

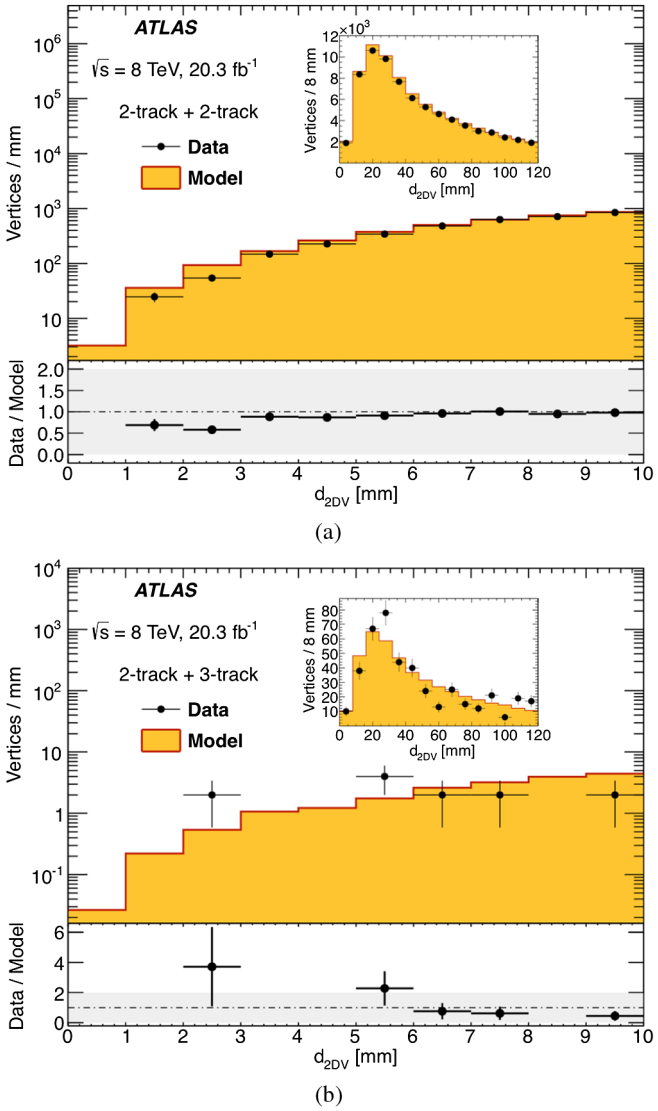

FIG. 7 (color online). The distribution of the distance d_{2DV} between (a) two 2-track vertices and (b) a 2-track vertex and a 3-track vertex with a combined mass above 10 GeV for the jets + E_T^{miss} stream data (data points) and in the model sample, in which the two vertices are in different events (histogram). A conservative 100% uncertainty on the model is shown in the data/model ratio plot. The inset shows the d_{2DV} distance up to values of 120 mm. The merged-vertex background estimate is determined from the area under the model distribution in the range $d_{2DV} < 1$ mm in (b).

B. Dilepton-vertex background estimation

Background DVs in the dilepton search may arise from two sources:

(i) The dominant background is due to accidental spatial crossings of unrelated lepton candidates that happen to come close enough to satisfy the vertex-reconstruction criteria.

(ii) Minor backgrounds, due to tracks originating from the PV wrongly associated with a DV, decays of SM long-lived particles, or cosmic-ray muons. The levels of background from these sources are determined to be negligible relative to the accidental-crossing background.

1. Background from accidental lepton crossing

The level of the accidental-crossing background is estimated by determining the crossing probability, defined as the probability for two unrelated lepton-candidate tracks to be spatially nearby and reconstructed as a vertex. Pairs of opposite-charge lepton candidates are formed, where each lepton candidate in a pair is from a different event and satisfies the lepton-selection criteria. The momentum vector of one of the two lepton candidates, selected at random, is rotated through all azimuthal angles by a step $\delta\phi$. At each rotation step, the two lepton candidates are subjected to a vertex fit and the DV selection criteria. If the pair satisfies the selection criteria, it is assigned a weighted probability $\delta\phi/2\pi$. Averaging the weighted probabilities over all pairs

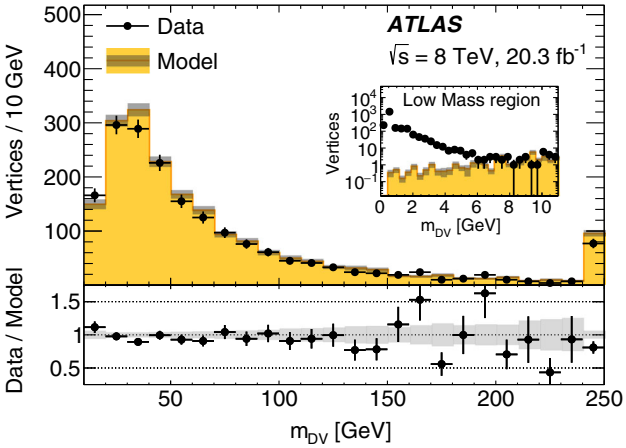

TABLE II. Estimated numbers of background vertices satisfying all of the dilepton signal selection criteria, arising from random combinations of lepton candidates. In each entry, the first uncertainty is statistical, and the second is systematic (see Sec. VII).

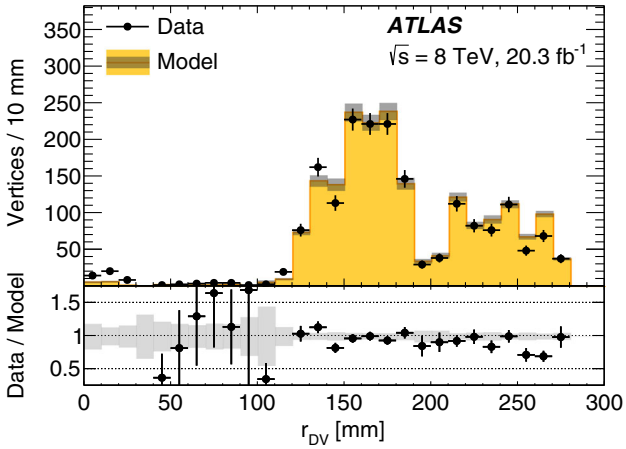
Channel	No. of background vertices ($\times 10^{-3}$)
e^+e^-	$1.0 \pm 0.2^{+0.3}_{-0.6}$
$e^\pm\mu^\mp$	$2.4 \pm 0.9^{+0.8}_{-1.5}$
$\mu^+\mu^-$	$2.0 \pm 0.5^{+0.3}_{-1.4}$



gives the probability for a lepton-candidate pair to accidentally form a vertex. The probability is observed to be independent of $\delta\phi$ for $\delta\phi < 0.03$. To obtain the final background estimate, this probability is multiplied by the number $N_{\ell\ell}$ of data events containing two opposite-charge lepton candidates that satisfy the lepton-selection criteria. This procedure yields the background predictions shown in Table II. Compared with these predictions, the background level for a 3-track vertex, where at least two of the tracks are lepton candidates, is negligible.

The validity of this method for estimating the number of dilepton DVs, including the assumption that the tracks are uncorrelated, is verified in several ways. Using $Z \to \mu^+\mu^-$ and $t\bar{t}$ MC samples, the procedure is applied to vertices formed from two lepton candidates, a lepton candidate and another track, or two tracks that are not required to be lepton candidates. It is observed that the method correctly predicts the accidental-crossing background to within about 10%. The background-estimation method is tested also on pairs of tracks in the data, excluding pairs of lepton candidates, with a variety of selection criteria. The predicted and observed numbers of background vertices are again found to agree to within 10% for all selection criteria. The method also reproduces well the distributions of $m_{\rm DV}$, $r_{\rm DV}$, $z_{\rm DV}$, $\hat{d}\cdot\hat{p}$, and the azimuthal angle between the two lepton candidates, in both MC simulation and data. As an example, Fig. 8 shows the $m_{\rm DV}$ and $r_{\rm DV}$ distributions observed for data vertices composed of two nonlepton tracks and the distributions predicted by pairing two tracks in different events. Some differences between the model and the data are seen at certain radii (e.g., $r_{\rm DV} < 50$ mm and $250 < r_{\rm DV} < 270$ mm), but these do not substantially affect the total number of DVs and are covered by the assigned systematic uncertainty (see Sec. VII A 2). The prediction is accurate down to DV masses of 6 GeV, well below the DV selection criterion of 10 GeV. At smaller masses, contributions from other background sources become significant.

This background-estimation method ignores the possibility of angular correlations between the leptons forming a background vertex. The associated systematic uncertainty is described in Sec. VII A 2.

(a)

(b)

FIG. 8 (color online). Distributions of the (a) vertex mass and (b) vertex position radius for vertices composed of two nonlepton tracks in the data sample (data points), and the predicted model distribution obtained from vertices formed by combining tracks from two different data events (shaded histograms). The ratio of the data to the model distributions is shown below each plot. The gray bands indicate the statistical uncertainties for the predicted distributions. The inset shows the mass distribution in the low-mass region, elsewhere $m_{\rm DV} > 10$ GeV is required. In (a), the highest bin shows the histogram overflow.

2. Minor backgrounds

Backgrounds from the following sources are found to be negligible relative to the accidental-crossing background, and are therefore neglected.

A potential source of background is prompt production of hard lepton pairs, notably from $Z \to \ell^+\ell^-$ decays. Requiring $\Delta_{xy} < 4$ mm and removing the $m_{\rm DV} > 10$ GeV requirement yields no dilepton-vertex candidates, so the data show no evidence for prompt background. Therefore, MC simulation is used to estimate the probability for leptons originating from $Z \to \ell^+\ell^-$ decays to satisfy the minimum-d_0 requirements, the probability for such leptons to satisfy the vertex requirements, and the

probability for a $Z \to \ell^+\ell^-$ event to pass the analysis kinematic requirements. Multiplying the product of these probabilities by the number of $Z \to \ell^+\ell^-$ events produced at ATLAS yields an estimate of 10^{-5} $Z \to \mu^+\mu^-$ events and 10^{-4} $Z \to e^+e^-$ events in the $\Delta_{xy} < 4$ mm sideband. Thus, the background from this source is negligible.

Background from cosmic-ray muons is studied with the ΔR_{cosmic} distribution of the two highest-p_{T} muon candidates in each event, which satisfy the selection criteria except the $\Delta R_{\text{cosmic}} > 0.04$ requirement. The distribution drops rapidly as ΔR_{cosmic} increases, with the highest pair having $\Delta R_{\text{cosmic}} = 0.014$. The pairs that also satisfy the DV selection criteria constitute less than 7% of this sample and have a similar ΔR_{cosmic} distribution, terminating at $\Delta R_{\text{cosmic}} \sim 0.0045$. Therefore, it is concluded that the rate for cosmic-ray background muons satisfying the $\Delta R_{\text{cosmic}} > 0.04$ requirement is several orders of magnitude below the accidental-crossing background. In the case of a partially reconstructed cosmic-ray muon crossing a reconstructed lepton candidate from a pp collision, the two tracks are uncorrelated and any contribution to the background is already accounted for in the results shown in Table II.

Background from decays of known long-lived hadrons is studied from vertices in which only one track is required to be a lepton candidate. It is found to be negligible, due to the small probability for a hadron to be misidentified as a lepton candidate and the mass resolution of the detector.

