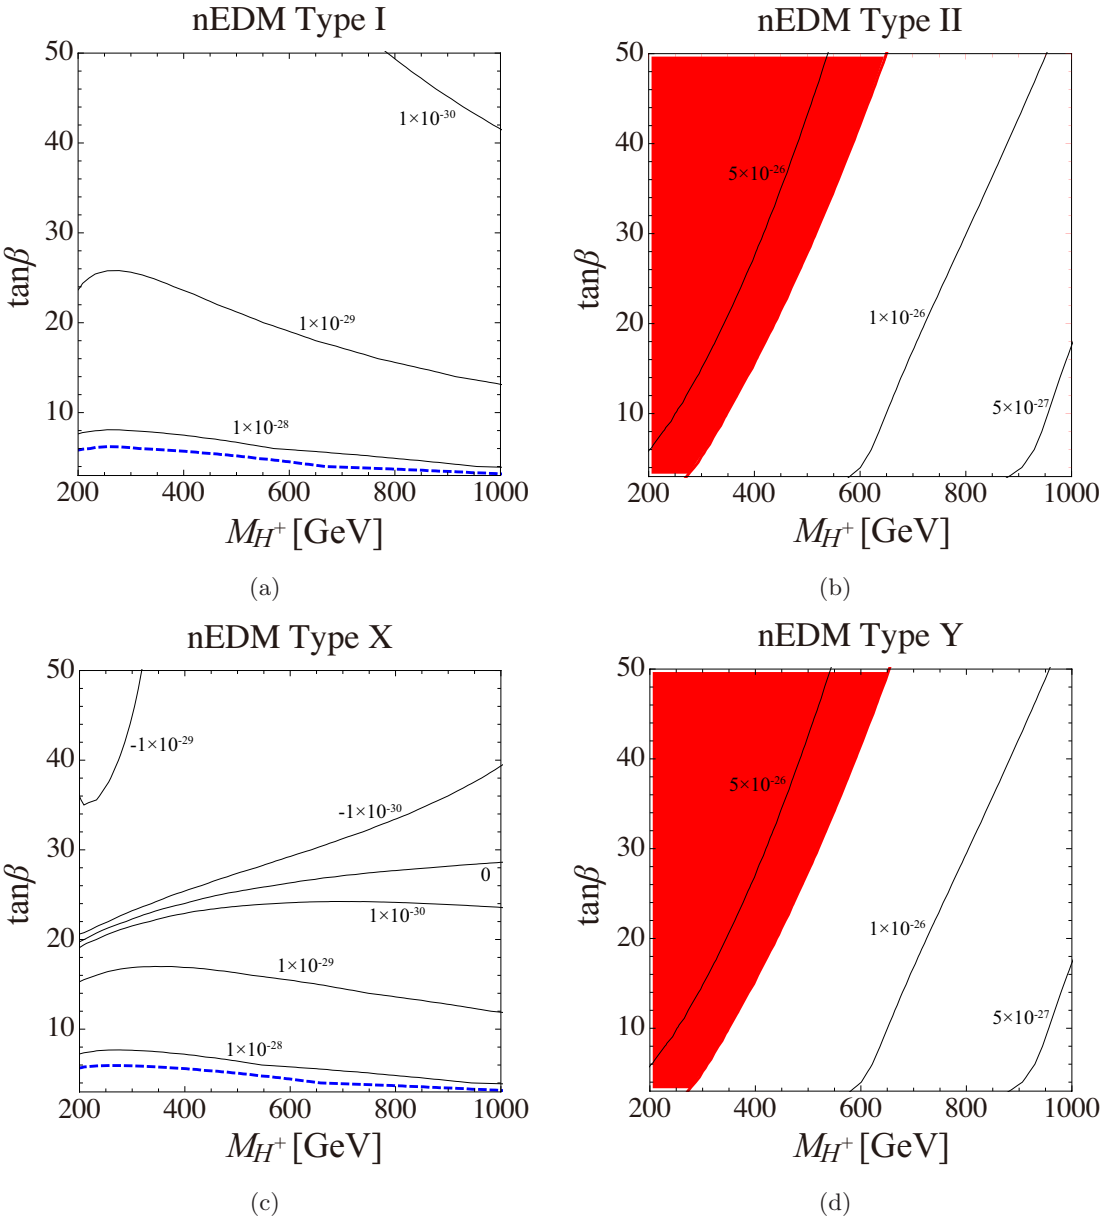

Figure 13. Neutron EDM on charged Higgs boson mass and $\tan\beta$ plane. The input parameters are the same as in figure fig:eEDM. The region filled with red color show the current bound [4]. The blue dashed lines are the future prospects given in table 3.

It is found that the neutron EDM in the type-X case has similar behavior to the type-I in low $\tan\beta$ region because the down quark Yukawa couplings in these two types are the same. The difference in high $\tan\beta$ region between figures 13(a) and 13(c) is due to the large $\tan\beta$ enhancement of the tau lepton Yukawa coupling. The behavior of the neutron EDM in the type-Y case is quite similar to the type-II case. This is because the cEDM contribution is dominant in both cases.

It is found in comparison of figure 8 with figure 13 that both measurements of the electron and neutron EDMs are complementary to each others in order to discriminate the 2HDMs. We may choose one from the four models in future.

JHEP01(2014)106

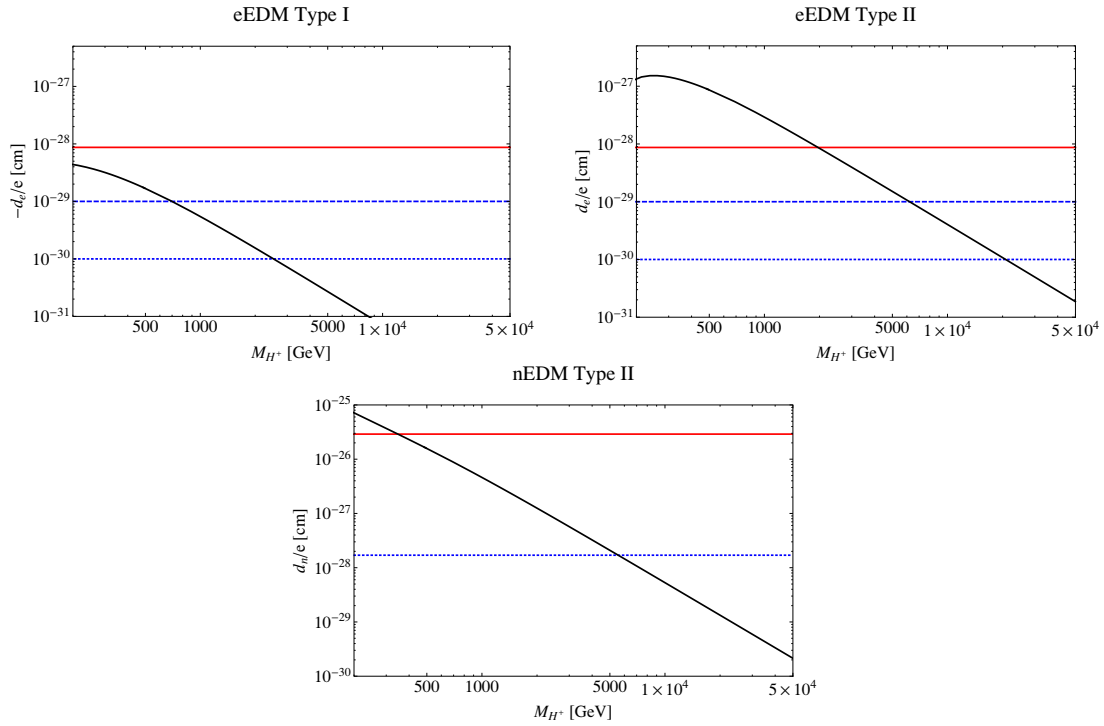

Figure 14. Electron and Neutron EDMs at large $m_H^{\pm}$ region in the type-II case. We take $\tan\beta = 10$, $\lambda_1 = \lambda_3 = \lambda_4 = \lambda_5 \sin 2\phi = 0.5$ and require the 126 GeV Higgs boson mass. The red and blue lines are current bounds [3, 4] and future prospects given in tables 2 and 3, respectively.

Before closing this section, we would like to give a comment on the constraints on the parameter space. We have shown that some parameter regions are constrained by EDMs in figures 8 and 13. The constrained regions have an overlap with other constraints, such as flavor physics [29, 30] or direct search of heavy Higgs bosons [31]. Note that it is known that the custodial SU(2) symmetry is broken in the Higgs potential in 2HDMs with the CP violation, and ρ parameter might deviate from one at the one loop level [32]. However, if heavy Higgs boson mass scale M is large or if coupling $\lambda_1 - \lambda_5$ are not large, this contribution is small. We checked that this contribution does not conflict with the current bound in all figure of this paper.

6 Conclusions and discussion

In this paper, we evaluated fermionic EDMs in 2HDMs with softly broken Z_2 symmetry. We started by calculating the Barr-Zee diagrams in a gauge invariant way by using the pinch technique. The modification by the gauge invariant calculation is 5%–8% numerically. This does not change the previous result drastically, but important because physical quantities must be calculated in a gauge invariant way. We evaluated the electron and neutron EDMs in all four types in the 2HDMs. We find that type-II and type-X 2HDMs are strongly constrained by the latest ACME experiment bound on the electron EDM. The electron and neutron EDM measurements will improve in the future experiments. They are possible to seek physics at $\mathcal{O}(10)$ TeV scale (figure 14). The electron and neutron EDMs

JHEP01(2014)106

have different sensitivities on the 2HDMs, and they are complementary to each other in discrimination of the type of 2HDMs.

We have not addressed that the contributions from non-Barr-Zee type diagrams in this paper. Although they are naively expected to be smaller than the contributions from the Barr-Zee diagrams, they would become important once experiments find the EDMs and start precise measurements. To evaluate them, we need to calculate all diagrams at two-loop level. This issue may be discussed elsewhere.

It is worth referring to relation between EWBG and EDMs. In the 2HDMs, it is known that EWBG may occur through a strongly first order electroweak phase transition [33–38]. For example, ref. [37] numerically showed that the 2HDMs with softly-broken Z_2 symmetry may accommodate a strongly first order phase transition when the lightest neutral Higgs boson is around 125 GeV. In order to achieve the EWBG, one needs some CP violation phases in Higgs potential. The EDM searches could indirectly constrain parameter space which achieve the EWBG. In this paper, we find that low $\tan\beta$ regions in 2HDMs are disfavored by electron EDM. On the other hand, in fact, a strongly first order phase transition, which is needed for EWBG, prefers low $\tan\beta$ region [37]. Therefore there is a tension between EWBG and current bound on the EDM.

A 2HDMs

In this appendix, we present mass spectrum and also interactions in 2HDMs, which are used in text.

A.1 Relations between mass and gauge eigenstates

While eight scalar fields are present in 2HDMs,

$$\sigma_{1,2}\,, \quad \pi^{\pm}_{1,2}\,, \quad \pi^{3}_{1,2}\,,$$

as in eq. (2.1), those states are not mass eigenstates, namely their mass matrices are not diagonalized. We call them the gauge eigenstates. Corresponding to them, there are eight

JHEP01(2014)106

mass eigenstates, which we denote them as

$$\begin{aligned} h_{1,2,3} &\quad \text{(neutral Higgs bosons)}, \\ H^{\pm} &\quad \text{(charged Higgs bosons)}, \\ \pi_{Z,W^{\pm}} &\quad \text{(would-be NG bosons)}. \end{aligned}$$

These two-types of states are related with orthogonal or unitary matrices which diagonalize the mass matrices. For the fields which include would-be NG bosons the matrices are given as

$$\begin{aligned} \begin{pmatrix} \pi_Z \\ \pi_A \end{pmatrix} &= \begin{pmatrix} \cos\beta & \sin\beta \\ -\sin\beta & \cos\beta \end{pmatrix} \begin{pmatrix} \pi_1^3 \\ \pi_2^3 \end{pmatrix}, \\ \begin{pmatrix} \pi_{W^{\pm}} \\ H^{\pm} \end{pmatrix} &= \begin{pmatrix} \cos\beta & \sin\beta \\ -\sin\beta & \cos\beta \end{pmatrix} \begin{pmatrix} \pi_1^{\pm} \\ \pi_2^{\pm} \end{pmatrix}. \end{aligned} \tag{A.1}$$

The matrix U for physical neutral Higgs bosons is given by a 3 by 3 matrix as

$$\begin{pmatrix} h_1 \\ h_2 \\ h_3 \end{pmatrix} = U^T \begin{pmatrix} \sigma_1 \\ \sigma_2 \\ \pi_A \end{pmatrix} = \begin{pmatrix} \omega_{h1}^{\sigma_1} & \omega_{h1}^{\sigma_2} & \omega_{h1}^{\pi_A} \\ \omega_{h2}^{\sigma_1} & \omega_{h2}^{\sigma_2} & \omega_{h2}^{\pi_A} \\ \omega_{h3}^{\sigma_1} & \omega_{h3}^{\sigma_2} & \omega_{h3}^{\pi_A} \end{pmatrix} \begin{pmatrix} \sigma_1 \\ \sigma_2 \\ \pi_A \end{pmatrix} \tag{A.2}$$

where

$$\sum_X \omega_i^X \omega_j^X = \delta_{ij}, \quad \sum_i \omega_i^X \omega_i^Y = \delta^{XY}. \tag{A.3}$$

These relations are useful to find relations among some couplings.

A.2 Higgs masses in 2HDMs

The mass terms for the neutral physical Higgs bosons are given by

$$\mathcal{L} \supset \frac{1}{2} \begin{pmatrix} \sigma_1 & \sigma_2 & \pi_A \end{pmatrix} \widetilde{\mathcal{M}}_{\rm N}^2 \begin{pmatrix} \sigma_1 \\ \sigma_2 \\ \pi_A \end{pmatrix}, \tag{A.4}$$

where

$$\begin{aligned} \left(\widetilde{\mathcal{M}}_{\rm N}^2\right)_{11} &= v_1^2\lambda_1 + M^2\sin^2\beta\,, \\ \left(\widetilde{\mathcal{M}}_{\rm N}^2\right)_{22} &= v_2^2\lambda_2 + M^2\cos^2\beta\,, \\ \left(\widetilde{\mathcal{M}}_{\rm N}^2\right)_{33} &= M^2 - v^2\lambda_5\cos(2\phi)\,, \\ \left(\widetilde{\mathcal{M}}_{\rm N}^2\right)_{21} = \left(\widetilde{\mathcal{M}}_{\rm N}^2\right)_{12} &= \left(v^2\lambda_{345} - M^2\right)\sin\beta\cos\beta\,, \\ \left(\widetilde{\mathcal{M}}_{\rm N}^2\right)_{31} = \left(\widetilde{\mathcal{M}}_{\rm N}^2\right)_{13} &= \frac{1}{2}v^2\lambda_5\sin(2\phi)\sin\beta\,, \\ \left(\widetilde{\mathcal{M}}_{\rm N}^2\right)_{32} = \left(\widetilde{\mathcal{M}}_{\rm N}^2\right)_{23} &= \frac{1}{2}v^2\lambda_5\sin(2\phi)\cos\beta\,, \end{aligned} \tag{A.5}$$

JHEP01(2014)106

where

$$\lambda_{345} = \lambda_3 + \lambda_4 + \lambda_5 \cos(2\phi)\,, \tag{A.6}$$

and M^2 is defined in eq. (2.4). This mass matrix satisfies

$$\widetilde{\mathcal{M}}^2_{\rm N} = U \begin{pmatrix} m^2_{h_1} & & \\ & m^2_{h_2} & \\ & & m^2_{h_3} \end{pmatrix} U^T. \tag{A.7}$$

In large M limit, we find the following expressions for mass and mixing angles.

$$\begin{aligned}
m^2_{h_1} &= \frac{v_1^4\lambda_1 + v_2^4\lambda_2 + 2v_1^2v_2^2\lambda_{345}}{v^2} + \mathcal{O}\left(M^{-2}\right), \\
m^2_{h_2} &= M^2\left(1 + \mathcal{O}\left(M^{-2}\right)\right), \\
m^2_{h_3} &= M^2\left(1 + \mathcal{O}\left(M^{-2}\right)\right). \\
\begin{pmatrix} \omega^{\sigma_1}_{h_1} \\ \omega^{\sigma_2}_{h_1} \\ \omega^{\pi_A}_{h_1} \end{pmatrix} &= \begin{pmatrix} \cos\beta\left(1 - X\sin^2\beta\right) \\ \sin\beta\left(1 + X\cos^2\beta\right) \\ -\frac{v_1v_2\lambda_5\sin(2\phi)}{M^2} \end{pmatrix} + \mathcal{O}\left(M^{-4}\right), \\
\begin{pmatrix} \omega^{\sigma_1}_{h_2} \\ \omega^{\sigma_2}_{h_2} \\ \omega^{\pi_A}_{h_2} \end{pmatrix} &= \begin{pmatrix} -\sin\beta\sin\theta \\ \cos\beta\sin\theta \\ \cos\theta \end{pmatrix} + \mathcal{O}\left(M^{-2}\right), \\
\begin{pmatrix} \omega^{\sigma_1}_{h_3} \\ \omega^{\sigma_2}_{h_3} \\ \omega^{\pi_A}_{h_3} \end{pmatrix} &= \begin{pmatrix} -\sin\beta\cos\theta \\ \cos\beta\cos\theta \\ -\sin\theta \end{pmatrix} + \mathcal{O}\left(M^{-2}\right),
\end{aligned} \tag{A.8}$$

where

$$\begin{aligned}
\tan(2\theta) &= \frac{\left(\cos^2\beta - \sin^2\beta\right)}{\sin^2\beta\cos^2\beta\left(\lambda_1 + \lambda_2 - 2\lambda_{345}\right) - \lambda_5\cos^2\phi}v^2\lambda_5\sin(2\phi), \\
X &= \frac{v_1^2\lambda_1 - v_2^2\lambda_2 - \left(v_1^2 - v_2^2\right)\lambda_{345}}{M^2}\,.
\end{aligned} \tag{A.9}$$

A.3 Interactions in 2HDMs

Couplings which are relevant to calculation for the gauge invariant Barr-Zee contributions are written in this subsection. Our convention of the sign in covariant derivative is

$$D_\mu = \partial_\mu + igV_\mu\,. \tag{A.10}$$

We denote s and c as sine and cosine of the Weinberg angle, respectively, in the following.

A.3.1 $\bar{f}$-f-V couplings

These couplings are the same as the SM case, but we show them here to establish our conventions. For neutral gauge bosons,

$$\mathcal{L} \supset -\sum_{G=\gamma,Z} \overline{f}\gamma^\mu g_{Gff} f G_\mu\,, \tag{A.11}$$

JHEP01(2014)106

where g_{Gff} contains chirality structure,

$$g_{Gff} = g^L_{Gff} P_L + g^R_{Gff} P_R \,, \tag{A.12}$$

where

$$\begin{aligned} g^L_{\gamma ff} &= eQ \,, \\ g^R_{\gamma ff} &= eQ \,, \\ g^L_{Zff} &= \frac{e}{sc} \left(T^3 - s^2 Q \right) , \\ g^R_{Zff} &= \frac{e}{sc} \left(-s^2 Q \right) . \end{aligned} \tag{A.13}$$

For W boson,

$$\mathcal{L} \supset -\frac{1}{\sqrt{2}} \overline{u} \gamma^\mu g_{Wud} d W^+_\mu + h.c. \,, \tag{A.14}$$

where

$$g_{Wud} = V_{\rm CKM} \frac{e}{s} P_L \,, \tag{A.15}$$

where $V_{\rm CKM}$ is for the CKM matrix.

A.3.2 Yukawa couplings

The Yukawa interaction terms are described as

$$- \begin{pmatrix} \overline{u} & \overline{d} \end{pmatrix} \begin{pmatrix} m_u^{\rm diag.} + \sum_s g_{uus} s & \sum_s g_{\overline{u}ds^+} s^+ \\ \sum_s g_{\overline{d}us^-} s^- & m_d^{\rm diag.} + \sum_s g_{dds} s \end{pmatrix} \begin{pmatrix} u \\ d \end{pmatrix} , \tag{A.16}$$

where $s = h_1, h_2, h_3, \pi_Z$, and $s^\pm = H^\pm, \pi_{W^\pm}$. We define g^V and g^A as

$$g = g^V + i\gamma^5 g^A . \tag{A.17}$$

Finally we find explicit expressions of the couplings. For the neutral Higgs bosons,

$$\begin{aligned} g^V_{uuh} &= \frac{m_u^{\rm diag.}}{v} \frac{1}{\sin\beta} \omega_h^{\sigma_2} , \\ g^A_{uuh} &= \frac{m_u^{\rm diag.}}{v} \frac{1}{\tan\beta} \omega_h^{\pi_A} , \\ g^V_{ddh} &= \begin{cases} \frac{m_d^{\rm diag.}}{v} \frac{1}{\cos\beta} \omega_h^{\sigma_1} & (i=1) \\ \frac{m_d^{\rm diag.}}{v} \frac{1}{\sin\beta} \omega_h^{\sigma_2} & (i=2) \end{cases} , \\ g^A_{ddh} &= \begin{cases} \frac{m_d^{\rm diag.}}{v} \tan\beta \omega_h^{\pi_A} & (i=1) \\ -\frac{m_d^{\rm diag.}}{v} \frac{1}{\tan\beta} \omega_h^{\pi_A} & (i=2) \end{cases} . \end{aligned} \tag{A.18}$$

Here, i corresponds to the same suffix of H_i which couples to down-type quarks.

JHEP01(2014)106

For the physical charged Higgs boson,

$$
\begin{aligned}
g^V_{\overline{u}dH^+} &= \frac{1}{\sqrt{2}}\left(V_{\rm CKM}\frac{m_d^{\rm diag.}}{v_i}\left(-\delta_{1i}\sin\beta+\delta_{2i}\cos\beta\right)-\frac{m_u^{\rm diag.}}{v_2}V_{\rm CKM}\cos\beta\right),\\
g^A_{\overline{u}dH^+} &= -\frac{i}{\sqrt{2}}\left(V_{\rm CKM}\frac{m_d^{\rm diag.}}{v_i}\left(-\delta_{1i}\sin\beta+\delta_{2i}\cos\beta\right)+\frac{m_u^{\rm diag.}}{v_2}V_{\rm CKM}\cos\beta\right),\\
g^V_{\overline{d}uH^-} &= -\frac{1}{\sqrt{2}}\left(V^\dagger_{\rm CKM}\frac{m_u^{\rm diag.}}{v_2}\cos\beta-\frac{m_d^{\rm diag.}}{v_i}V^\dagger_{\rm CKM}\left(-\delta_{1i}\sin\beta+\delta_{2i}\cos\beta\right)\right),\\
g^A_{\overline{d}uH^-} &= \frac{i}{\sqrt{2}}\left(V^\dagger_{\rm CKM}\frac{m_u^{\rm diag.}}{v_2}\cos\beta+\frac{m_d^{\rm diag.}}{v_i}V^\dagger_{\rm CKM}\left(-\delta_{1i}\sin\beta+\delta_{2i}\cos\beta\right)\right),
\end{aligned}
\tag{A.19}
$$

where i in the suffix is again the same suffix of H_i which couples to down-type quarks. Sometime the followings are useful:

$$
\begin{aligned}
g_{\overline{u}dH^+} &= g^L_{\overline{u}dH^+}P_L+g^R_{\overline{u}dH^+}P_R \qquad\qquad (A.20)\\
&= +\sqrt{2}\left[\left(-\frac{m_u^{\rm diag.}}{v}V_{\rm CKM}\frac{1}{\tan\beta}\right)P_L+\left(V_{\rm CKM}\frac{m_d^{\rm diag.}}{v}\left(-\delta_{1i}\tan\beta+\delta_{2i}\frac{1}{\tan\beta}\right)\right)P_R\right],\\
g_{\overline{d}uH^-} &= g^L_{\overline{d}uH^-}P_L+g^R_{\overline{d}uH^-}P_R\\
&= -\sqrt{2}\left[\left(-\frac{m_d^{\rm diag.}}{v}V^\dagger_{\rm CKM}\left(-\delta_{1i}\tan\beta+\delta_{2i}\frac{1}{\tan\beta}\right)\right)P_L+\left(V^\dagger_{\rm CKM}\frac{m_u^{\rm diag.}}{v}\frac{1}{\tan\beta}\right)P_R\right].
\end{aligned}
$$

A.3.3 $\mathcal{L}_{\rm WWW}$

These couplings are the same as the SM case, but we show them here to establish our conventions.

$$
\begin{aligned}
\mathcal{L}\supset-\sum_{G=\gamma,Z}ig_{WWG}\Big\{&\left(\partial^\alpha W^{+\beta}\right)W^{-\mu}G^\nu(g_{\alpha\mu}g_{\beta\nu}-g_{\alpha\nu}g_{\beta\mu})\\
&+W^{+\beta}(\partial^\alpha W^{-\mu})G^\nu(g_{\alpha\nu}g_{\beta\mu}-g_{\alpha\beta}g_{\mu\nu})\\
&+W^{+\beta}W^{-\mu}(\partial^\alpha G^\nu)(g_{\alpha\beta}g_{\mu\nu}-g_{\alpha\mu}g_{\beta\nu})\Big\},
\end{aligned}
\tag{A.21}
$$

where

$$
\begin{aligned}
g_{WWA} &= e\,,\\
g_{WWZ} &= \frac{e}{s}c\,.
\end{aligned}
\tag{A.22}
$$