VII. SYSTEMATIC UNCERTAINTIES AND CORRECTIONS

The dominant systematic uncertainties are those associated with the efficiency for reconstructing displaced electrons and with the jet and $E_{\text{T}}^{\text{miss}}$ selection criteria. Since the background level is low, uncertainties on the background estimation have a minor effect on the results of the analysis. The methods for evaluation of the systematic uncertainties are described in detail below.

A. Background-estimation uncertainties

1. Multitrack DV background uncertainties

The choice of the $m_{\text{DV}} > 10$ GeV mass range for determining the scale factor f (see Sec. VI A 1), as well as differences between the m_{DV} distribution of the vertices and that of the model, are a source of systematic uncertainty on the background prediction. To estimate this uncertainty, f is obtained in the modified mass ranges $m_{\text{DV}} > 5$ GeV and $m_{\text{DV}} > 15$ GeV. The resulting 10% change in the background prediction for DVs passing the final selection requirements is used as a systematic uncertainty. An additional uncertainty of 10% is estimated from the variation of F^{stream} as the selection criteria are varied (see Sec. VI A 1). Compared with these uncertainties, the uncertainty on the much smaller merged-vertex background level is negligible.

2. Dilepton background uncertainties

The background-estimation procedure for the dilepton search (see Sec. VI B 1) normalizes the background to the number $N_{\ell\ell}$ of events containing two lepton candidates that could give rise to a DV that satisfies the selection criteria. Contrary to the underlying assumption of the background estimation, the two lepton candidates may be correlated, impacting their probability for forming a high-m_{DV} vertex. To study the impact of such correlation, $N_{\ell\ell}$ is recalculated twice, placing requirements on the azimuthal angle between the two lepton candidates, $\Delta\phi_{\ell\ell}$, of $0.5 < \Delta\phi_{\ell\ell} < \pi$ and $0 < \Delta\phi_{\ell\ell} < \pi - 0.5$. The resulting variation yields the relative uncertainty estimates on $N_{\ell\ell}$ of $^{+0\%}_{-54\%}$, $^{+19\%}_{-49\%}$, and $^{+13\%}_{-50\%}$ for the $\mu^+\mu^-$, $e^\pm\mu^\mp$, and e^+e^- channels, respectively.

An uncertainty of 15% on the background prediction is estimated from the validation studies performed using MC simulation and data, described in Sec. VI B 1. The resulting systematic uncertainties are shown in Table II.

B. Signal-efficiency uncertainties and corrections

1. Trigger efficiency

The muon trigger efficiency is studied with a "tag-and-probe" method, in which the invariant-mass distribution of pairs of tracks is fitted to the sum of a $Z \to \mu^+\mu^-$ peak and a background contribution. To reduce the background, one of the muon candidates (the "tag") is required to be identified as a muon. The muon-trigger efficiency is determined from the fraction of $Z \to \mu^+\mu^-$ decays in which the other muon candidate (the "probe") satisfies the trigger criteria. Based on the results of this study in data and MC simulation, a correction of $\Delta\epsilon = -2.5\%$ is applied to the MC-predicted trigger efficiency. A total uncertainty of $\sigma_\epsilon = 1.7\%$ is estimated by comparing the trigger efficiency as a function of the muon candidate p_{T} in data and MC simulation, and by comparing the results of the tag-and-probe method, applied to Drell-Yan MC, with MC generator-level information. Similar studies of the trigger selections used for the electron channels lead to $\Delta\epsilon = -1.5\%$ and $\sigma_\epsilon = 0.8\%$ for the $p_{\text{T}} > 120$ GeV photon trigger, and $\Delta\epsilon = -0.5\%$, $\sigma_\epsilon = 2.1\%$ for the two-photon $p_{\text{T}} > 40$ GeV trigger. The jets and $E_{\text{T}}^{\text{miss}}$ triggers are fully efficient after the off-line cuts.

2. Off-line track-reconstruction efficiency

The uncertainty associated with the reconstruction efficiency for tracks that originate far from the IP is estimated by comparing the decay radius distributions for K_S^0 mesons in data and MC simulation. The comparison is carried out with the ratio

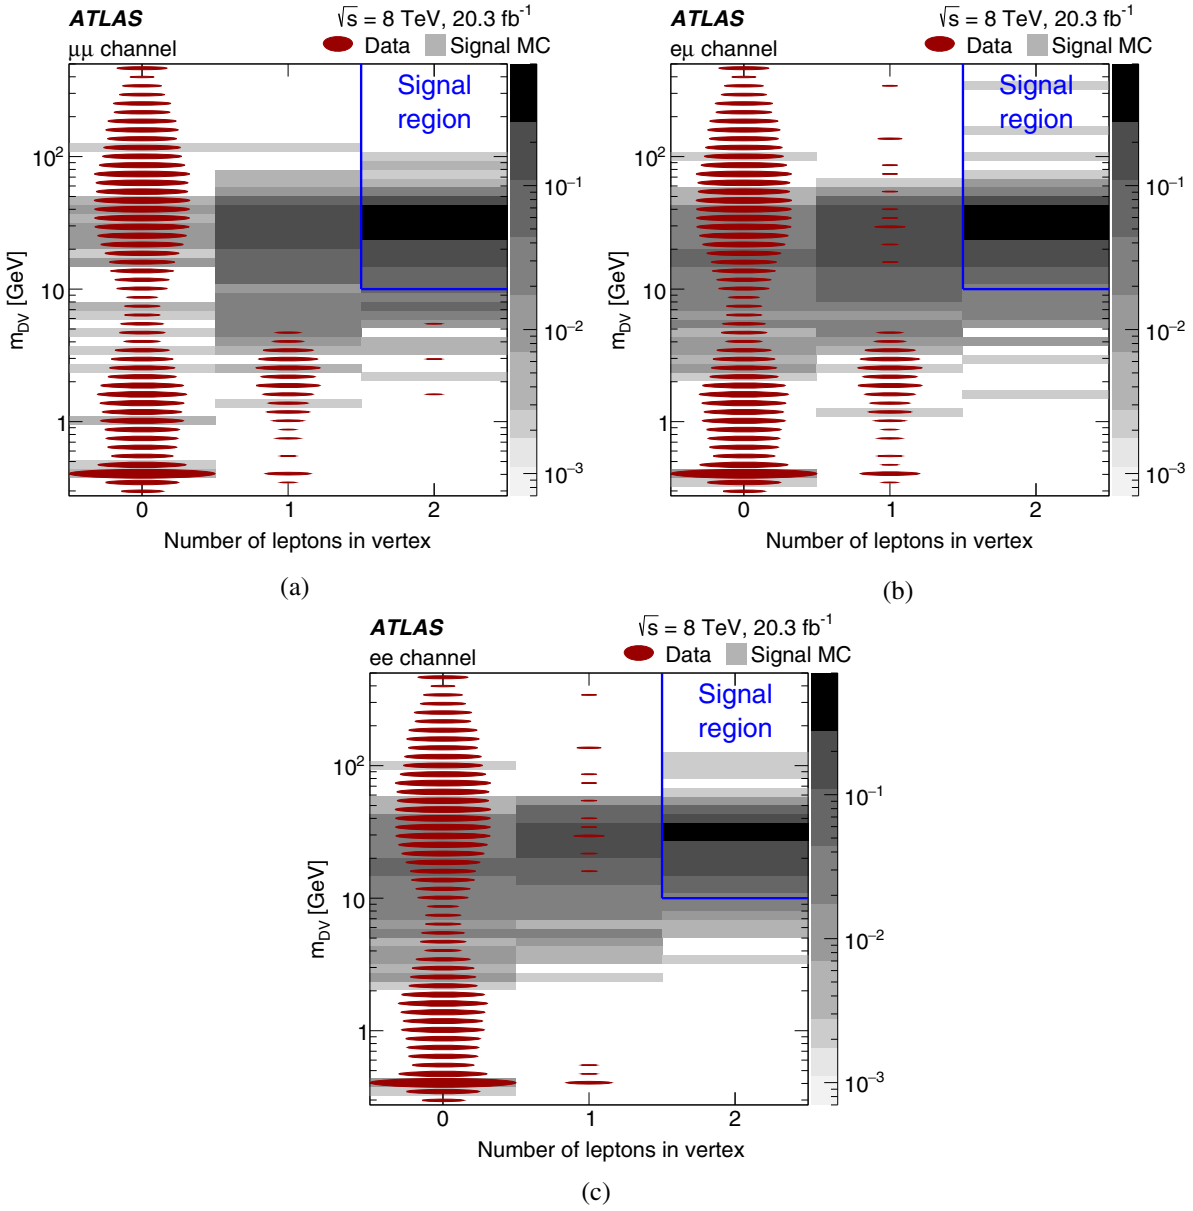


FIG. 9 (color online). The distribution of dilepton-vertex candidates in terms of the vertex mass versus the number of lepton candidates in the vertex, in the (a) $\mu^+\mu^-$, (b) $e^\pm\mu^\mp$, and (c) e^+e^- search channels. The data distributions are shown with red ovals, the area of the oval being proportional to the logarithm of the number of vertex candidates in that bin. The gray squares show the $\tilde{g}(600\ \mathrm{GeV}) \to qq[\tilde{\chi}_1^0(50\ \mathrm{GeV}) \to \mu\mu\nu/e\mu\nu/ee\nu]$ signal MC sample. The shape of the background m_{DV} distribution arises partly from the lepton-candidate p_{T} requirements. The signal region defined by the two-lepton and $m_{\mathrm{DV}} \to 10$ GeV requirements is indicated.

$$\rho_i(K_S^0) = \frac{N_i^{\mathrm{data}}(K_S^0)}{N_i^{\mathrm{MC}}(K_S^0)}, \tag{8}$$

where $i = 1, \ldots, 4$ labels four radial regions between 5 mm and 40 mm, and $N_i^{\mathrm{data/MC}}(K_S^0)$ is the number of K_S^0 mesons in radial region i in data/MC simulation, obtained by fitting the two-track mass distributions. In the calculation of $N_i^{\mathrm{MC}}(K_S^0)$, the K_S^0 candidates in MC are weighted so that their $|\eta|$ and p_{T} distributions match those seen in the data. The ratio $\rho_i(K_S^0)$ is constructed separately for $|\eta| < 1$ and $|\eta| \geq 1$. The difference $\Delta\rho_i(K_S^0) = \rho_i(K_S^0) - \rho_1(K_S^0)$ quantifies the radial dependence of the data-MC discrepancy. The discrepancy is largest in the outermost radial region, with $\Delta\rho_4(K_S^0) = -0.03$ for $|\eta| < 1$ and $\Delta\rho_4(K_S^0) = -0.2$ for $|\eta| \geq 1$. The statistical uncertainties on $\rho_i(K_S^0)$ are negligible compared to these discrepancies.