A.3.4 W^+-W^--h couplings

$$
\mathcal{L}\supset\sum_h g_{WWh}W^+_\mu W^{-\mu}h+\frac{1}{2}g_{ZZh}Z_\mu Z^{-\mu}h\,,
\tag{A.23}
$$

where

$$
\begin{aligned}
g_{WWh} &= 2\frac{m_W^2}{v}\left[\cos\beta\omega_h^{\sigma_1}+\sin\beta\omega_h^{\sigma_2}\right],\\
g_{ZZh} &= 2\frac{m_Z^2}{v}\left[\cos\beta\omega_h^{\sigma_1}+\sin\beta\omega_h^{\sigma_2}\right].
\end{aligned}
\tag{A.24}
$$

JHEP01(2014)106

By using eq. (A.3), we find that

$$\sum_h g^A_{\ell\ell h} g_{WWh} = 0\,. \tag{A.25}$$

A.3.5 V-H^+-H^- couplings

$$\mathcal{L} \supset +i\left(H^+\partial_\mu H^- - H^-\partial_\mu H^+\right)\left(g_{\gamma H^+H^-}A^\mu + g_{ZH^+H^-}Z^\mu\right), \tag{A.26}$$

where

$$\begin{aligned} g_{\gamma H^+H^-} &= e, \\ g_{ZH^+H^-} &= \frac{1}{2}\frac{e}{sc}\left(c^2 - s^2\right). \end{aligned} \tag{A.27}$$

A.3.6 $W^\pm$-$H^\mp$-h couplings

$$\begin{aligned} \mathcal{L} \supset &+ ig_{hW^-H^+}\left(h\partial_\mu H^+ - H^+\partial_\mu h\right)W^{-\mu} \\ &+ ig_{hW^+H^-}\left(h\partial_\mu H^- - H^-\partial_\mu h\right)W^{+\mu}, \end{aligned} \tag{A.28}$$

where

$$g_{hW^\pm H^\mp} = \pm\frac{1}{2}\frac{e}{s}\left(-\sin\beta\omega_h^{\sigma_1} + \cos\beta\omega_h^{\sigma_2} \mp i\omega_h^{\pi_A}\right). \tag{A.29}$$

By using eq. (A.3), we find that

$$\sum_h g_{hW^+H^-}g_{WWh} = 0\,. \tag{A.30}$$

A.3.7 s^+-s^--h couplings

$$\begin{aligned} \mathcal{L} \supset &+ g_{H^+H^-h}H^+H^-h \\ &+ g_{\pi_{W^+}\pi_{W^-}h}\pi_{W^+}\pi_{W^-}h \\ &+ g_{\pi_{W^+}H^-h}\pi_{W^+}H^-h + g_{H^+\pi_{W^-}h}H^+\pi_{W^-}h \\ &+ \frac{1}{2}g_{\pi_Z\pi_Z h}\pi_Z\pi_Z h, \end{aligned} \tag{A.31}$$

where

$$\begin{aligned} g_{H^+H^-h} &= +\frac{v_1}{v^2}\left(-v_1^2\lambda_3 + v_2^2(-\lambda_1 + \lambda_4 + \lambda_5\cos(2\phi))\right)\omega_h^{\sigma_1} \\ &\quad + \frac{v_2}{v^2}\left(-v_2^2\lambda_3 + v_1^2(-\lambda_2 + \lambda_4 + \lambda_5\cos(2\phi))\right)\omega_h^{\sigma_2} \\ &\quad + \frac{v_1v_2}{v}\lambda_5\sin(2\phi)\omega_h^{\pi_A}, \\ g_{\pi_{W^+}\pi_{W^-}h} &= -\frac{m_h^2}{2m_W^2}g_{W^+W^-h}\,, \\ g_{\pi_{W^+}H^-h} &= -\frac{m_{H^\pm}^2 - m_h^2}{m_W}g_{hW^+H^-}\,, \\ g_{H^+\pi_{W^-}h} &= +\frac{m_{H^\pm}^2 - m_h^2}{m_W}g_{hW^-H^+}\,, \\ g_{h\pi_Z\pi_Z} &= -\frac{m_h^2}{2m_Z^2}g_{ZZh}\,. \end{aligned} \tag{A.32}$$

JHEP01(2014)106

A.3.8 $W^{\pm}$-$\pi^{\mp}$-h couplings

$$\begin{aligned}\mathcal{L} \supset &+ ig_{hW^-\pi^+}\left(h\partial_\mu\pi^+ - \pi^+\partial_\mu h\right)W^{-\mu} \\ &+ ig_{hW^+\pi^-}\left(h\partial_\mu\pi^- - \pi^-\partial_\mu h\right)W^{+\mu},\end{aligned} \tag{A.33}$$

where

$$g_{hW^\pm\pi^\mp} = \pm\frac{1}{2m_W}g_{WWh}\,. \tag{A.34}$$

A.3.9 V-$W^{\pm}$- $\pi^{\mp}$ couplings

$$\mathcal{L} \supset + \sum_{V=\gamma,Z}\left(g_{VW^-\pi^+}V_\mu W^{-\mu}\pi^+ + g_{VW^+\pi^-}V_\mu W^{+\mu}\pi^-\right), \tag{A.35}$$

where

$$\begin{aligned}g_{\gamma W^\mp\pi^\pm} &= +em_W\,, \\ g_{ZW^\mp\pi^\pm} &= -es_W m_Z\,.\end{aligned} \tag{A.36}$$

A.3.10 Some four-point couplings

$$\begin{aligned}\mathcal{L} \supset &+ g_{H^-\pi_{W^+}\pi_{W^-}\pi_{W^+}}H^-\pi_{W^+}\pi_{W^-}\pi_{W^+} \\ &+ \frac{1}{2}g_{H^-\pi_{W^+}\pi_Z\pi_Z}H^-\pi_{W^+}\pi_Z\pi_Z \\ &+ g_{H^-\pi_{W^+}H^-H^+}H^-\pi_{W^+}H^-H^+\end{aligned} \tag{A.37}$$

where

$$\begin{aligned}g_{H^-\pi_{W^+}\pi_{W^-}\pi_{W^+}} &= \sum_h \frac{1}{m_W}g_{hW^+H^-}g_{\pi_{W^+}\pi_{W^-}h}\,, \\ g_{H^-\pi_{W^+}\pi_Z\pi_Z} &= \sum_h \frac{1}{m_W}g_{hW^+H^-}g_{\pi_Z\pi_Z h}\,, \\ g_{H^-\pi_{W^+}H^-H^+} &= \sum_h \frac{1}{m_W}g_{hW^+H^-}g_{hH^+H^-}\,.\end{aligned} \tag{A.38}$$

B EDM formula details

In this section we present formulae for the Barr-Zee contributions to fermionic EDMs and cEDMs.

B.1 Fermion loops ($h\gamma\gamma$ and $hZ\gamma$)

After substituting eqs. (3.19) and (3.20) for eq. (4.3), we find the fermion loop contributions to the EDMs for fermion ℓ are

$$\begin{aligned}\left(\frac{d_\ell}{e}\right)_{\text{fermion}} = &-\frac{m_\ell}{(4\pi)^4}\sqrt{2}G_F\sum_f\sum_h\sum_{G=\gamma,Z}N_c Q_f\left(g^L_{G\ell\ell}+g^R_{G\ell\ell}\right) \\ &\times\left[\frac{g^A_{h\ell\ell}}{m_\ell/v}\frac{g^V_{hff}}{m_f/v}\mathcal{I}^G_1(m_f,m_h)+\frac{g^V_{h\ell\ell}}{m_\ell/v}\frac{g^A_{hff}}{m_f/v}\mathcal{I}^G_2(m_f,m_h)\right],\end{aligned} \tag{B.1}$$

JHEP01(2014)106

where

$$\mathcal{I}_1^G(m_f,m_h) = \left(g_{Gff}^L + g_{Gff}^R\right)\frac{m_f^2}{m_h^2-m_G^2}\left(I_1(m_f,m_G)-I_1(m_f,m_h)\right),$$
$$\mathcal{I}_2^G(m_f,m_h) = \left(g_{Gff}^L + g_{Gff}^R\right)\frac{m_f^2}{m_h^2-m_G^2}\left(I_2(m_f,m_G)-I_2(m_f,m_h)\right), \tag{B.2}$$

and where[4]

$$I_1(m_1,m_2) = \int_0^1 dz\,(1-2z(1-z))\,\frac{m_2^2}{m_1^2-m_2^2z(1-z)}\ln\frac{m_2^2z(1-z)}{m_1^2},$$
$$I_2(m_1,m_2) = \int_0^1 dz\frac{m_2^2}{m_1^2-m_2^2z(1-z)}\ln\frac{m_2^2z(1-z)}{m_1^2}. \tag{B.4}$$

B.2 Charged Higgs loops ($h\gamma\gamma$ and $hZ\gamma$)

By substituting the result in eq. (3.21) into eq. (4.3), we find the charged Higgs contribution to the EDMs,

$$\left(\frac{d_\ell}{e}\right)_{\text{scalar}} = +\frac{m_\ell}{(4\pi)^4}\sqrt{2}G_F\sum_h\sum_{G=\gamma,Z}\left(g_{G\ell\ell}^L+g_{G\ell\ell}^R\right)\frac{g_{h\ell\ell}^A}{m_\ell/v}\frac{g_{hH^+H^-}}{v}\mathcal{I}_3^G(m_H^\pm,m_h) \tag{B.5}$$

where

$$\mathcal{I}_3^G(m_H^\pm,m_h) = -\frac{1}{2}g_{GH^+H^-}\frac{v^2}{m_h^2-m_G^2} \tag{B.6}$$
$$\times\left[\left(I_1(m_{H^\pm},m_G)-I_1(m_{H^\pm},m_h)\right)-\left(I_2(m_{H^\pm},m_G)-I_2(m_{H^\pm},m_h)\right)\right].$$

B.3 W loops ($h\gamma\gamma$ and $hZ\gamma$)

The EDM contributions from W boson loops are

$$\left(\frac{d_\ell}{e}\right)_W = +\frac{m_\ell}{(4\pi)^4}\sqrt{2}G_F\sum_h\sum_{G=\gamma,Z}\left(g_{G\ell\ell}^L+g_{G\ell\ell}^R\right)\frac{g_{h\ell\ell}^A}{m_\ell/v}\frac{g_{WWh}}{2m_W^2/v}\mathcal{I}_W^G(m_h), \tag{B.7}$$

where

$$\mathcal{I}_W^G(m_h) = g_{WWG}\frac{2m_W^2}{m_h^2-m_G^2} \tag{B.8}$$
$$\times\left[-\frac{1}{4}\left\{\left(6-\frac{m_G^2}{m_W^2}\right)+\left(1-\frac{m_G^2}{2m_W^2}\right)\frac{m_h^2}{m_W^2}\right\}\left[I_1(m_W,m_h)-I_1(m_W,m_G)\right]\right.$$
$$\left.+\left\{\left(-4+\frac{m_G^2}{m_W^2}\right)+\frac{1}{4}\left(6-\frac{m_G}{m_W^2}+\left(1-\frac{m_G}{2m_W^2}\right)\frac{m_h^2}{m_W^2}\right)\right\}\left[I_2(m_W,m_h)-I_2(m_W,m_G)\right]\right].$$

[4]The functions $f(z)$ and $g(z)$ in refs. [12, 13] are related to I_1 and I_2 as follows:

$$I_1(m_1,m_2) = -2\frac{m_2^2}{m_1^2}f\left(\frac{m_1^2}{m_2^2}\right),\quad I_2(m_1,m_2) = -2\frac{m_2^2}{m_1^2}g\left(\frac{m_1^2}{m_2^2}\right). \tag{B.3}$$

JHEP01(2014)106

B.4 $H^{\mp}W^{\pm}\gamma$

In this paper we first find the EDM contributions from $H^{\mp}W^{\pm}\gamma$ vertices which are generated by W and charged Higgs boson loops. The detail of this derivation is given in appendix C. The contributions to the EDMs are

$$\frac{d_\ell}{e} = -\frac{m_\ell}{(4\pi)^4}\sqrt{2}G_F\mathcal{S}_\ell\sum_h\left(\frac{g^A_{\ell\ell h}}{m_\ell/v}\frac{g_{WWh}}{2m_W^2/v}\frac{e^2}{2s^2}\mathcal{I}_4(m_h^2,m_H^2)+\frac{g^A_{\ell\ell h}}{m_\ell/v}\frac{g_{HHh}}{v}\mathcal{I}_5(m_h^2,m_H^2)\right), \tag{B.9}$$

where

$$\begin{aligned}\mathcal{I}_4\left(m_h^2,m_H^2\right) &= \frac{m_W^2}{m_H^2-m_W^2}\left(I_4\left(m_W^2,m_h^2\right)-I_4\left(m_H^2,m_h^2\right)\right),\\ \mathcal{I}_5\left(m_h^2,m_H^2\right) &= \frac{m_W^2}{m_H^2-m_W^2}\left(I_5\left(m_W^2,m_h^2\right)-I_5\left(m_H^2,m_h^2\right)\right),\end{aligned} \tag{B.10}$$

and where

$$\begin{aligned}I_4\left(m_1^2,m_h^2\right) &= \int_0^1 dz\left(z(1-z)^2-4(1-z)^2+\frac{m_H^2-m_h^2}{m_W^2}z(1-z)^2\right)\\ &\qquad\times\frac{m_1^2}{m_W^2(1-z)+m_h^2z-m_1^2z(1-z)}\ln\left(\frac{m_W^2(1-z)+m_h^2z}{m_1^2z(1-z)}\right),\\ I_5\left(m_1^2,m_h^2\right) &= +2\int_0^1 dz\frac{m_1^2z(1-z)^2}{m_H^2(1-z)+m_h^2z-m_1^2z(1-z)}\ln\left(\frac{m_H^2(1-z)+m_h^2z}{m_1^2z(1-z)}\right),\end{aligned} \tag{B.11}$$

and s is sine of the Weinberg angle. Here we have used the following relations among the coupling,

$$\begin{aligned}\mathrm{Im}\left(\frac{g^R_{H^+\bar{\nu}e}}{\sqrt{2}m_e/v}\frac{g_{W^+H^-h}}{e/(2s_W)}\right) &= \frac{g^A_{eeh}}{m_e/v},\\ \mathrm{Im}\left(\frac{g^R_{H^+\bar{u}d}}{\sqrt{2}m_d/v}\frac{g_{W^+H^-h}}{e/(2s_W)}\right) &= \frac{g^A_{ddh}}{m_d/v},\\ \mathrm{Im}\left(\frac{g^R_{H^-\bar{d}u}}{\sqrt{2}m_u/v}\frac{g_{W^-H^+h}}{e/(2s_W)}\right) &= \frac{g^A_{uuh}}{m_u/v}.\end{aligned} \tag{B.12}$$

B.5 CEDMs

The effective Hamiltonian for the cEDM is defined as eq. (4.7). We find

$$d_q^c = +\frac{m_q}{(4\pi)^4}\sqrt{2}G_F\sum_f\sum_h 2g_s^2\frac{m_f^2}{m_h^2}\left[\frac{g^A_{hqq}}{m_q/v}\frac{g^V_{hff}}{m_f/v}I_1(m_f,m_h)+\frac{g^V_{hqq}}{m_q/v}\frac{g^A_{hff}}{m_f/v}I_2(m_f,m_h)\right]. \tag{B.13}$$

C Derivation for effective $H^-W^+\gamma$ vertex

In this appendix, we present explicit derivation of the effective $H^-W^+\gamma$ vertex, which is generated from bosonic loop diagrams, in 2HDMs.

JHEP01(2014)106

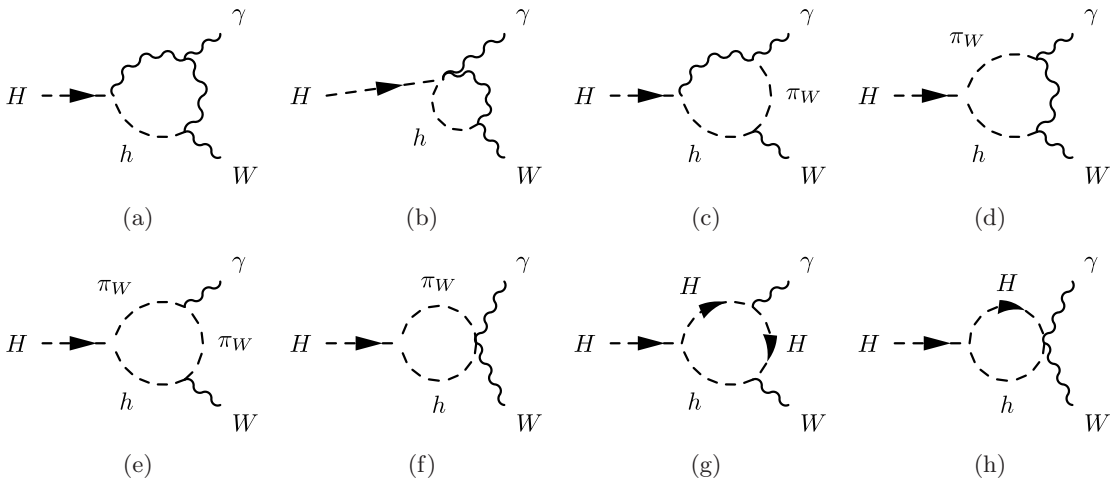

Figure 15. Diagrams for the vertex corrections to $H^-W^+\gamma$. Figures 15(a)–15(f) depend on the gauge fixing parameter ξ, while figures 15(g) and 15(h) are independent of ξ.

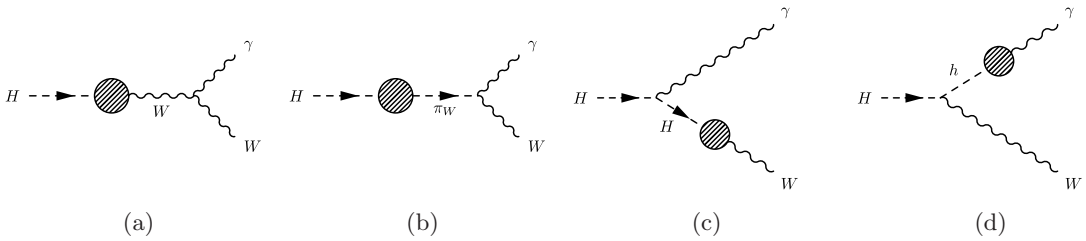

Figure 16. Diagrams of wave function type corrections.

There are two types of loop diagrams; vertex corrections (figure 15) and wave function corrections (figure 16). The diagrams in figure 16(d) give nothing because of C-invariance. The contributions from figure 16(c) is always proportional to p_2^ν. Thus they do not contribute to the on-shell amplitude of $H^\mp \to W^\mp\gamma$ nor the EDM at two-loop level by the same discussion in section 3. Hence what we need to calculate are only the diagrams in figures 15, 16(a), and 16(b). In this section, we calculate these diagrams in 't Hooft-Feynman gauge.

First, let us consider the diagrams in figures 15(a)–15(f). These diagrams depend on

JHEP01(2014)106

the gauge fixing parameter of W boson. We find

$$\begin{aligned}\sum \text{Figs. 15(a)-15(f)} =& +\frac{i}{(4\pi)^{D/2}}\Gamma(3-D/2)\left(p_{2\mu}p_{1\nu}-p_2p_1g_{\mu\nu}\right)\sum_h eg_{W^+H^-h}g_{WWh} \\ &\times\int_{x+y+z=1}\frac{-2yz-4z+4-\frac{m_H^2-m_h^2}{m_W^2}2yz}{\left[m_W^2(1-z)+m_h^2z-p_2^2z(1-z)-2p_1p_2yz\right]^{3-D/2}} \\ &+\frac{i}{(4\pi)^{D/2}}g_{\mu\nu}\sum_h eg_{W^+H^-h}g_{WWh} \\ &\times\left[\Gamma(2-D/2)\int_0^1 dz\frac{-(1+z)}{\left[m_W^2z+m_h^2(1-z)-p_H^2z(1-z)\right]^{2-D/2}}\right. \\ &-\frac{m_H^2-m_h^2}{m_W^2}\Gamma(2-D/2)\int_0^1 dz\frac{\frac{1}{2}(-1+2z)}{\left[m_W^2z+m_h^2(1-z)-p_H^2z(1-z)\right]^{2-D/2}} \\ &+\left(p_H^2-m_H^2\right)\Gamma(3-D/2) \\ &\left.\times\int_{x+y+z=1}\frac{1}{\left[m_W^2(1-z)+m_h^2z-p_2^2z(1-z)-2p_1p_2yz\right]^{3-D/2}}\right],\end{aligned} \tag{C.1}$$

where $p_H^2=(p_1+p_2)^2$. We find $g_{\mu\nu}$ terms, which are not gauge invariant. We will show these terms are canceled with other diagrams, that is, the pinch contributions.

The diagrams in figures 15(g) and 15(h) are independent from the gauge fixing parameter.

$$\begin{aligned}\text{Fig. 15(g)}+\text{Fig. 15(h)} =& -\frac{i}{(4\pi)^{D/2}}\Gamma(3-D/2)\left(p_{2\mu}p_{1\nu}-p_2p_1g_{\mu\nu}\right)\sum_h eg_{W^+H^-h}g_{HHh} \\ &\times\int_{x+y+z=1}\frac{4yz}{\left[m_H^2(1-z)+m_h^2z-p_2^2z(1-z)-2p_1p_2yz\right]^{3-D/2}} \\ &-\frac{i}{(4\pi)^{D/2}}\Gamma(2-D/2)g_{\mu\nu}\sum_h eg_{W^+H^-h}g_{HHh} \\ &\times\int_0^1 dz\frac{-1+2z}{\left[m_H^2z+m_h^2(1-z)-p_H^2z(1-z)\right]^{2-D/2}}.\end{aligned} \tag{C.2}$$

Next we calculate the diagrams in figures 16(a) and 16(b). First we define the following notation for self-energies.

$$= i\Pi^\mu_{H^-W^+}(p)=ip^\mu\Pi_{H^-W^+}\left(p^2\right), \tag{C.3}$$

$$= i\Pi_{H^-\pi_{W^+}}\left(p^2\right). \tag{C.4}$$

The direction of the momentum of Π^μ_{HW} is shown in its figure. Using this notation, we find

$$\begin{aligned}\text{Fig. 16(a)} + \text{Fig. 16(b)} =& \frac{-ig_{\mu\nu}}{p_H^2-m_W^2}\left(-em_Wi\Pi_{H^-\pi_{W^+}}\left(p_H^2\right)-em_W^2\Pi_{H^-W^+}\left(p_H^2\right)\right) \\ &+\left(p_2^2-m_W^2\right)\frac{-ig_{\mu\nu}}{p_H^2-m_W^2}\left(-e\Pi_{H^-W^+}\left(p_H^2\right)\right).\end{aligned} \tag{C.5}$$

JHEP01(2014)106

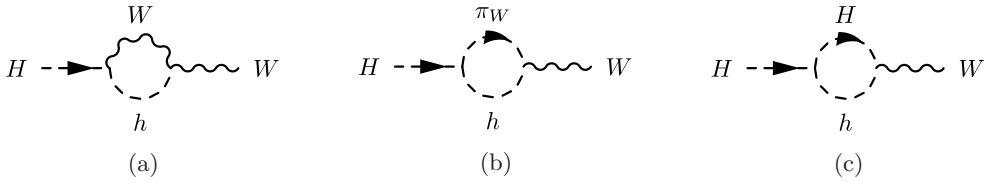

Figure 17. Diagrams for $\Pi_{H^-W^+}$.

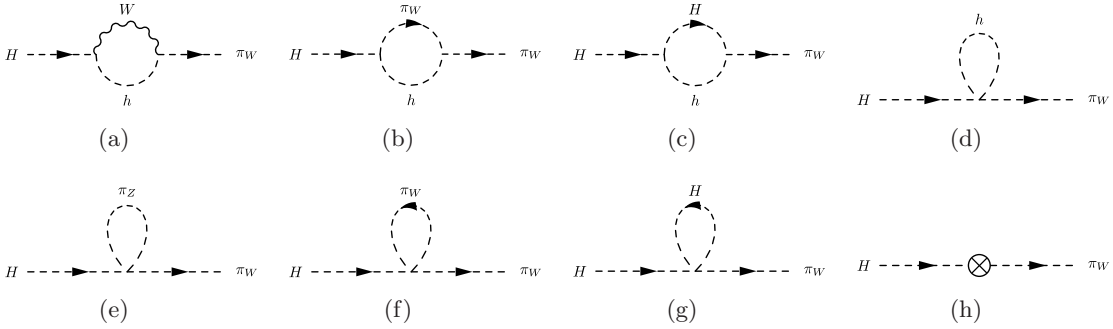

Figure 18. Diagrams for $\Pi_{H^-\pi_{W^+}}$. The last one is for the counter term.

Here we ignored $p_2^\mu p_2^\nu$ terms because they do not contribute to the EDMs as we discussed in section 3. Note that the $\left(p_2^2 - m_W^2\right)$ term does not also contribute to the on-shell amplitudes nor the EDMs at two-loop level. If we calculate the EDMs with this term, we immediately see that q^2 dependence completely canceled out. Thus, we only need the first term in eq. (C.5).