To propagate this maximal discrepancy into a conservative uncertainty on the signal efficiency, DV daughter tracks are randomly removed from signal-MC vertices before performing the vertex fit. The single-track removal probability is taken to be $\Delta\rho_4(K_S^0)/2$ in each of the

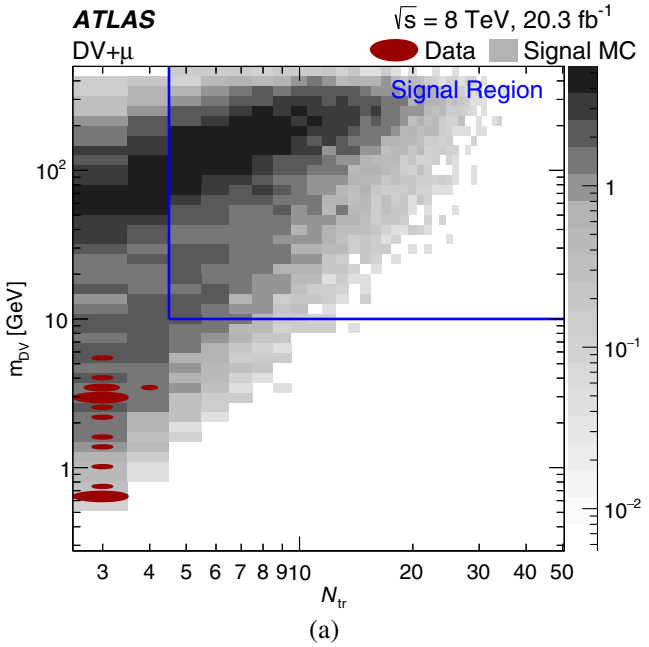

FIG. 10 (color online). The distribution of (a) DV + muon and (b) DV + electron candidates in terms of the vertex mass versus the number of tracks in the vertex. The data distribution is shown with red ovals, the area of each oval being proportional to the logarithm of the number of vertex candidates in that bin. The gray squares show the $\tilde{q}(700\ \mathrm{GeV}) \to q[\tilde{\chi}_1^0(494\ \mathrm{GeV}) \to \ell qq]$ RPV signal MC sample. The signal region $N_{\mathrm{tr}} \geq 5$, $m_{\mathrm{DV}} \to 10$ GeV is indicated.

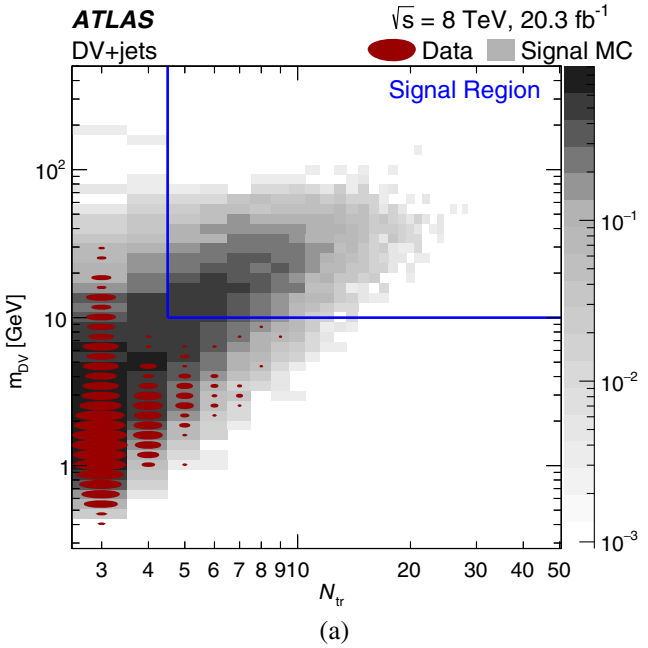

FIG. 11 (color online). The distribution of (a) DV + jets and (b) DV + $E_{\mathrm{T}}^{\mathrm{miss}}$ candidates in terms of the vertex mass versus the number of tracks in the vertex. The data distribution is shown with red ovals, the area of each oval being proportional to the logarithm of the number of vertex candidates in that bin. The gray squares show the $\tilde{g}(1.1\,\mathrm{TeV}) \to qq[\tilde{\chi}_1^0(400\,\mathrm{GeV}) \to \tilde{G}Z]$ GGM signal MC sample in (a) and the $[\tilde{g}(1.4\ \mathrm{TeV}) \to \tilde{\chi}_1^0(100\ \mathrm{GeV})qq/g]$ split-supersymmetry sample in (b). The signal region $N_{\mathrm{tr}} \geq 5, m_{\mathrm{DV}} > 10$ GeV is indicated.

two $|eta|$ regions. The resulting change in the DV efficiency is taken as the tracking-efficiency systematic uncertainty. This uncertainty is evaluated separately for each value of $c\tau$, and is generally around 1%.

3. Off-line lepton-identification efficiency

The lepton-identification efficiency uncertainty is determined in ATLAS using $Z \to \ell\ell$ decays and is typically less than 1%. For this analysis, an additional

TABLE III. Model-independent 95% confidence-level upper limits on the visible cross section for new physics in each of our searches.

Channel	Upper limit on visible cross section [fb]
DV + jet	0.14
DV + $E_{\mathrm{T}}^{\mathrm{miss}}$	0.15
DV + muon	0.15
DV + electron	0.15
e^+e^-	0.14
$\mu^+\mu^-$	0.14
$e^\pm\mu^\mp$	0.15

uncertainty associated with identification of high-d_0 leptons is evaluated.

For muons, this is done by comparing a cosmic-ray muon simulation to cosmic-ray muon candidates in data. The events are required to pass the muon trigger and to have two muon candidates that fail the muon veto (see Sec. IV B 1). The MC muons are weighted so that their η and ϕ distributions are in agreement with those of the data. Comparing the ratio of the muon candidate d_0 distributions in data and in MC simulation yields a d_0-dependent efficiency correction that is between 1% and 2.5%, with an average value of 1.5%. The uncertainty associated with this procedure is taken from the statistical uncertainty, and is 2% on average.

Unlike in the case of cosmic-ray muons, there is no easily identifiable, high-rate source of large-d_0 electrons. Therefore, the performance of the simulation is validated by comparing the electron-identification efficiency $\epsilon_e(z_0)$ as a function of the longitudinal impact parameter z_0 of the

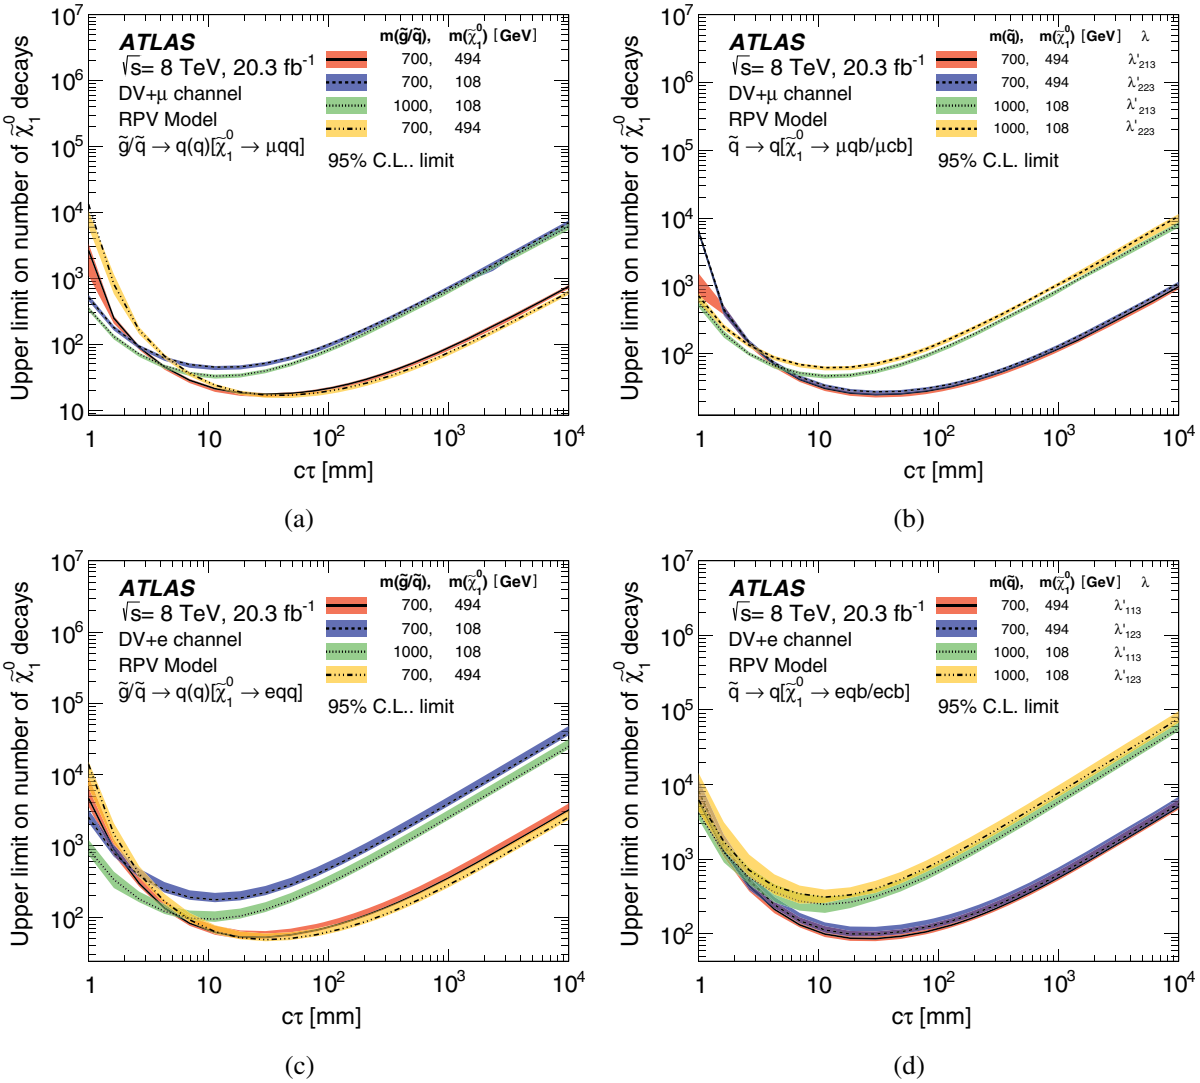

FIG. 12 (color online). RPV-scenario upper limits at 95% confidence level on the number of neutralinos in 20.3 fb^{-1} that decay into (a) μqq (with q indicating a u- or d-quark), (b) μqb and μcb (indicated by the nonzero RPV couplings λ'_{213} and λ'_{223}, respectively), (c) eqq, and (d) eqb and ecb (λ'_{113} and λ'_{123}, respectively). The upper limits account for the vertex-level efficiency for each value of the neutralino proper decay distance $c\tau$. The different curves show the results for different masses of the primary gluino or squark and of the long-lived neutralino, while the shaded bands indicate $\pm 1\sigma$ variations in the expected limit.

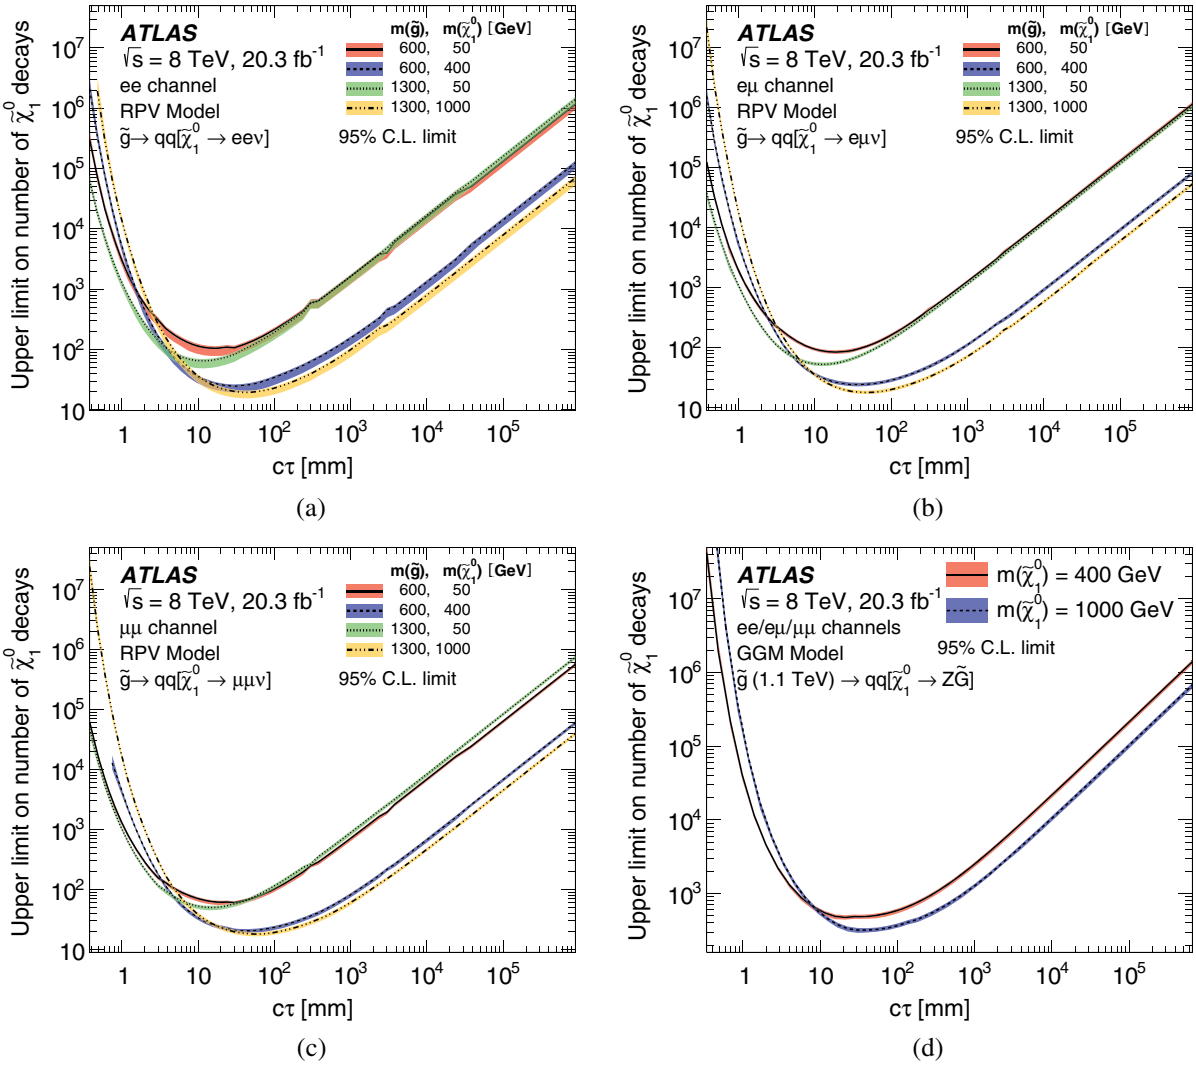

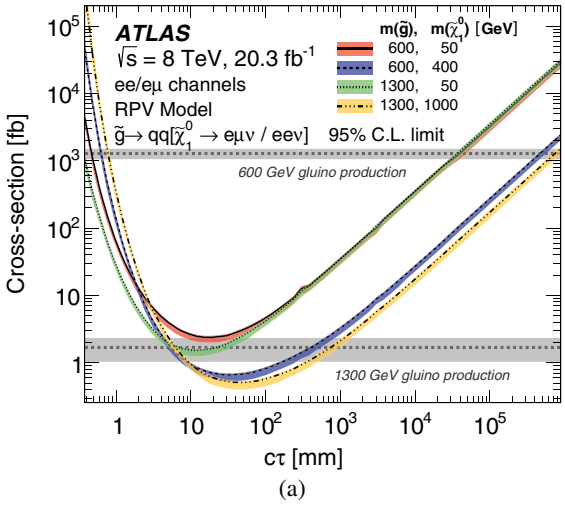

FIG. 13 (color online). Upper limits at 95% confidence level on the number of neutralinos in 20.3 fb^{-1} that decay into (a) $ee\nu$ in the RPV model, (b) $e\mu\nu$ in the RPV model, (c) $\mu\mu\nu$ in the RPV model, and (d) $Z\tilde{G}$ in the GGM model. The upper limits account for the vertex-level efficiency for each value of the neutralino proper decay distance $c\tau$. The different curves show the results for different masses of the primary gluino and of the long-lived neutralino, while the shaded bands indicate $\pm 1\sigma$ variations in the expected limit. In some cases limits are terminated for $c\tau \lesssim 1$ mm due to limited statistical precision.

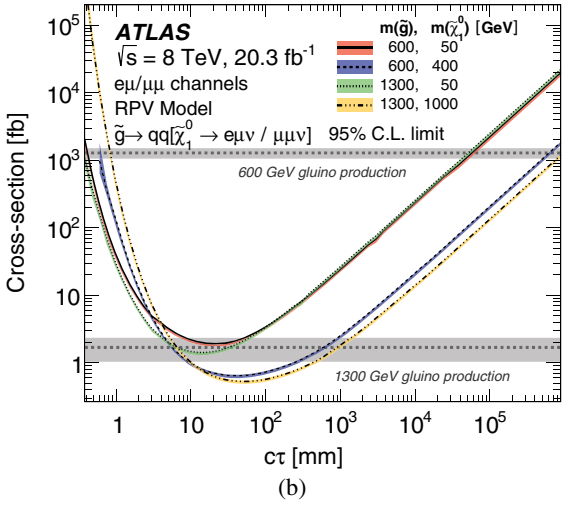

electron candidate in data and MC simulation, measured with the tag-and-probe method using $Z \to e^+e^-$ events. It is observed that $\epsilon_e(z_0)$ is consistent in data and in MC simulation to better than 1% for $|z_0| < 250$ mm, beyond which there are too few events for an accurate measurement. Furthermore, the value of ϵ_e obtained with the tag-and-probe method is consistent to within 1% with that determined from MC generator-level information. This data-MC agreement in $\epsilon_e(z_0)$ is taken as an indication that the d_0 dependence of the efficiency, $\epsilon_e(d_0)$, is also well described by simulation. In signal MC samples, the function $\epsilon_e(d_0)$ varies by about 10% due to kinematic correlations between d_0 and factors that affect the efficiency, such as the value of r_{DV} and the boost of the LLP. To account for the possibility of an additional d_0 dependence that may not be well simulated, a systematic uncertainty of 10% on the electron-identification efficiency is assigned. This conservative uncertainty weakens the upper limits by less than 1%.

4. Jets and $E_{\text{T}}^{\text{miss}}$ reconstruction

The impact on the signal efficiency of uncertainties in the jet-energy scale calibration and jet-energy resolution is evaluated following the methods described in Refs. [57] and [58], respectively. An additional uncertainty on the jet p_{T} is evaluated for jets that originate from the decay of an LLP, by linearly parametrizing the p_{T} mismeasurement in MC simulation as a function of r_{DV} and z_{DV}. The only significant dependence observed is a relative p_{T}

FIG. 14 (color online). The 95% confidence-level upper limits, obtained from the dilepton search, on the production cross section for a pair of gluinos of different masses that decay into two quarks and a long-lived neutralino in different models: (a) the RPV scenario with a pure λ_{121} coupling, (b) the RPV scenario with a pure λ_{122} coupling. All relevant final-state lepton-flavor combinations are used. The shaded bands around the observed limits indicate $\pm 1\sigma$ variations in the expected limit, while the horizontal bands show the theoretical cross sections and their uncertainties. In some cases limits are terminated for $c\tau \lesssim 1$ mm due to limited statistical precision.

mismeasurement of $(4 \pm 1) \times 10^{-5}(r_{\mathrm{DV}}/\mathrm{mm})$, which is propagated to the jet-selection efficiency as a systematic uncertainty. To account for possible mismodeling of trackless jets, an uncertainty is obtained by varying the requirement on $\sum_{\mathrm{tr}} p_{\mathrm{T}}$ for these jets. Systematic uncertainties in the $E_{\mathrm{T}}^{\mathrm{miss}}$ measurement are evaluated with the methods described in Refs. [53,54] and propagated to the efficiency uncertainty. The impact of uncertainties in the simulation of initial-state radiation is estimated by varying the p_{T} distribution of the primary particles according to the distribution observed in MADGRAPH5 [59]

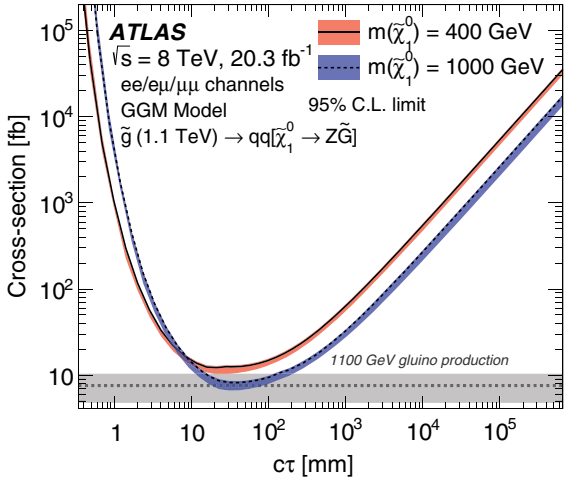

FIG. 15 (color online). The 95% confidence-level upper limits, obtained from the dilepton search, on the production cross section for a pair of gluinos of mass 1.1 TeV that decay into two quarks and a long-lived neutralino in the GGM scenario for two values of the neutralino mass. For further details see Fig. 14.

samples. The resulting efficiency uncertainty varies between 2% and 10%.

5. Multiple pp interactions

The dependence of the reconstruction efficiency on the number of pp interactions per bunch crossing is studied by varying the average number of interactions per LHC bunch crossing in the simulation by 4%. This value reflects uncertainties in the detector acceptance, trigger efficiency, and modeling of additional pp interactions. The resulting relative uncertainty is typically of order 1% or less.

VIII. RESULTS

Figure 9 shows the distribution of m_{DV} versus the number of associated lepton candidates in the selected data sample before the final selection requirements on these variables are applied. The distributions of m_{DV} versus the number of tracks in the vertex obtained for the multitrack-DV search are shown in Figs. 10 and 11. No events are seen in the signal region for any of the seven channels. In addition, no same-charge dilepton vertices are seen with $m_{\mathrm{DV}} > 10$ GeV. The distributions expected for some of the signal samples are also shown for comparison.