Figure 17 shows the diagrams for $\Pi_{H^-W^+}(p^2)$. We find

$$\begin{aligned} i\Pi_{H^-W^+}(p^2) = &+\frac{i}{(4\pi)^{D/2}}\Gamma(2-D/2)g_{WWh}g_{hW^+H^-}\int_0^1 dx \frac{-(2-x)+\frac{m_H^2-m_h^2}{m_W^2}(x-\frac{1}{2})}{\left[m_W^2(1-x)+m_h^2 x - p^2x(1-x)\right]^{2-D/2}} \\ &+\frac{i}{(4\pi)^{D/2}}\Gamma(2-D/2)g_{HHh}g_{hW^+H^-}\int_0^1 dx \frac{1-2x}{\left[m_H^2 x+m_h^2(1-x) - p^2x(1-x)\right]^{2-D/2}}. \end{aligned} \tag{C.6}$$

Figure 18 shows the diagrams for $\Pi_{H^-\pi_{W^+}}(p^2)$. We find figures 18(d)–18(g) are canceled by figure 18(h), so we do not calculate them. Figure 18(h) is the counter term for $H - \pi_W$ mixing, and it is also related with the counter terms for the Higgs tadpoles (figure 19(i)),

$$\delta_{H^-\pi_{W^+}} = \sum_h \frac{1}{m_W} g_{hW^+H^-}\delta_h\,, \tag{C.7}$$

where δ's are defined through

$$\mathcal{L} \supset -\delta_{H^-\pi_{W^+}} H^-\pi_{W^+} + \sum_h \delta_h h\,. \tag{C.8}$$

It is easy to find this relation by analyzing the Higgs potential. We take renormalization conditions in which all tadpole diagrams are completely canceled by their counter terms.

JHEP01(2014)106

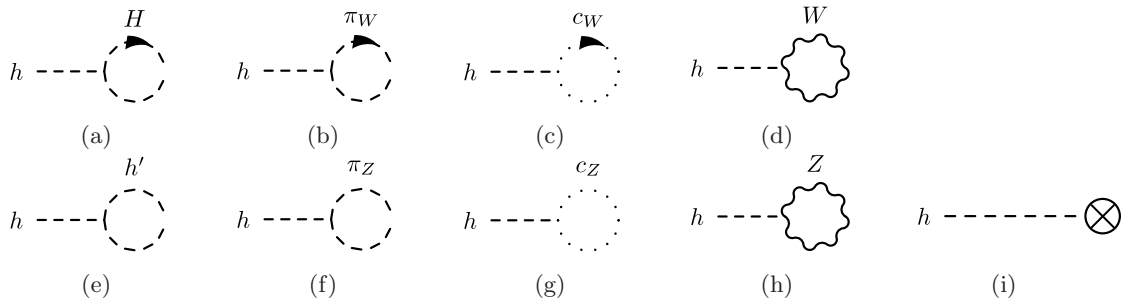

Figure 19. Tadpoles diagrams.

Then $\delta_{H^-\pi_{W^+}}$ is not arbitrary but should be calculated from the tadpole diagrams and eq. (C.8). We show the tadpole diagrams in figure 19. After calculating tadpole diagrams, using eq. (C.7), we find

$$\begin{aligned}
\text{Fig. 18(h)} = &-(\text{Fig. 18(d)} + \text{Fig. 18(e)} + \text{Fig. 18(f)} + \text{Fig. 18(g)}) \\
&+ i\sum_h \left(\frac{m_H^2 - m_h^2}{2m_W^3} g_{WWh} g_{hW^+H^-} + \frac{g_{HHh} g_{hW^+H^-}}{m_W}\right) \int_\ell \frac{1}{\ell^2 - m_h^2} \\
&- i\sum_h \frac{g_{HHh} g_{hW^+H^-}}{m_W} \int_\ell \frac{1}{\ell^2 - m_H^2} \\
&+ i\sum_h \frac{m_h^2}{2m_W^3} g_{HHh} g_{hW^+H^-} \int_\ell \frac{1}{\ell^2 - m_W^2}.
\end{aligned} \tag{C.9}$$

Now we have calculated all the diagrams shown in figure 18, and we find

$$\begin{aligned}
i\Pi_{H^-\pi_{W^+}} = &+ \frac{\Gamma(2 - D/2)}{(4\pi)^{D/2}} \frac{1}{2m_W} g_{WWh} g_{W^+H^-h} \\
&\times \int_0^1 dx \left[\frac{p^2(1+2x) + m_h^2}{\left[m_W^2 x + m_h^2(1-x) - p^2 x(1-x)\right]^{2-D/2}} \right. \\
&\left. + \frac{m_H^2 - m_h^2}{m_W^2} \frac{m_W^2 - p^2(1-2x)}{\left[m_W^2 x + m_h^2(1-x) - p^2 x(1-x)\right]^{2-D/2}} \right] \\
&- \frac{\Gamma(2-D/2)}{(4\pi)^{D/2}} \frac{1}{m_W} g_{HHh} g_{W^+H^-h} p^2 \int_0^1 dx \frac{1-2x}{\left[m_H^2 x + m_h^2(1-x) - p^2 x(1-x)\right]^{2-D/2}}.
\end{aligned} \tag{C.10}$$

We have finished preparing to calculate figure 16(a) + figure 16(b). Substituting

JHEP01(2014)106

eqs. (C.6) and (C.10) into the first term in eq. (C.5), then we find

$$\begin{aligned}\text{Fig. 16(a)} + \text{Fig. 16(b)} = & -ig_{\mu\nu}\frac{1}{(4\pi)^{D/2}}\Gamma(2-D/2)eg_{W^+H^-h} \\ & \times \left[g_{WWh}\int_0^1 dx \frac{-(1+x)+\frac{m_H^2-m_h^2}{2m_W^2}(1-2x)}{\left[m_W^2 x + m_h^2(1-x) - p_H^2 x(1-x)\right]^{2-D/2}} \right. \\ & + g_{WWh}\frac{p_H^2-m_H^2}{2\left(p_H^2-m_W^2\right)}\int_0^1 dx \frac{1}{\left[m_W^2 x + m_h^2(1-x) - p_H^2 x(1-x)\right]^{2-D/2}} \\ & \left. + g_{HHh}\int_0^1 dx \frac{(1-2x)}{\left[m_H^2 x + m_h^2(1-x) - p_H^2 x(1-x)\right]^{2-D/2}} \right]. \end{aligned} \tag{C.11}$$

Here we dropped the $(p_2^2 - m_W^2)g_{\mu\nu}$ term because it does not contribute to what we are interested in. Note that the first term in the bracket in eq. (C.11) is canceled with eq. (C.1), and the second term is canceled with eq. (C.2).

So far we have calculated many diagrams, vertex corrections and wave function corrections. The corrections are not so simple and some of them canceled out, so we give a short summary so far here. After summing up all the correction we have calculated so far, we find

$$\begin{aligned} & + \frac{i}{(4\pi)^{D/2}}\Gamma(3-D/2)\left(p_{2\mu}p_{1\nu} - p_2 p_1 g_{\mu\nu}\right) \\ & \quad \times \left(+ \sum_h e g_{W^+H^-h} g_{WWh} \int_{x+y+z=1} \frac{-2yz - 4z + 4 - \frac{m_H^2-m_h^2}{m_W^2}2yz}{\left[m_W^2(1-z) + m_h^2 z - p_2^2 z(1-z) - 2p_1p_2yz\right]^{3-D/2}} \right. \\ & \qquad \left. - \sum_h e g_{W^+H^-h} g_{HHh} \int_{x+y+z=1} \frac{4yz}{\left[m_H^2(1-z) + m_h^2 z - p_2^2 z(1-z) - 2p_1p_2yz\right]^{3-D/2}} \right) \\ & + \frac{i}{(4\pi)^{D/2}} g_{\mu\nu}\left(p_H^2 - m_H^2\right)\sum_h e g_{W^+H^-h} g_{WWh} \\ & \quad \times \left[+\Gamma(3-D/2)\int_{x+y+z=1} \frac{1}{\left[m_W^2(1-z) + m_h^2 z - p_2^2 z(1-z) - 2p_1p_2yz\right]^{3-D/2}} \right. \\ & \qquad \left. -\Gamma(2-D/2)\frac{1}{2\left(p_H^2-m_W^2\right)}\int_0^1 dx \frac{1}{\left[m_W^2 x + m_h^2(1-x) - p_H^2 x(1-x)\right]^{2-D/2}} \right]. \end{aligned} \tag{C.12}$$

Note that the last two terms are not gauge invariant in the sense that we discussed in section 3. Since they are proportional to $p_H^2 - m_H^2$, if we take the charged Higgs boson on-shell, they are dropped and the result becomes gauge invariant. However, now we need to take the charged Higgs boson off shell, so we still need some other terms to cancel them.

To find a gauge invariant set for the Barr-Zee diagrams, we need to take into account for the pinch contributions shown in figure 20. After pinching the fermion propagators with

JHEP01(2014)106

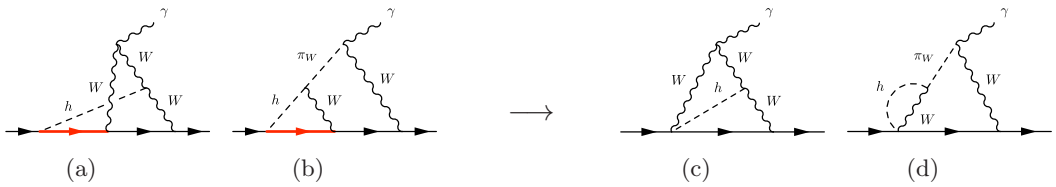

Figure 20. Pinch contributions.

red color in figures 20(a) and 20(b), the pinch contributions for $H^-W^+\gamma$ effective vertex for the Barr-Zee diagrams arise. They are schematically shown in figures 20(c) and 20(d). We denote their contributions as $\Gamma_{\rm P}^{\mu\nu}$ and $i\Pi_{\rm P}$, respectively. Then we find

$$i\Gamma_{\rm P}^{\mu\nu}(p_1,p_2) = -i\frac{\Gamma(3-D/2)}{(4\pi)^{D/2}} e g_{W^+H^-h} g_{WWh} g^{\mu\nu} \times \left(p_H^2 - m_H^2\right) \int_{x+y+z=1} \frac{1}{\left[m_W^2(1-z) + m_h^2 z - p_2^2 z(1-z) - 2p_1p_2yz)\right]^{3-D/2}}, \tag{C.13}$$

$$i\Pi_{\rm P}(p_H^2) = +\frac{\Gamma(2-D/2)}{(4\pi)^{2-D/2}} \frac{1}{2m_W} g_{W^+H^-h} g_{WWh} \left(p_H^2 - m_H^2\right) \times \int_0^1 dx \frac{1}{\left[m_W^2 x + m_h^2(1-x) - p_H^2 x(1-x)\right]^{2-D/2}}. \tag{C.14}$$

Using eq. (C.5), we find that $\Gamma_{\rm P}^{\mu\nu}$ and $i\Pi_{\rm P}$ completely cancel the second term in eq. (C.12), namely these pinch contributions really make the effective vertex correction gauge invariant.

ABSTRACT

We study general aspects of the CP-violating effects on the baryon asymmetry of the Universe (BAU) and electric dipole moments (EDMs) in models extended by an extra Higgs doublet and a singlet, together with electroweak-interacting fermions. In particular, the emphasis is on the structure of the CP-violating interactions and dependences of the BAU and EDMs on masses of the relevant particles. In a concrete mode, we investigate a relationship between the BAU and the electron EDM for a typical parameter set. As long as the BAU-related CP violation predominantly exists, the electron EDM has a strong power in probing electroweak baryogenesis. However, once a BAU-unrelated CP violation comes into play, the direct correlation between the BAU and electron EDM can be lost. Even in such a case, we point out that verifiability of the scenario still remains with the help of Higgs physics.

1. Introduction

The particle content of the standard model (SM) has been completed by the discovery of the 125 GeV Higgs boson at the Large Hadron Collider (LHC) [1]. So far, there is no clear signal beyond the SM in laboratory experiments. Nevertheless, the cosmological problems such as the origin of the baryon asymmetry of the Universe (BAU) and identification of the cold dark matter still remain unsolved within the SM.

One of the mechanisms for generating the BAU is electroweak baryogenesis (EWBG) [2,3]. In this scenario, the BAU arises during the electroweak phase transition (EWPT), and its feasibility depends on properties of models at the GeV/TeV scales. From the viewpoint of the testability, EWBG is the first scenario that is verified or falsified by the ongoing and upcoming experiments, among others. As is well known, the SM has the two drawbacks that prevent it from generating the BAU: absence of both a strong first-order EWPT [4] and a sufficient amount of CP violation [5]. Supersymmetric (SUSY) models may naturally solve those issues simultaneously. For example, in the minimal SUSY SM model (MSSM), a light scalar top (stop) could induce the strong first-order EWPT, and the fermionic superpartners provide the substantial amount of CP violation. However, it turns out that the light stop scenario in the MSSM is not consistent with the LHC Run 1 data such as the Higgs signal strengths and the direct stop searches [6]. In addition, the light stop scenario in more general framework beyond the MSSM is also found to be incompatible with the current LHC data [7]. Given this fact, the colored particles may no longer the candidates for archiving the strong first-order EWPT. Therefore, whatever a UV theory might be, the possibility of EWBG can be investigated in the framework of an effective field theory of non-colored particles after integrating out irrelevant heavy degrees of freedom, *i.e.*,

$$\text{UV theories} \supset \text{multi-Higgs} + \text{EW-interacting fermions}. \tag{1}$$

Experiments that are most sensitive to the CP violation are measurements of the electric dipole moments (EDMs) of electron, neutron and atoms etc. Clarifying relationships between the BAU-related CP violations and the EDMs are indispensable for the test of the EWBG scenario. In some analyses in the literature, the CP-violating effect is incorporated by higher dimensional operators assuming only one Higgs doublet and by which the BAU is evaluated. In such a case, the CP-violating effects peculiar to the finite temperature, such as a resonant enhancement pointed out in Ref. [8],

are missing, which drastically changes the correlation between the BAU and EDM.