Given the lack of a signal observation, 95% confidence-level upper limits on the total visible cross section for new physics are shown in Table III.

Furthermore, for each of the physics scenarios considered, 95% confidence-level upper limits on the signal yields and production cross sections are calculated for different values of the proper decay distance $c\tau$ of the LLP and presented in the figures in this section. The limits are calculated using the CL_S prescription [60] with the profile likelihood used as the test statistic, using the

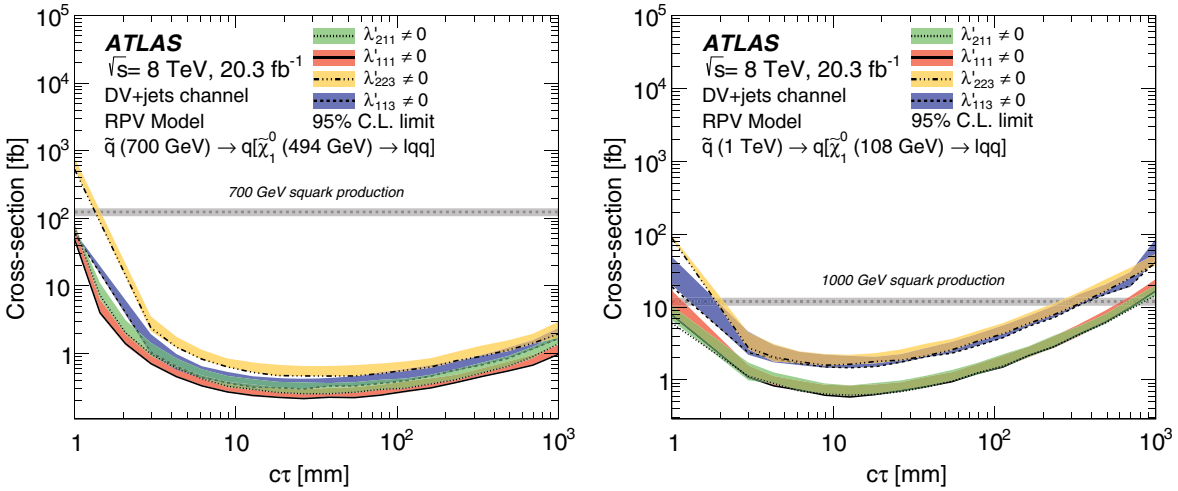

FIG. 16 (color online). The 95% confidence-level upper limits, obtained from the DV + jets search, on the production cross section for a pair of squarks in the RPV scenario, with the neutralino decaying to a lepton and two quarks, according to the nonzero λ' couplings indicated in each case. The squark and neutralino masses are (a) 700 GeV and 494 GeV or (b) 1 TeV and 108 GeV, respectively, representing the results for different neutralino masses and boosts. For further details see Fig. 14.

HistFitter [61] framework. Uncertainties on the signal efficiency and background expectation are included as nuisance parameters, and the CL_S values are calculated by generating ensembles of pseudoexperiments corresponding to the background-only and signal-plus-background hypotheses.

Since less than one background event is expected in all cases and no events are observed, the observed limits are very close to the expected limits.

In the case of the dilepton and DV + lepton searches, where the trigger and reconstruction depend almost exclusively on the signal DV, upper limits on the number of vertices produced in 20.3 fb^{-1} of data are presented for each channel, accounting for the vertex-level efficiency at each value of $c\tau$. Figure 12 shows these number limits for the DV + lepton search signatures. The limits are given separately for different masses of the long-lived neutralino and the primary squark or gluino, as well as for different λ'_{ijk} couplings, which give rise to light- or heavy-flavor quarks in the final state (see Sec. V for a discussion of the heavy-flavor and mass impact on efficiency). The number limits for the dilepton search signatures are shown in Fig. 13 for the final states ee, $\mu\mu$, $e\mu$, as well as for the combination of $Z \to ee$, $Z \to \mu\mu$, and $Z \to \tau\tau$.

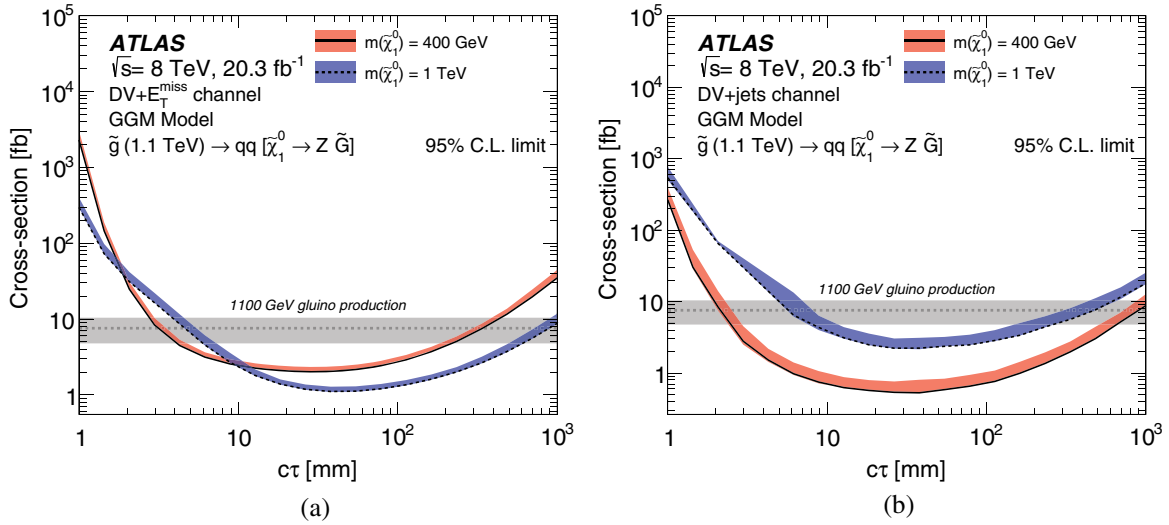

FIG. 17 (color online). The 95% confidence-level upper limits, obtained from the (a) DV + $E_{\mathrm{T}}^{\mathrm{miss}}$ and (b) DV + jets searches, on the production cross section for a pair of gluinos of mass 1.1 TeV that decay into two quarks and a long-lived neutralino in the GGM scenario. For further details see Fig. 14.