In this Letter, we clarify similarities and differences between the BAU-related CP violation and the EDM-related one with particular emphasis on the structure of the interactions and the mass dependences of the relevant particles. As an illustration, we consider a framework in which the Higgs sector is augmented by an additional Higgs doublet and a singlet, and in addition, $SU(2)_L$ doublet fermions and singlet fermion are introduced to accommodate CP violation for baryogenesis. In our setup, the structure of the CP-violating interactions are more generic than those in SUSY models. We evaluate the CP-violating source term for the BAU in the closed-time-path formalism and relate it with the electron EDM. The correlation between the two CP-violating quantities is elucidated as functions of the EW-interacting fermion masses.

As a specific example, we consider a next-to-MSSM-like model and work out the relationship between the BAU and electron EDM. It is found that the electron EDM is the useful probe of the baryogenesis favored region as long as the BAU-related CP violation predominately exists in the model. However, there is a case in which a BAU-unrelated CP violation, if it exists, alters the intimate connection between the BAU and EDM, which makes it difficult to test EWBG via the electron EDM experiment only. Nevertheless, such a specific case is possible only in the case that the doublet-singlet Higgs boson mixing exists, which is needed for a tree-potential-driven strong first-order EWPT, and thus still testable in combination with Higgs physics.

2. General aspects of CP-violating effects on the BAU and EDMs

Before going to present our model, we here give a simple but rather generic argument about the relationship between the BAU-related CP violation and EDM. For illustrative purposes, we consider the framework in which two Higgs doublets and two species of EW-interacting fermions (denoted as $\psi_{i,j}$) are present. For definite, ψ_i is assumed to be Dirac fermion and ψ_j Majorana fermion. This setup applies to the bino-driven EWBG in the MSSM [9], the singlino-driven EWBG in the next-to-MSSM [10] and the Z'ino-driven EWBG in the U(1)′-MSSM [11] in proper limits. We expect that the following discussion would hold in other cases by making an appropriate translation.

Let us parameterize the relevant interactions as

$$\mathcal{L} = \frac{1}{\sqrt{2}}\bar{\psi}_i\big(c_L v_a P_L + c_R v_b P_R\big)\psi_j + \text{h.c.}, \tag{2}$$

where $v_{a,b}$ $(a,b=1,2)$ denote the Higgs vacuum expectation values (VEVs), and $c_{L,R}$ are the complex parameters. With this Lagrangian, we evaluate the source terms in the diffusion equation of ψ_i in the closed-time-path formalism [8]. The vector current of ψ_i has the form

$$\partial_\mu j^\mu_{\psi_i} = S_{\psi_i}, \tag{3}$$

where only the CP-violating source term is shown on the right-hand side. In a VEV insertion approximation [8], S_{ψ_i} to leading order is induced by the process shown in Fig. 1, which is cast into the form

$$\begin{aligned} S_{\psi_i}(X) &= \kappa_S \cdot 2m_i m_j \text{Im}(c_L c_R^*) v^2(X)\dot{\beta}(X)\mathcal{I}^f_{ji} \\ &\equiv C_{\text{BAU}}\text{Im}(c_L c_R^*), \end{aligned} \tag{4}$$

where $\kappa_S = +1$ for $(a,b)=(2,1)$, $\kappa_S=-1$ for $(a,b)=(1,2)$ and $\kappa_S=0$ for $(a,b)=(1,1),\ (2,2)$. $m_{i,j}$ are the masses of $\psi_{i,j}$, $\dot{\beta}(X)$ is the time derivative of $\beta(X)=\tan^{-1}(v_2(X)/v_1(X))$, and $\mathcal{I}^f_{ji}$ denotes a thermal function as will be given below. One can see that $S_{\psi_i}(X)$ would vanish not only for $\text{Im}(c_L c_R^*)=0$ but also the cases in which one of the following condition is fulfilled: $v(X)=0$, $\dot{\beta}(X)=0$ and $\mathcal{I}^f_{ji}=0$. Since the EWPT is of first order, the Higgs VEVs depend on a spacetime variable X, and the profiles of which can be determined by static bubble configurations at a nucleation temperature. In most cases, the shapes of $v(X)$ and $\beta(X)$ would be approximated by kink-type configurations, so the $\dot{\beta}(X)$ is proportional to a variation of $\beta(X)$ along the line connecting broken and symmetric phases. In the MSSM, $\dot{\beta}(X)$ roughly scales as $1/m_A^2$ [12], where m_A is the CP-odd Higgs boson mass, which implies that $S_{\psi_i}(X)$ in Eq. (4) would completely disappear if the Higgs sector is composed of only one Higgs doublet, as already indicated in the case of $\kappa_S=0$. From this argument, it is expected that the presence of the extra Higgs boson with a nonzero VEV may be essential for successful EWBG, regardless of the strong first-order EWPT realization. Here, it should be reminded that there is another type of the source term that is not suppressed in the large m_A limit, which may appear as a higher order correction to the approximation we have made here (see, *e.g.*, Refs. [13,14]). As long as the BAU is explained by a resonant enhancement, which is indeed the case in our analysis, such a source term would not play a central role.[1]

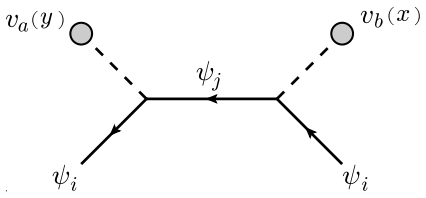

Fig. 1. A representative scattering process of ψ_i with the Higgs bubble walls, which leads to a dominant CP-violating source term for the BAU.

The behavior of the thermal function $\mathcal{I}^f_{ji}$ is somewhat complicated, and in some specific region it is strongly governed by the finite temperature physics. The explicit form of $\mathcal{I}^f_{ji}$ is [8]

$$\begin{aligned} \mathcal{I}^f_{ji} = \int_k \frac{k^2}{\omega_j\omega_i}\Big[\Big\{\big(1-2\text{Re}(n_i)\big)I_{ji} + (i\leftrightarrow j)\Big\} \\ - 2\big(\text{Im}(n_j)+\text{Im}(n_i)\big)G_{ji}\Big], \end{aligned} \tag{5}$$

where $\int_k = \int_0^\infty dk/(4\pi^2)$, $n_i = 1/(e^{(\omega_i - i\Gamma_i)/T}+1)$, $\omega_i = \sqrt{k^2+m_i^2}$, with Γ_i being the thermal widths of ψ_i. Here, I_{ij} and G_{ij} are respectively expressed by

$$I_{ij} = \Gamma_+\left[\frac{\omega_+}{(\omega_+^2+\Gamma_+^2)^2} + \frac{\omega_-}{(\omega_-^2+\Gamma_+^2)^2}\right], \tag{6}$$

$$G_{ij} = \frac{1}{2}\left[\frac{\omega_+^2-\Gamma_+^2}{(\omega_+^2+\Gamma_+^2)^2} - \frac{\omega_-^2-\Gamma_+^2}{(\omega_-^2+\Gamma_+^2)^2}\right], \tag{7}$$

where $\omega_\pm = \omega_i \pm \omega_j$ and $\Gamma_+ = \Gamma_i + \Gamma_j$. One can see that $\mathcal{I}^f_{ji}$ vanishes if $\Gamma_i = \Gamma_j = 0$. Since $\Gamma_{i,j} \simeq gT$, where g represents a typical coupling in a model and T a temperature, $S_{\psi_i}(X)$ first emerges to order of $\mathcal{O}(g^4)$ assuming $|c_L| = |c_R| \simeq g$.

[1] As nicely reviewed in Ref. [3] (see also Ref. [15]), it is known that the VEV insertion approximation is vulnerable to theoretical uncertainties and may yield an overestimated BAU compared to an all-order VEV resummation method [13,14,16]. However, it is shown in a scalar toy model that the resonance enhancement is still effective in more consistent treatment of transport equations [17]. Although a practical application to the EWBG remains open, especially for a fermion case, we expect that the VEV insertion method would give a reasonable order-of-magnitude estimate of the BAU.

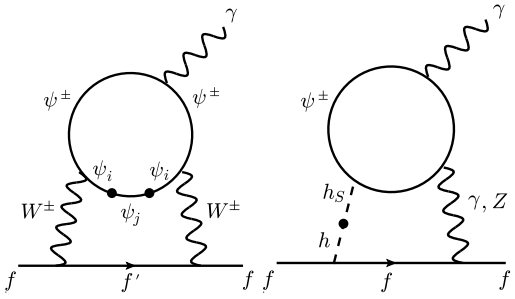

Fig. 2. Two-loop Barr–Zee diagrams induced by the BAU-related CP violation (left) and the BAU-unrelated one (right). The blobs indicate the mass insertions. Here, h and h_S are the Higgs bosons coming from the doublet and singlet, respectively. The size of the h-h_S mixing is intimately related to strength of the strong first-order EWPT in the tree potential driven scenario.

As is well known, S_{ψ_i} has a resonant enhancement at $m_i = m_j$, the behavior of which comes from G_{ij}. Since $\omega_{i,j} \gg \Gamma_{i,j}$, one may approximate G_{ij} as

$$G_{ij} \simeq -\frac{1}{2}\frac{\omega_-^2 - \Gamma_+^2}{(\omega_-^2 + \Gamma_+^2)^2} + \mathcal{O}\left(\frac{1}{\omega_+^2}\right). \tag{8}$$

One can see that G_{ij} has a peak at $\omega_- = 0$, which can yield the dominant source for the BAU.

We now study the impact of $\mathrm{Im}(c_L c_R^*)$ on the EDM. Since the new fermions have the EW charges, the following interactions exist.

$$\mathcal{L} = \frac{g_2}{\sqrt{2}}\left(\overline{\psi^+}\gamma^\mu \psi_i W_\mu^+ + \overline{\psi}_i \gamma^\mu \psi^+ W_\mu^-\right) - e\overline{\psi^+}\gamma^\mu \psi^+ A_\mu, \tag{9}$$

where $\psi^\pm$ denote electrically charged members in the $\mathrm{SU}(2)_L$ multiplet fermion. We assume that ψ_i is the neutral member of the same multiplet. In this case, the WW-mediated Barr–Zee diagram is induced, as shown in Fig. 2.[2] The EDM of a fermion f using the mass insertion method is given by

$$\begin{aligned}\frac{d_f^{WW}}{e} &= \mp\frac{\alpha_{\mathrm{em}}^2}{64\pi^2 s_W^4}\frac{m_f m_{\psi^\pm} m_j v_a v_b}{m_W^4}\mathrm{Im}(c_L c_R^*) F_{WW} \\ &\equiv C_{\mathrm{EDM}}^{WW}\,\mathrm{Im}(c_L c_R^*).\end{aligned} \tag{10}$$

where the negative (positive) sign is the case that f is up-type (down-type) fermion, $F_{WW} = (f_{WW}(r_i, r_+) - f_{WW}(r_j, r_+))/(m_i^2 - m_j^2)$ with $r_i = m_i^2/m_W^2$, $r_j = m_j^2/m_W^2$ and $r_\pm = m_{\psi^\pm}^2/m_W^2$. The explicit form of f_{WW} is given in Ref. [21]. We emphasize that unlike $S_{\psi_i}(X)$ in Eq. (4), Eq. (10) does not vanish for $(a, b) = (1, 1)$ or $(2, 2)$, in addition, d_f^{WW}/e is not enhanced at $m_i = m_j$, which are the prominent differences between the two CP-violating quantities. One may find that $d_f^{WW}/e \propto m_f m_j/m_i^3$ for $m_i \gg m_j$ and $d_f^{WW}/e \propto m_f/(m_i m_j)$ for $m_j \gg m_i$, which signifies another distinct feature of the EDM as discussed below. In what follows, we confine ourself to the cases of $(a, b) = (2, 1)$ and $(1, 2)$.

It is worth making a comment on that the mass insertion method used in Eq. (10) not only makes it easy to see the relationship between the CP-violating source term and the EDM but also gives the numerically good approximation.

[2] Here, we assume that the Higgs sector is CP conserving and extra Higgs bosons are sufficiently heavy. Under this assumption, the charged Higgs W-mediated Barr–Zee contribution induced by the same CP phase would be subdominant and the following discussion would not be altered drastically. The case without this assumption will be given in [18]. For a discussion of the EDMs in the CP-violating MSSM and 2HDM, see, *e.g.*, Refs. [19,20].

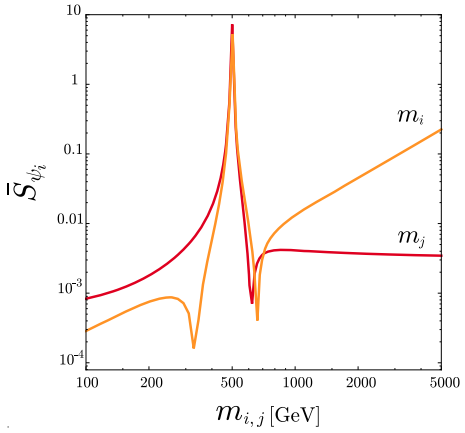

Fig. 3. $\bar{S}_{\psi_i}$ as a function of m_i with a fixed m_j and the other away around. We set $\tan\beta = 1$ and the fixed mass is 500 GeV.

Eliminating $\mathrm{Im}(c_L c_R^*)$ in Eq. (4) using Eq. (10), one finds

$$S_{\psi_i} = \frac{C_{\mathrm{BAU}}}{C_{\mathrm{EDM}}^{WW}}\left(\frac{d_f^{WW}}{e}\right). \tag{11}$$

In order to see the correlation between S_{ψ_i} and d_f^{WW}/e in more detail, we define

$$\bar{S}_{\psi_i} = \frac{C_{\mathrm{BAU}}}{v^2(X)\dot{\beta}(X) C_{\mathrm{EDM}}^{WW}} \cdot \left(\frac{d_f^{WW}}{e}\right)_{\mathrm{EXP}}. \tag{12}$$

In what follows, we consider the electron EDM as the experimental constraint, *i.e.*, $|d_e^{\mathrm{exp}}| = 8.7 \times 10^{-29}\ e \cdot \mathrm{cm}$ [22]. Here, we get rid of $v^2(X)\dot{\beta}(x)$ in C_{BAU} since it is rather model dependent.

In Fig. 3, $\bar{S}_{\psi_i}$ is plotted as a function of m_i with a fixed m_j or the other away around. As an example, we take $\tan\beta = 1$, and the fixed mass is set to 500 GeV. As explained above C_{BAU} has a peak at $m_i = m_j$. However, the decoupling behaviors in the large mass limits are substantially different from each other. For the varying m_j case, $\bar{S}_{\psi_i}$ becomes more or less flat in the large mass region while it grows for the varying m_i case. The latter is due to the rapid suppression of C_{EDM}^{WW} that scales as m_j/m_i^3 as mentioned above. Note that $\mathrm{Im}(c_L c_R^*) \gtrsim 1$ for $m_i \gtrsim 1$ TeV since d_f^{WW}/e is fixed.

Now we move on to discuss a possibility that the aforementioned correlation between the CP-violating source term and the EDM is spoiled by contamination of BAU-unrelated CP violation. As delineated below, such a situation can arise when we address the issue of the strong first-order EWPT.

The SM Higgs sector has to be extended in such a way that the EWPT is of first order. There are two representative cases for achieving this:

- Thermal loop driven case
- Tree potential driven case

For example, the former corresponds to the SM, MSSM and a two Higgs doublet model (2HDM) and so on. In such cases, the cubic-like terms arising from the bosonic thermal loops play an essential role in inducing the first-order EWPT. In the latter case, on the other hand, a specific structure of a tree-level Higgs potential is the dominant source for generating a barrier separating the two degenerate minima at a critical temperature. One of such an example is the EWPT in the SM with a real singlet Higgs boson (rSM) [23,24]. In this case, nonzero doublet-singlet Higgs mixing

terms are responsible for the strong first-order EWPT.[3] Once the singlet Higgs field (S) exists, it is conceivable that the following interactions may give rise to an extra source for CP violation.

$$\mathcal{L} = \overline{\psi^+}(g^S + i\gamma_5 g^P)\psi^+ S. \tag{13}$$

If the doublet-singlet Higgs mixing is present, the Higgs-photon(Z)-mediated Barr–Zee diagrams could be generated, as depicted in Fig. 2. In this case, the EDM is the sum of those diagrams, in addition to d_f^{WW}.

$$\frac{d_f}{e} = \frac{d_f^{WW}}{e} + \frac{d_f^{H\gamma}}{e} + \frac{d_f^{HZ}}{e}. \tag{14}$$

As far as EWBG is concerned, the new CP-violating phase appearing in Eq. (13) is not directly related to baryogenesis. Therefore, the linear correlation between the CP-violating source term and the EDM in Eq. (11) no longer hold. One of the interesting possibilities is that if a cancellation among those contributions becomes effective, it is possible for d_f to be made highly suppressed but with the nonzero d_f^{WW}, so the BAU-related CP violation is not constrained by a single EDM experiment in this case.

Nevertheless, one may probe such a parameter space with Higgs physics since the nonzero doublet-singlet Higgs mixing parameter and $g^{S,P}$ would lead to some deviations in the Higgs signal strengths. We will explicitly demonstrate this possibility in the next section.

So far, we have exclusively focused on the relationship between the CP-violating source term and the EDM. Here, we comment on the dependence of $\mathrm{Im}(c_L c_R^*)$ on the baryon number density (n_B) briefly. Under some mild assumptions, one may have

$$n_B = \kappa_B \frac{S_{\mathrm{CPV}}}{\sqrt{\Gamma_{\mathrm{CPC}}}}, \tag{15}$$

where κ_B is a coefficient. S_{CPV} is a CP-violating term arising from S_{ψ_i} discussed above and Γ_{CPC} a CP-conserving particle changing rate. For the latter, for example, the interactions in Eq. (2) induce

$$\Gamma_{\psi_i}(X) = \frac{1}{T}\Big[\big(|c_L|^2 v_a^2(X) + |c_R|^2 v_b^2(X)\big)\mathcal{F}_{ji} + 2\mathrm{Re}\big(c_L c_R^*\big) v_1(X) v_2(X) m_i m_j \mathcal{R}_{ji}\Big], \tag{16}$$

where $\mathcal{F}_{ji}$ and $\mathcal{R}_{ji}$ are the thermal functions presented in Ref. [11]. As studied in Ref. [27], Γ_{ψ_i} also has the resonant behavior at $m_i = m_j$, rendering n_B smaller. It should be emphasized that a cancellation between the first and second terms in Γ_{ψ_i} can happen depending on the choice of $\mathrm{Arg}(c_L c_R^*)$ and $m_{i,j}$. Therefore, n_B does not necessarily take its maximal value at $\mathrm{Arg}(c_L c_R^*) = \pi/2$ or $-\pi/2$, which may relax the EDM constraint to some extent.

3. A model

Now, we define our model and give basic ingredients for calculating the BAU and the electron EDM (previous studies along the same line can be found in Refs. [15,28]). The particle content of the Higgs and the new EW-interacting fermion sectors in the model is shown in Table 1. The total Lagrangian is given by

$$\mathcal{L} = \mathcal{L}_{\mathrm{2HDM}} + \frac{1}{2}\partial_\mu S \partial^\mu S - V_S - V_{\Phi S} + \mathcal{L}_{\tilde{\Phi}\tilde{S}},$$

[3] In singlet-extended models, there could be a nontrivial minimum on the singlet field axis induced by another phase transition prior to the EWPT. In contrast to this, the EWPT could occur by multi-steps which was first discussed in the 2HDM [25]. For a recent study on the multi-step EWPT, see, *e.g.*, Refs. [15,26].

Table 1
Particle content of the Higgs and the new EW-interacting fermion sectors.

Particles	$SU(3)_C \times SU(2)_L \times U(1)_Y$	Z_2
Φ_1	$(\mathbf{1},\ \mathbf{2},\ 1/2)$	$-$
Φ_2	$(\mathbf{1},\ \mathbf{2},\ 1/2)$	$+$
S	$(\mathbf{1},\ \mathbf{1},\ 0)$	$-$
$\tilde{\Phi}_1$	$(\mathbf{1},\ \mathbf{2},\ -1/2)$	$-$
$\tilde{\Phi}_2$	$(\mathbf{1},\ \mathbf{2},\ 1/2)$	$+$
$\tilde{S}^0$	$(\mathbf{1},\ \mathbf{1},\ 0)$	$-$

$$\begin{aligned}\mathcal{L}_{\tilde{\Phi}\tilde{S}} = &\sum_{i=1,2} \overline{\tilde{\Phi}_i} i\bar{\sigma}^\mu D_\mu \tilde{\Phi}_i + \overline{\tilde{S}^0} i\bar{\sigma}^\mu \partial_\mu \tilde{S}^0 \\ &- \epsilon_{ab}\Bigg[\sum_{j=1,2}\Big(\tilde{\Phi}_1^a c_{1j}\Phi_j^b + \tilde{\Phi}_2^a c_{2j}(i\tau^2\Phi_j^{b*})\Big)\tilde{S}^0 \\ &\qquad + (\mu + \lambda S)\tilde{\Phi}_1^a \tilde{\Phi}_2^b + \mathrm{h.c.}\Bigg] \\ &+ \frac{1}{2}(\mu_{\tilde{S}} + \kappa S)\tilde{S}^0\tilde{S}^0 + \mathrm{h.c.},\end{aligned} \tag{17}$$

where $\tilde{\Phi}_{1,2}$ and $\tilde{S}^0$ are the two-component spinors, and $\epsilon_{12} = -\epsilon_{21} = +1$. As is the case in the MSSM, to avoid a lepton flavor violation, we impose a matter parity under which new EW-interacting fermions are odd and the SM fermions are even. Furthermore, as in the ordinary 2HDM, another Z_2 symmetry ($\Phi_1 \to -\Phi_1$ and $\Phi_2 \to \Phi_2$) is enforced to evade tree-level Higgs-mediated flavor-changing-neutral current processes. Depending on Z_2 charge assignments for the fermions, four types of the Yukawa interactions are possible. However, the following analysis does not depend on those types since the top Yukawa coupling is the only relevant that is common to all the types.

The Higgs fields are parametrized as

$$\Phi_{i=1,2}(x) = \begin{pmatrix}\phi_i^+ \\ \phi_i^0\end{pmatrix} = \begin{pmatrix}\phi_i^+ \\ \frac{1}{\sqrt{2}}(v_i + h_i(x) + i a_i(x))\end{pmatrix}, \tag{18}$$

$$S(x) = v_S + h_S(x), \tag{19}$$

where $v_1 = v\cos\beta$, $v_2 = v\sin\beta$ with $v = 246$ GeV.

In the following, we consider a CP-conserving Higgs sector and take a rSM-like limit in which $\sin(\beta-\alpha) = 1$, where α denotes a mixing angle between two CP-even Higgs bosons ($h_{1,2}$). In this case, only one state (defined as h) has the VEV and gives the masses of the gauge bosons and fermions. Since the strong first-order EWPT is assumed to be driven by the tree-Higgs potential, the heavy Higgs bosons do not necessarily have the so-called non-decoupling effect which is needed in the thermal loop driven strong first-order EWPT case [29] (for a recent work, see, *e.g.*, Ref. [30]). The detailed comparison between the two cases will be given elsewhere [18].

Since we have the singlet Higgs boson in this model, h mixes with h_S through a mixing γ as

$$\begin{pmatrix}h \\ h_S\end{pmatrix} = \begin{pmatrix}c_\gamma & -s_\gamma \\ s_\gamma & c_\gamma\end{pmatrix}\begin{pmatrix}H_1 \\ H_2\end{pmatrix}. \tag{20}$$

In our scenario, H_1 is the SM-like Higgs boson whose mass is 125 GeV, and H_2 is the singlet-like Higgs boson which is assumed to be heavier than H_1. Another CP-even Higgs boson originated from the Higgs doublet is denoted as H_3 which is heavier than H_2.

In response to Z_2 charges assignments of $\tilde{\Phi}_{1,2}$ and $\tilde{S}$, there are several types of the interactions among the new EW-interacting fermions and Higgs bosons [18]. Here, we focus on one of them as an example. The Z_2 charge assignment is listed in Table 1.