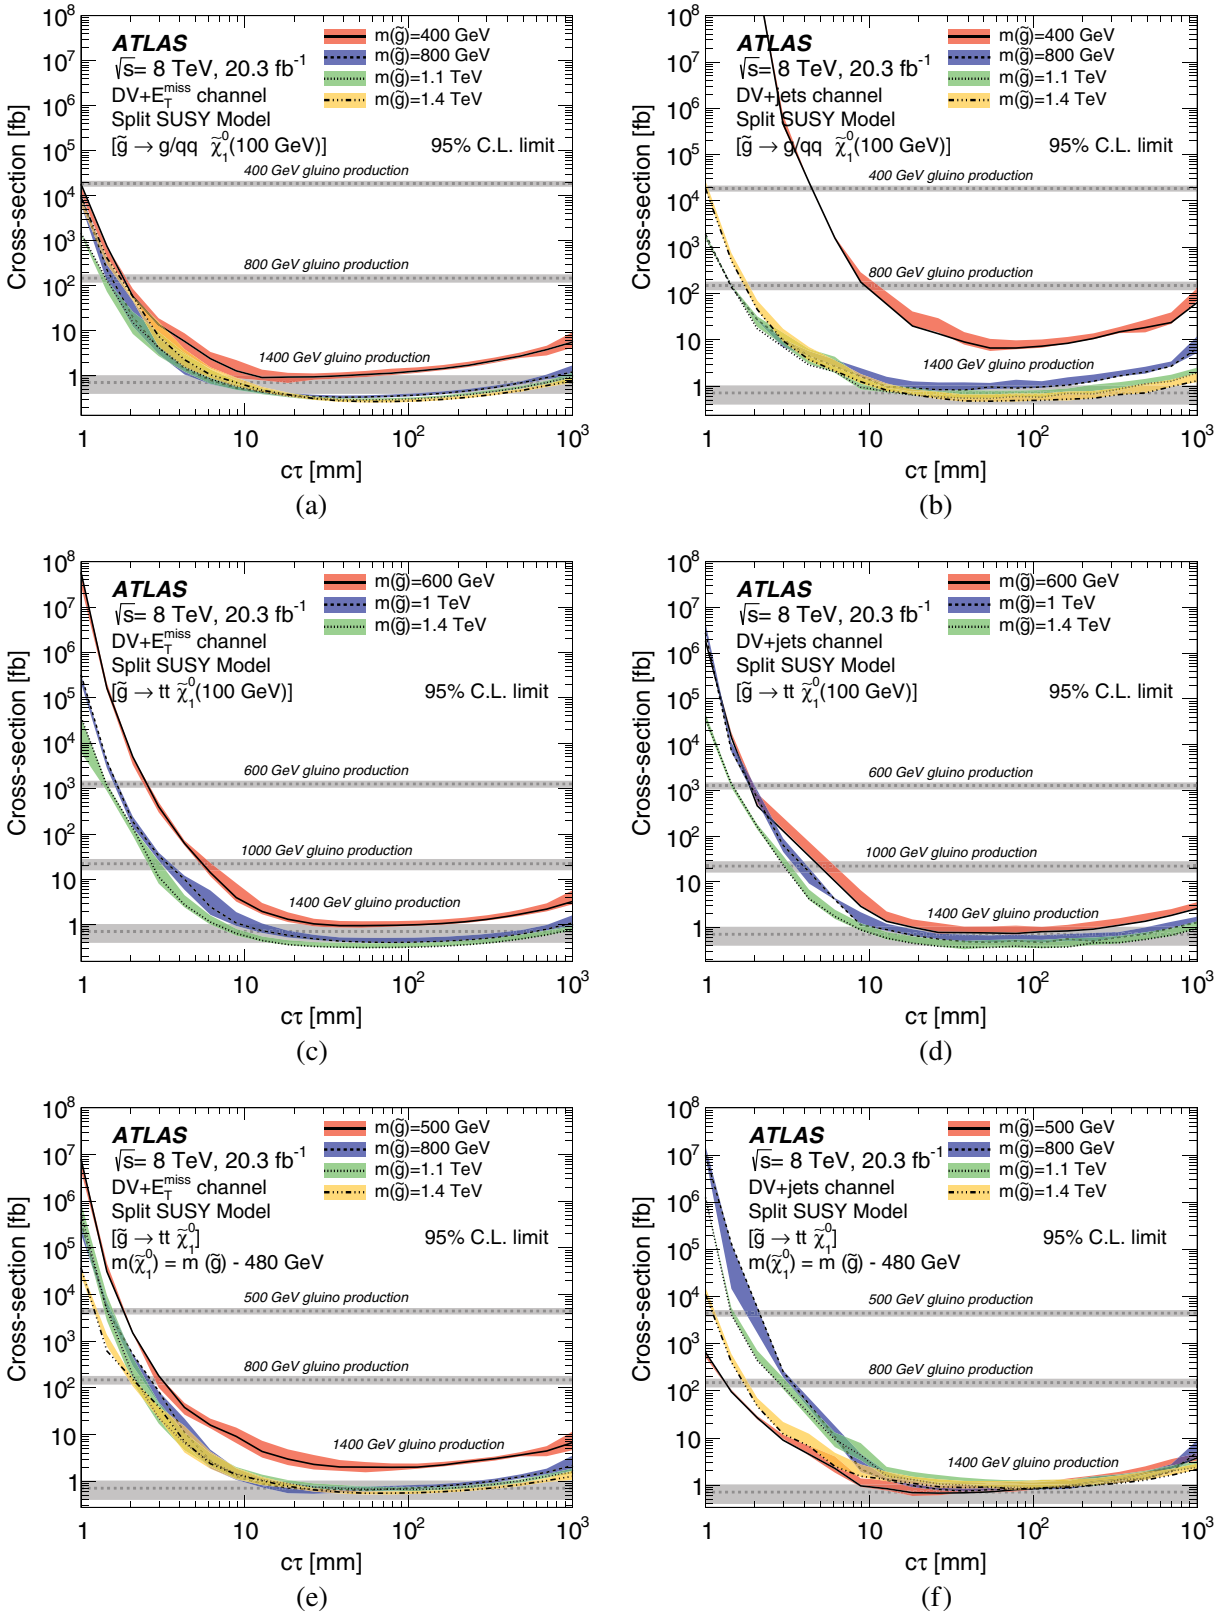

FIG. 18 (color online). The 95% confidence-level upper limits, obtained from the (a), (c), (e) DV + $E_{\mathrm{T}}^{\mathrm{miss}}$ and (b), (d), (f) DV + jets searches, on the cross section for gluino pair production in the split-supersymmetry model, with the gluino decaying to a neutralino plus either (a), (b) a gluon or a light-quark pair or (c), (d), (e), (f) a pair of top quarks. The mass of the neutralino is 100 GeV in (a), (b), (c), (d) and is 480 GeV smaller than the gluino mass in (e), (f). For further details see Fig. 14.

In addition, limits on the production cross sections for events are presented for the different simulated scenarios.

Figures 14 and 15 show cross-section upper limits obtained with the dilepton-DV search. Upper limits are shown for gluino-pair production in the RPV scenario, with neutralino decays determined by the choice of nonzero RPV coupling λ_{121} or λ_{122}, as well as within the GGM scenario with leptonic decays of the Z boson. For example, the RPV scenario is excluded for gluino mass $m_{\tilde{g}} = 600$ GeV, neutralino mass $m_{\tilde{\chi}_1^0} = 400$ GeV, and neutralino proper decay distance in the range $0.7 < c\tau < 3 \times 10^5$ mm.

Cross-section upper limits obtained with the multitrack-DV search are shown in the remaining figures. These limits are calculated up to proper decay distances of $c\tau = 1$ m, to avoid inaccuracies associated with reweighting events to very high lifetimes when the efficiency depends on both LLPs in the event.

Figure 16 shows the upper limits on the production cross section of two squarks in the RPV scenario, with different squark and neutralino masses, as well as different λ' parameters governing the neutralino decay. These limits are obtained with the DV + jets search, which results in tighter limits than the DV + lepton searches for this scenario. These results exclude a $m_{\tilde{q}} = 1$ TeV squark for $m_{\tilde{\chi}_1^0} = 108$ GeV and $2.5 < c\tau < 200$ mm with either light- or heavy-quark neutralino decays. Figure 17 shows the cross-section upper limits for gluino-pair production within the GGM scenario, using hadronic Z decays. The scenario is excluded, for instance, for $m_{\tilde{g}} = 1.1$ TeV and $m_{\tilde{\chi}_1^0} = 400$ GeV in the proper decay distance range $3 < c\tau < 500$ mm.

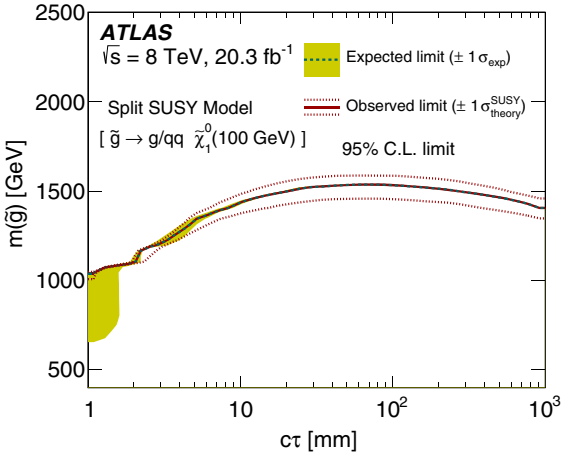

FIG. 19 (color online). The 95% confidence-level excluded regions lie below the curves shown in the mass-versus-$c\tau$ plane for the split-supersymmetry samples, with the gluino decaying into a gluon or light quarks, plus a 100 GeV neutralino. The shaded bands indicate $\pm 1\sigma$ variations in the expected limit, while the dotted lines indicate the effect of varying the production cross section by 1 standard deviation. The expected and observed limits are identical.

Figure 18 shows the upper limits on gluino-pair production cross section in the split-supersymmetry model. These limits are obtained from the results of the DV + $E_{\mathrm{T}}^{\mathrm{miss}}$ and DV + jets searches. The sensitivity is greater for the cases with $m_{\tilde{\chi}_1^0} = 100$ GeV than for those with $m_{\tilde{\chi}_1^0} = m_{\tilde{g}} - 480$ GeV, and the DV + $E_{\mathrm{T}}^{\mathrm{miss}}$ search performs better than DV + jets in these scenarios, excluding $m_{\tilde{g}} < 1400$ GeV in the range of proper decay lengths 15 mm $< c\tau < 300$ mm.

In Figs. 19 and 20, the region of gluino mass versus proper decay distance that is excluded by these limits is shown. The limit for each point in parameter space is taken from the channel that is expected to yield the most stringent limit, which is DV + $E_{\mathrm{T}}^{\mathrm{miss}}$ for most points. For the region

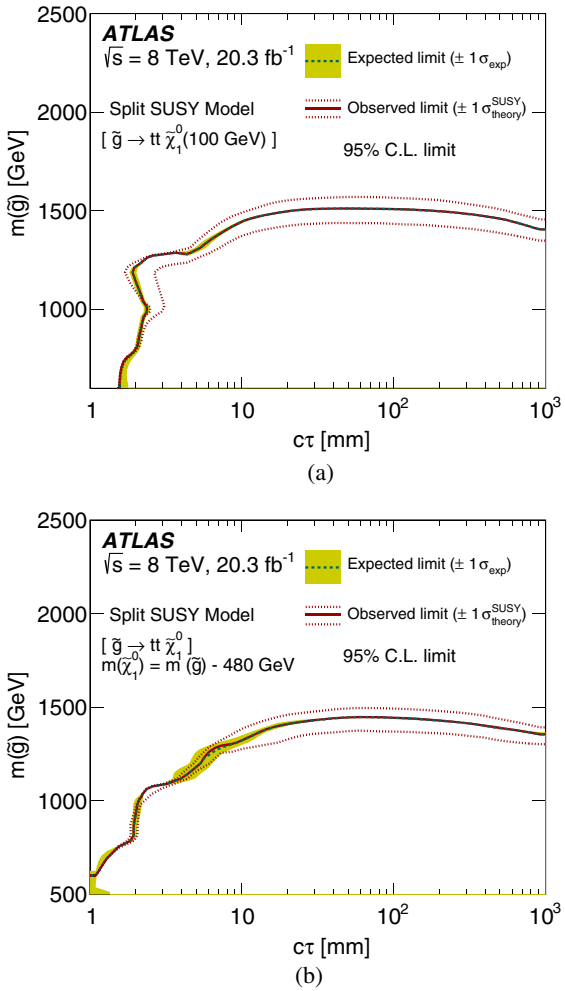

FIG. 20 (color online). The 95% confidence-level excluded regions lie below the curves shown in the mass-versus-$c\tau$ plane for the split-supersymmetry samples, with the gluino decaying into (a) a top quark pair and a 100 GeV neutralino, or (b) a top quark pair and a neutralino with a mass that is 480 GeV smaller than the gluino mass. The shaded bands indicate $\pm 1\sigma$ variations in the expected limit, while the dotted lines indicate the effect of varying the production cross section by 1 standard deviation. The expected and observed limits are identical.

of parameter space where the sensitivity is greatest, $20\ \text{mm} < c\tau < 250\ \text{mm}$ and $m_{\tilde{\chi}_1^0} = 100\ \text{GeV}$, gluino masses of $m_{\tilde{g}} < 1500\ \text{GeV}$ are excluded. This range of masses is comparable to or slightly larger than those excluded by prompt searches [62], searches for long-lived R-hadrons stopped in the ATLAS calorimeter [17], or searches for stable, massive, charged particles [19].

IX. SUMMARY AND CONCLUSIONS

This article reports on a search for long-lived particles decaying into two leptons or five or more charged particles. In the latter case, events are selected using associated lepton candidates, jets, or missing transverse momentum. The main signature of the search is a displaced vertex with an invariant mass greater than 10 GeV. This signature corresponds to a wide variety of new-physics models, many of which have not been searched for previously. The search uses the full data sample of pp collisions collected by the ATLAS detector at the LHC with a center-of-mass energy of $\sqrt{s} = 8$ TeV and an integrated luminosity of 20.3 fb^{-1}. Less than one background event is expected in each of the channels, and no events are observed. Upper limits are provided on the number of long-lived particle decays in the data sample and on the cross section for production of particles that give rise to the search signatures in a variety of supersymmetric models. These upper limits exclude significant regions of the parameter space of new-physics models with particle masses within reach of the LHC.

ACKNOWLEDGMENTS

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently. We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWFW and FWF, Austria; ANAS, Azerbaijan; SSTC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC, and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST, and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR, and VSC CR, Czech Republic; DNRF, DNSRC, and Lundbeck Foundation, Denmark; EPLANET, ERC, and NSRF, European Union; IN2P3-CNRS, CEA-DSM/IRFU, France; GNSF, Georgia; BMBF, DFG, HGF, MPG, and AvH Foundation, Germany; GSRT and NSRF, Greece; RGC, Hong Kong SAR, China; ISF, MINERVA, GIF, I-CORE, and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; BRF and RCN, Norway; MNiSW and NCN, Poland; GRICES and FCT, Portugal; MNE/IFA, Romania; MES of Russia and NRC KI, Russian Federation; JINR; MSTD, Serbia; MSSR, Slovakia; ARRS and MIZŠ, Slovenia; DST/NRF, South Africa; MINECO, Spain; SRC and Wallenberg Foundation, Sweden; SER, SNSF, and Cantons of Bern and Geneva, Switzerland; NSC, Taiwan; TAEK, Turkey; STFC, the Royal Society, and Leverhulme Trust, United Kingdom; DOE and NSF, United States of America. The crucial computing support from all WLCG partners is acknowledged gratefully, in particular from CERN and the ATLAS Tier-1 facilities at TRIUMF (Canada), NDGF (Denmark, Norway, Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy), NL-T1 (Netherlands), PIC (Spain), ASGC (Taiwan), RAL (UK), and BNL (USA) and in the Tier-2 facilities worldwide.