The relevant interactions among the EW-interacting fermions and Higgs bosons are

$$\mathcal{L}^{\rm int}_{\tilde{\Phi}\tilde{S}} \ni -\sum_{i=1,2} H_i \overline{\tilde{H}^+}\left(g^S_{H_i\tilde{H}\tilde{H}} + i\gamma_5 g^P_{H_i\tilde{H}\tilde{H}}\right)\tilde{H}^+ + \left[\overline{\tilde{H}^0}\left(c_L^{\tilde{H}^0\tilde{S}}\phi_2^0 P_L + c_R^{\tilde{H}^0\tilde{S}}\phi_1^0 P_R\right)\tilde{S} + \text{h.c.}\right], \tag{21}$$

where the fermions are expressed in terms of the four-component spinors. Each coupling is respectively given by

$$g^S_{H_1\tilde{H}\tilde{H}} = |\lambda|\cos\phi_{\lambda\tilde{H}} s_\gamma, \quad g^P_{H_1\tilde{H}\tilde{H}} = -|\lambda|\sin\phi_{\lambda\tilde{H}} s_\gamma, \tag{22}$$

$$g^S_{H_2\tilde{H}\tilde{H}} = |\lambda|\cos\phi_{\lambda\tilde{H}} c_\gamma, \quad g^P_{H_2\tilde{H}\tilde{H}} = -|\lambda|\sin\phi_{\lambda\tilde{H}} c_\gamma, \tag{23}$$

$$c_L^{\tilde{H}^0\tilde{S}} = -c_{12}e^{-i\phi_{\tilde{S}}/2}, \quad c_R^{\tilde{H}^0\tilde{S}} = c_{21}^* e^{i(\phi_{\tilde{H}}+\phi_{\tilde{S}}/2)}, \tag{24}$$

where we have defined $\lambda = |\lambda|e^{i\phi_\lambda}$, $\mu + \lambda v_S = |\mu + \lambda v_S|e^{i\phi_{\tilde{H}}}$, $\mu_{\tilde{S}} = |\mu_{\tilde{S}}|e^{i\phi_{\tilde{S}}}$ and $\phi_{\lambda\tilde{H}} = \phi_\lambda - \phi_{\tilde{H}}$. As discussed in the previous section, the interactions in the second line of Eq. (21) plays an essential role in generating the CP-violating term that fuels the BAU. For notational simplicity, we define $\phi = -(\phi_{\tilde{H}} + \phi_{\tilde{S}})$ hereafter.

4. Numerical analysis

Following a calculation method formulated and developed in Refs. [8,27,31], we estimate n_B by

$$n_B = \frac{-3\Gamma_B^{(s)}}{2D_q\lambda_+}\int_{-\infty}^{0} dz' n_L(z') e^{-\lambda_- z'}, \tag{25}$$

where $\lambda_\pm = \left[v_w \pm \sqrt{v_w^2 + 4\mathcal{R}D_q}\right]/(2D_q)$, $\Gamma_B^{(s)}$ is a baryon number changing rate in the symmetric phase, v_w is a velocity of the bubble wall, D_q is a diffusion constant of the quarks, and $\mathcal{R}$ is a relaxation term, which is $(15/4)\Gamma_B^{(s)}$ in our model. n_L is the total number density of all the left-handed quarks and leptons [27,31,32]. We follow the estimation of n_L performed in [27].

Since the EWPT is reduced to that in the rSM, we adopt S2 scenario investigated in Ref. [24] as a benchmark in which $m_{H_2} = 170$ GeV, $\cos\gamma \simeq 0.94$ and $v_C/T_C = 206.75\,\text{GeV}/111.76\,\text{GeV}$. In addition, we take $\tan\beta = 1$, $v_w = 0.4$, $\Gamma_{\tilde{H}} = 0.025T$, $\Gamma_{\tilde{S}} = 0.003T$, and use an approximation, $\dot{\beta} = v_w\Delta\beta/L_w$ taking $\Delta\beta = 0.015$. Under this assumption, n_B does not depend on L_w. Moreover, the constant VEV but $v_C/2$ is used in calculating n_B, which may give a simple approximation of kink-type VEV [18]. For the heavy Higgs boson masses, we set 400 GeV, and for a softly Z_2 broken mass, which is a mixing mass between Φ_1 and Φ_2, 250 GeV is taken. For the other parameters, we refer to the values adopted in Ref. [11]. In the following, the electron EDM is calculated in the mass eigenbasis of the neutral fermions rather than the mass insertion method, although the both are not much numerically different.

We first present the case where the electron EDM is induced by only the WW-mediated Barr–Zee diagram. In Fig. 4, contours of $Y_B/Y_B^{\rm obs}$ and $|d_e|$ are shown in the $(m_{\tilde{H}}, m_{\tilde{S}})$ plane. We take $|c_L^{\tilde{H}^0\tilde{S}}| = |c_R^{\tilde{H}^0\tilde{S}}| = 0.42$, $\phi = 225^\circ$ and $|\lambda| = 0$. Here, ϕ is chosen in such a way that the cancellation in $\Gamma_{\rm CPC}$ is effective. In this figure, the orange region is excluded by the current experimental limit of the electron EDM, $|d_e^{\rm exp}| < 8.7\times10^{-29}\ e\cdot\text{cm}$, and the dashed line corresponds to $|d_e| = 1.0\times10^{-29}\ e\cdot\text{cm}$ which is reachable by the future experiments [33]. The black solid (dashed) line indicates $Y_B/Y_B^{\rm obs} = 1$ (0.1). One can see that $|d_e|$ gets rapidly suppressed as $m_{\tilde{H}}$ increases but does not in the large $m_{\tilde{S}}$ case, as discussed in Sec. 2. Furthermore, the BAU is sufficiently generated if $m_{\tilde{H}} \simeq m_{\tilde{S}}$

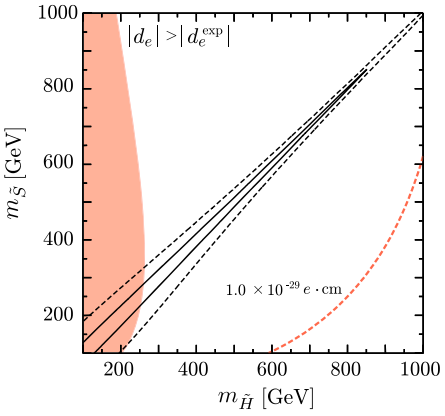

Fig. 4. The contours of $Y_B/Y_B^{\rm obs}$ and $|d_e|$ in the $(m_{\tilde{H}}, m_{\tilde{S}})$ plane. The region colored in orange is excluded by the current experimental limit of the electron EDM, and the orange dashed line corresponds to $|d_e| = 1.0\times10^{-29}\ e\cdot\text{cm}$. The black solid and dashed lines represent $Y_B/Y_B^{\rm obs} = 1$ and 0.1, respectively. We set $|c_L^{\tilde{H}^0\tilde{S}}| = |c_R^{\tilde{H}^0\tilde{S}}| = 0.42$ and $\phi = 225^\circ$. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

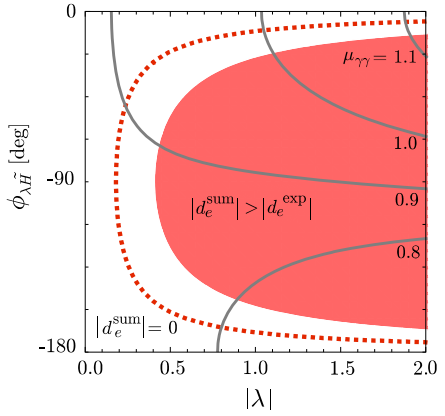

Fig. 5. Impact of BAU-unrelated CP violation on $|d_e|$. The region colored in red is excluded by the current experimental limit of the electron EDM, and the red dashed line corresponds to $|d_e^{\rm sum}| = |d_e^{WW} + d_e^{H\gamma}| = 0$. The gray lines represent $\mu_{\gamma\gamma} =$ 1.1, 1.0, 0.9 and 0.8 from top to bottom. The input parameters are the same as in Fig. 4, but with $m_{\tilde{H}} = 300$ GeV and $m_{\tilde{S}} = 277$ GeV, which gives $Y_B/Y_B^{\rm obs} = 1$. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

due to the resonant effect. Our result shows that the successful EWBG region would be entirely verified by the future experiments of the electron EDM even if the BAU calculated here is underestimated by a factor of 10 or even more due to lack of precise knowledge of the bubble profiles etc.

Next, we consider the case in which the BAU-unrelated CP-violating phase $\phi_{\lambda\tilde{H}}$ comes into play. Fig. 5 shows the electron EDM in the $(|\lambda|, \phi_{\lambda\tilde{H}})$ plane. In this figure, we take the same input parameters as in Fig. 4, but with $m_{\tilde{H}} = 300$ GeV and $m_{\tilde{S}} = 277$ GeV, which yields $Y_B/Y_B^{\rm obs} = 1$. Here, we define $d_e^{\rm sum} = d_e^{WW} + d_e^{H\gamma}$. Note that d_e^{HZ} is accidentally suppressed with a factor of $(1/4 - \sin^2\theta_W) \simeq 0.02$ and thus numerically unimportant. While the red region is excluded by the current limit of the electron EDM, the dashed line indicates the exquisite cancellation between d_e^{WW} and $d_e^{H\gamma}$, resulting in $d_e^{\rm sum} = 0$.

In such a case, it is worth while to consider the other EDMs which might be complementary. The naive estimates show that $d_u \sim -1/3(m_u/m_e)d_e^{WW}$ and $d_d \sim 2/3(m_d/m_e)d_e^{WW}$ under the condition of $d_e^{\rm sum} = 0$, which lead to $d_n \sim d_p \sim \mathcal{O}(1)\times10^{-28}\ e\cdot\text{cm}$. Although the current experimental bounds of d_n and d_p are not

strong enough to probe this parameter region, the future experiments might be accessible. For example, it is expected that $|d_n| < 3 \times 10^{-28}$ $e \cdot$cm at the Spallation Neutron Source [34] and $|d_n| < 1 \times 10^{-28}$ $e \cdot$cm at TRIUMF [34], and the future experimental sensitivity of d_p would be 10^{-29} $e \cdot$cm at Brookhaven National Laboratory [35]. Since it seems impossible to have the sufficient BAU with more suppressed d_n and d_p than such experimental sensitivities, the EWBG-viable region in this model would be fully tested. Detailed analysis with extensive numerical work will be conducted in Ref. [18].

Since $d_e^{H\gamma}$ is correlated with the signal strength of the Higgs decay to two gammas (denoted by $\mu_{\gamma\gamma}$, for the explicit formula, see, *e.g.,* Ref. [36]), we also examine it. $\mu_{\gamma\gamma}$ is represented by the gray lines: $\mu_{\gamma\gamma} = 1.1,\ 1.0,\ 0.9,$ and 0.8 from top to bottom. The whole region is still within the 2σ region of the current LHC data, $\mu_{\gamma\gamma} = 1.17 \pm 0.27$ (ATLAS) and $\mu_{\gamma\gamma} = 1.14^{+0.26}_{-0.23}$ (CMS). We remark that the sensitivity of $\mu_{\gamma\gamma}$ is expected to be improved up to $\mathcal{O}(5)$%, and Higgs coupling to the gauge bosons ($\cos\gamma$ in the current setup) up to $\mathcal{O}(0.1)$% at future colliders such as the high-luminosity LHC (HL-LHC) [37], International Linear Collider (ILC) [38] and TLEP [39]. Therefore, the testability of EWBG in this scenario still persists.

Before closing this section, we briefly mention about the differences between our results and those in Refs. [15,28]. In Ref. [28], $d_e^{WW} = 0$ if the two vector-like fermion masses are degenerate, and the dominant contribution in d_e may come from the $d_e^{H\gamma}$-type Barr–Zee diagram. As pointed out in [28,40], this contribution could be canceled by the singlet Higgs boson if exists. This cancellation mechanism is in stark contrast to our case in which $d_e^{H\gamma} \simeq -d_e^{WW} \neq 0$. In Ref. [15], on the other hand, one may obtain $d_e (\simeq d_e^{H\gamma}) = 0$ without relying on any cancellation mechanism while maintaining the BAU, which differs from our case as well. Correspondingly, $\mu_{\gamma\gamma}$ in the most EWBG-viable region in each model can be different.

5. Conclusions

We have studied the relationship between the CP-violating source term for the BAU and the EDMs in the framework where the extra Higgs doublet and the singlet as well as the new EW-interacting fermions ($\psi_{i,j}$) are introduced. We scrutinized the ratio $\bar{S}_{\psi_i}$ (defined by Eq. (12)) as functions of the EW-interacting fermion masses. In the region where new fermions are degenerate, $\bar{S}_{\psi_i}$ is resonantly enhanced due to the thermal effect appearing in the source term. In the large mass limits of the fermions, on the other hand, $\bar{S}_{\psi_i}$ gets milder or larger depending on the fermion species, and the behaviors of which are mostly governed by the property of the loop function of the EDM rather than that of the CP-violating source term for the BAU.

As a concrete example, we considered the next-to-MSSM-like model and investigated the correlation between the BAU and the electron EDM for a typical parameter set. It is found that as long as the BAU-related CP violation predominantly exists, the current electron EDM places some constraints on the EWBG-favored region, and more importantly, it would probe the whole region if it is improved up to 1.0×10^{-29} $e \cdot$cm. However, once the BAU-unrelated CP violation comes into action, the strong connection between the BAU and electron EDM is not guaranteed any more, which makes it challenging to probe the parameter space with the electron EDM only. Nevertheless, even in such a case, the scenario could be probed with the aid of Higgs physics.