Model Magnet Development of D1 Beam Separation Dipole for the HL-LHC Upgrade

Tatsushi Nakamoto, Michinaka Sugano, Qingjin Xu, Hiroshi Kawamata, Shun Enomoto, Norio Higashi, Akira Idesaki, Masami Iio, Yukiko Ikemoto, Ruri Iwasaki, Nobuhiro Kimura, Toru Ogitsu, Naoki Okada, Ken-ichi Sasaki, Makoto Yoshida, and Ezio Todesco

***Abstract*—KEK has been conducting the design study of the beam separation dipole magnet, D1, for the High Luminosity LHC (HL-LHC) upgrade within a framework of the CERN-KEK collaboration. The D1 magnet has a coil aperture of 150 mm using Nb-Ti superconducting cable and the nominal dipole field of 5.6 T can be generated at 12 kA and 1.9 K. A field integral of 35 T·m is required. The development of the 2-m-long model magnet has been started since May 2013. This paper describes the development status of the short model magnet as well as advancement of the fundamental design studies.**

***Index Terms*—Collared yoke, LHC upgrade, Nb-Ti, radiation resistance, superconducting dipole.**

I. Introduction

WHILE LHC, even at 60% of its nominal energy, has been producing remarkable experimental results on particle physics, including the discovery of Higgs boson, a major upgrade to increase the data production by a factor of ten is planned around 2020 to exploit its full potential [1], [2]. To achieve a higher luminosity, superconducting and conventional magnets for the insertion regions at both sides of the ATLAS and CMS experiments will need to be replaced to provide a smaller beam size at the interaction point through a reduction in β^* [3]. KEK has participated in the design study of the High Luminosity LHC (HL-LHC) upgrade within the framework of the CERN-KEK collaboration and has been conducting the design study of the new beam separation dipole magnet (D1) including the development of a short model magnet. In the HL-LHC machine, the resistive D1 magnets will be replaced by superconducting dipole magnets with a larger coil aperture (150 mm) and a higher field integral (35 T·m). So far, a series of conceptual design studies on the new D1 has been carried out [4]–[6]. Main design requirements were specified in May 2013, after which the short model development was started at KEK. In this paper, development status of the short model as well as advancement of the fundamental design studies are presented. Detailed electromagnetic and mechanical analyses are reported in [7].

II. Magnet Overview

A. Design Guideline

Main design requirements for the new D1 are the large coil aperture of 150 mm and the field integral of 35 T·m [3]. Nominal dipole field has been set around 6 T and the whole mechanical magnet length should be 7 m or shorter: the D1 production magnets are supposed to be tested in the 7-m-deep vertical cryostat at KEK. Nominal field beyond 7 T is not considered since it would lead to a significant design difficulty while the benefit of a shorter magnet length would be marginal. In particular, due to the large aperture, and despite the nominal field of only 6 T, the control of iron saturation effects on the field quality and suppression of the stray field outside the cryostat are design issues. This is complicated by the limited transverse space available in the LHC tunnel, which dictates an upper limit to the magnet size. The field design already relies on the iron steel cryostat as a flux return [6].

Other important design requirements are the radiation heat load and the cooling capability. The total heat load of the cold mass and the local peak heat load in the coil are estimated to be 90 W and 1.3 mW/cm^3, respectively, at the HL-LHC design luminosity of 5×10^{34} cm^{-2} sec^{-1}. The magnet design must be compatible with an ultimate peak luminosity that is 50% higher than the original design one. For this reason, the design parameters of the total heat load and the local peak heat load are set to 135 W and 2 mW/cm^3, respectively. The magnet must be operated to withstand a total dose of 25 MGy in its lifetime: the dose was remarkably reduced due to the insertion of a heavily shielded beam screen in the bore [8].

The following is the design guideline of the new D1.

- Use of spare unit lengths of the LHC Nb-Ti superconducting cable from the main dipole (MB) outer layer, wrapped with the polyimide insulation.

See http://www.ieee.org/publications_standards/publications/rights/index.html for more information.

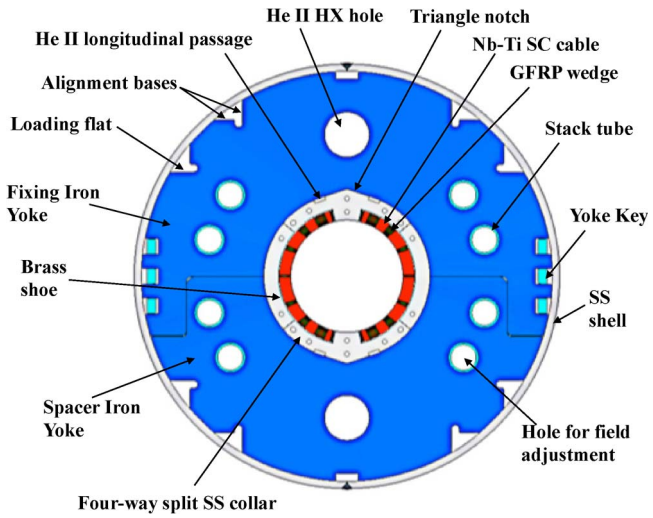

Fig. 1. Cross-sectional view of the D1 beam separation dipole magnet for the HL-LHC.

- Operational temperature of 1.9 K by superfluid helium cooling while operating around 75% of short sample current (i.e., 25% margin on the load-line).
- A single layer coil for better cooling capability and to leave more space to the iron yoke for reducing the fringe field.
- Enhancement of the amount of iron yoke in the cross section accomplished by "a collared yoke structure" like RHIC magnets [9] and LHC MQXA quadrupoles [10].
- A yoke outer diameter of 550 mm, same as J-PARC SCFM [11], enabling reuse of the assembly jigs and relevant facilities at KEK.
- Use of radiation resistant materials for the coil parts: wedges, end spacers.

B. Magnet Design

A cross-sectional view of the new D1 beam separation superconducting dipole magnet for the HL-LHC is shown in Fig. 1. The main design parameters for the 2-m-long model magnet and the 7-m-long production magnet are listed in Table I. The magnet cross section including the cable arrangement and the iron yoke shape is designed in 2-D employing ROXIE [12]. The field quality is optimized at the collision energy while variation of the multipole components due to the iron saturation during the excitation is kept within an acceptable range. The coil end shape is fully covered by the iron yoke and is optimized in view of the production magnet with the aim of minimizing the field integrals of the multipole components and the peak field. The coil end shape obtained for the production magnet is kept for the 2-m-model magnet. The results of optimization are listed in Table II. The field integral multipole minimization for the production magnet might still be insufficient due to the limited adjustable parameters in a single layer coil, but it can be reduced by tuning the coil cross section in the straight section in the future. Large drifts in the field integral of the multipole components in the 2-m-model are observed: the coil center is not sufficiently far from the coil ends and the current at the coil ends influence the field quality even around the center of the magnet. Some skew components come from the coil lead-end since the top and the bottom coils have a rotational symmetry.

TABLE I
MAIN DESIGN PARAMETERS OF THE D1 BEAM SEPARATION DIPOLE MAGNET FOR THE HL-LHC

Design parameters	2 m model	Production
General		
Field integral	10.3 T·m	35 T·m
Coil aperture	150 mm	
Nominal dipole field	5.58 T	
Coil peak field	6.45 T at center 6.71 T at coil end	
Load-line ratio	75 % at center 78 % at coil end	
Field Quality	$< 10^{-4}$ w.r.t the main field	
Nominal current	12.0 kA	
Operation temperature	1.9 K	
Magnetic length	1.85 m	6.27 m
Stored energy	340 kJ/m	
Differential Inductance	4.0 mH/m	
Number of coil layer	1	
Number of turns in quadrant	44 (4+8+13+19)	
Coil mechanical length	2.00 m	6.46 m
Magnet mechanical length	2.50 m	6.96 m
Cold mass weight	3.8 tons	12 tons
Cable unit length per coil	175 m	568 m
Lorenz force per quater ΣF_x & ΣF_y	1.53 & -0.64 MN/m	
Heat load	135 W in total, 2 mW/cm^3 at local peak	
Radiation dose	> 25 MGy	
Superconducting Cable		
Superconductor	Nb-Ti	
Cable type	LHC MB outer cable	
Strand diameter	0.825 mm	
Coating	Sn5wt%Ag	
Copper to SC ratio	1.95	
Filament diameter	6 μm	
Number of filament	6500	
RRR	> 150	
Critical current (9 T, 1.9 K)	> 380 A	
Number of strand	36	
Cable bare width	15.1 mm	
Cable bare mid-thickness	1.480 mm	
Keystone angle	0.9°	
Transposition pitch	100 mm	
Insulation		
1st & 2nd layer	APICAL (0.05 mm thick, 11 mm wide), 1/2 overwrap	
3rd layer	PIXEO (0.069 mm thick, 9 mm wide), adhesive, 2 mm gap wrap	

TABLE II
FIELD COMPUTATION RESULTS FOR 2-D AND 3-D MODELS OF THE D1 DIPOLE MAGNET FOR THE HL-LHC

	2D	3D, production	3D, 2 m model
Dipole field, B_1, at the center (T)	5.59	5.60	5.66
$\int B_1 dl$ (T·m)	----	35.2	10.3
$\int B_3 dl / \int B_1 dl \times 10000$ (unit)	-0.265	8.27	24.5
$\int B_5 dl / \int B_1 dl \times 10000$ (unit)	-0.144	-1.46	-4.47
$\int B_7 dl / \int B_1 dl \times 10000$ (unit)	-0.134	-0.63	-1.66
$\int A_1 dl / \int B_1 dl \times 10000$ (unit)	----	-1.40	-4.73
$\int A_3 dl / \int B_1 dl \times 10000$ (unit)	----	0.772	2.66

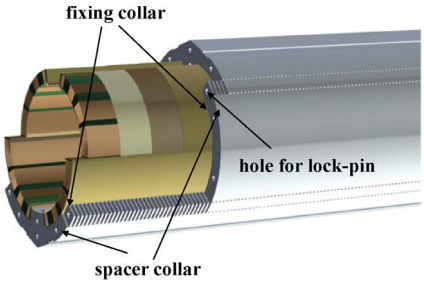

Fig. 2. Side cut view of collared coil.

A single layer coil consists of 44 turns of the Nb-Ti superconducting cable from the LHC MB outer layer with wedges and end spacers made of newly developed glass fiber reinforced plastic (GFRP). The GFRP wedges were utilized in the recent accelerator superconducting magnets [10], [11] and are cost-effective in a small number of magnet production like the new D1. The insulated superconducting cables are supplied by CERN. An LHC-MQXA type insulation with radiation resistant prepreg was considered for the cable insulation in the beginning. However, the standard cable insulation scheme for the LHC MB outer layer using APICAL and PIXEO polyimide tapes supplied by KANEKA was chosen for the new D1 coil because of its sufficient cooling capability of around a few mW/cm^3 [13]. In addition to adhesive cable insulation of PIXEO, cyanate ester resin (BT2160RX by Mitsubishi Gas Chemical) is used for the adhesion of the coil parts such as wedges and end spacers. For the electrical insulation to ground, two sets of double layer of 0.125 mm thick polyimide sheets (Upilex-RN by UBE Industries) surround the coil in accordance with the traditional method.

Four-way split collars are utilized to pre-assemble a pair of the top and bottom coils to provide a minimal azimuthal pre-stress around a few MPa, but the final pre-stress is given by the following yoking process [10]. Usually, superconducting dipole coils were assembled with a pair of vertically spilt collars [14]. But this concept seems to be inadequate for the new D1 where the collar azimuth would be quite longer while the width is kept narrow. An unwanted warp of the collar may arise in the blanking process and compromise the final dimensions. Due to this, the four-way split collar concept with a moderated aspect ratio is adopted for the new D1. A sub-stack of the collars is alternately laminated by the 2.3-mm-thick "fixing collar" and the 2.6-mm-thick "spacer collar" and four sub-stacks surrounding the coils are connected by the lock-pins through the holes at the end of the fixing collar, as illustrated in Fig. 2. The collar serves to align the pole of the superconducting coil with respect to the magnet structure: the triangle notches at the top and the bottom of the inner circle of the iron yoke determine the position of the coils. Outer surface of the right and left collars has the alignment feature around the median plane, not shown in Fig. 2, to orient the collar with respect to the triangle notch of the yoke at the initial stage of the yoking process. Mechanical behaviors mentioned above will be demonstrated by the mechanical short model study prior to the model magnet fabrication. The collars are made of non-magnetic stainless steels (NSSC-130S, formerly known as YUS-130S) showing a very low and stable permeability ratio of

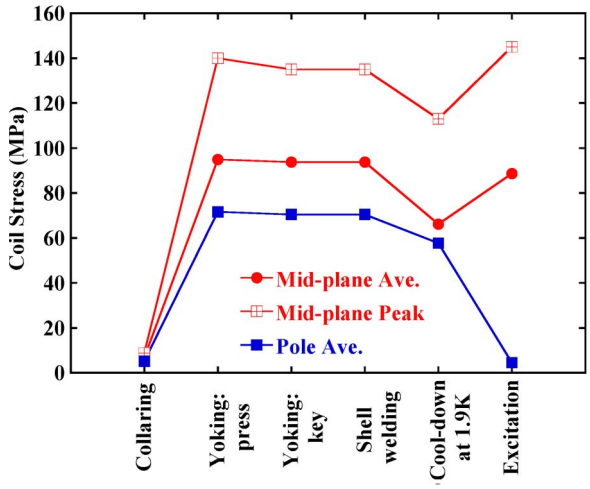

Fig. 3. FEM simulation results of the azimuthal coil stress at the fabrication processes and at the excitation at cold. For safety margin, 110% nominal current is taken for the FEM simulation at "Excitation".

1.002 at 4.2 K. The stainless steel collars are utilized at the coil straight section and the return-end. At the lead-end, however, the pole lead including the ramp box beyond the coil layer is clamped by the GFRP collars.

The iron yokes are made of low carbon steels (EFE by JFE steel) showing a yield strength of 240 MPa. A sub-stack of the iron yokes is about 200 mm long and is made by alternately laminating the 5.6-mm-thick "fixing yokes" having three key slots for each side and the 6.0-mm-thick "spacer yokes". The laminated iron yokes of the sub-stack are firmly connected with stacking tubes by a cold shrinkage fit through holes introduced in the yoke to control the iron saturation effects. The horizontal median plane of the iron yoke has a taper of 0.15 mm and the key slots of the fixing yoke are off-centered by 0.15 mm as well. When the top and bottom iron yokes are compressed through the loading flats by the hydraulic press, the yoke arc is deformed like a cantilever. The median plane gap is eventually closed and the key slots of the top and bottom yokes are aligned to enable the insertion of the lock keys [10], [11]. The coil pre-stress is kept by the lock keys after the release of the press. Finally, two halves of stainless steel shells are longitudinally welded to complete the pressure vessel. Finite Element simulation results by ANSYS for the azimuthal coil stress during the fabrication processes, cooling down, and excitation up to 110% of nominal current are shown in Fig. 3. The coil pre-stress at the pole at assembly is designed to be 80 MPa so that the coil is under compression at the pole even during excitation. The performed ANSYS simulations [6], [7] have not revealed any serious problem in the magnet structure.

The magnet is cooled by superfluid helium at 1.9 K and two saturated superfluid helium heat exchangers (HXs) are inserted in the holes of the top and bottom of the iron yoke to absorb the maximal heat load of 135 W. To ensure that the superconducting coil is kept under the lambda point, a longitudinal void fraction of 4% is necessary. This will serve as the cooling passage from the superconducting coil to the HXs [15]. The collars are designed to have embosses of 0.2 mm and the laminated collar sub-stack provides the required systematic gap for the superfluid helium. Besides, two grooves are foreseen near the

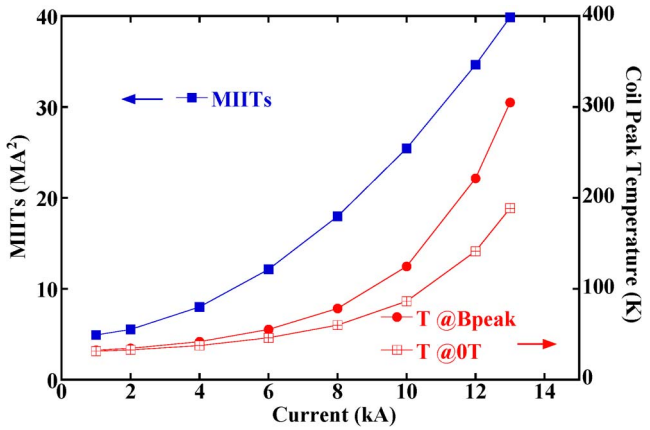

Fig. 4. MIITs estimation and predicted coil temperature at the peak field and the lowest field (i.e., zero).

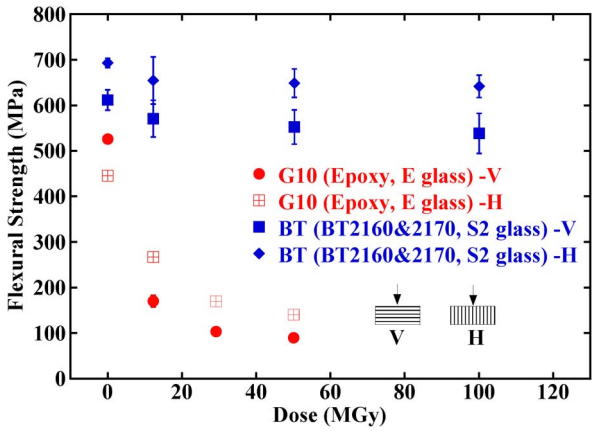

Fig. 5. Flexural strength of the new radiation resistant GFRP (BT) after γ-ray irradiation up to 100 MGy. Number of each sample is three. The data for the standard G10 GFRP are shown as a reference.

triangle alignment feature of the outer surface of the collar substack, to allow the longitudinal flow. In this way, the superfluid helium to deliver the heat from the coil can efficiently reach the HXs through the gaps between the iron yoke laminations with a typical packing factor of 98%.

In terms of the quench protection, the D1 magnet is standalone and quench protection heaters could be eliminated by using a dump resistor of 75 mΩ with the assumption of a detection threshold of 100 mV and a shutdown delay of 10 ms, as shown in Fig. 4. For the 13 kA quench current (nominal is 12 kA), with grounding at the middle of the resistor, the maximum coil temperature is 300 K and the maximum terminal voltage of 490 V. This suggests that protection without the protection heaters is viable. Further quench protection study to analyze the peak voltage in the coil is ongoing.

III. Development Status

A. Radiation Resistant GFRP

A new radiation resistant GFRP was successfully developed for the new D1 in the HL-LHC and for the J-PARC COMET superconducting magnet [16] in collaboration with ARISAWA. The GFRP is made from a lamination of the boron-free S-2 glass cloth with Bismaleimide-Triazine resin (blend of BT2160 and BT2170 by Mitsubishi Gas Chemical). The laminated prepreg cloths were cured at a maximum temperature of 220 °C. The BT GFRP was irradiated by γ-rays at room temperature and in vacuum at JAEA Takasaki. The radiation resistance was experimentally evaluated, as shown in Fig. 5. The flexural strength of the BT GFRP was determined as a function of the radiation dose up to 100 MGy. Each data point represents test results of three samples. While the standard G10 made of epoxy resin shows a rather rapid degradation even at 10 MGy, the BT GFRP seems to be functional up to 100 MGy without significant degradation for both testing directions with respect to the lamination direction.

B. Test Coil Fabrication for the 2 m Model

CAD/CAM modeling for the D1 coil has been carried out by using the ROXIE output. An example is shown in Fig. 6.

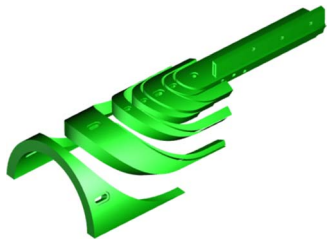

Fig. 6. CAD model for end spacers and ramp box at the lead-end for the model magnet.

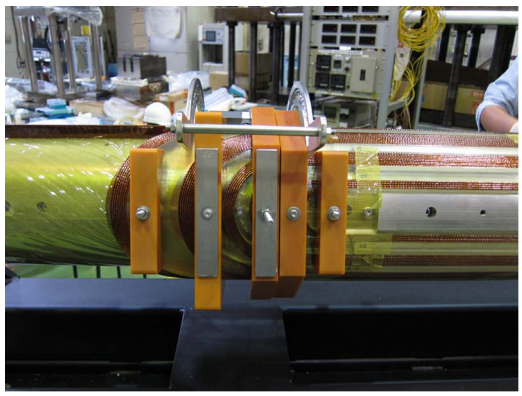

Fig. 7. Picture of practice coil winding.

Machining of the wedges, the end spacers and the ramp box for the test coil fabrication has begun. In parallel, practice coil windings using coil parts made by 3-D rapid prototyping were performed to tune the end spacer shape and to check the winding tooling as shown in Fig. 7.

Measurements of the cable size under azimuthal compressive stress in several loading patterns were carried out to characterize the mechanical behavior of the coil. Fig. 8 shows an example of the thickness measurements of a stack of 22 cables as a function of the compressive stress. The obtained cable size and Young's modulus were used in the computational studies and the magnet design.

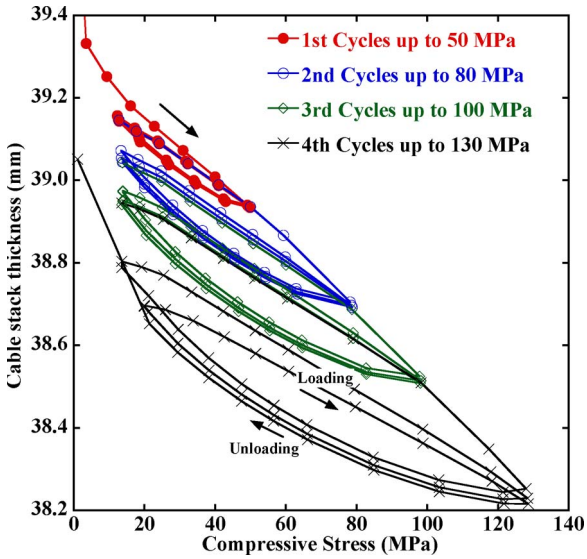

Fig. 8. Cable stack thickness measurement at room temperature as a function of compressive stress. The stack consists of 22 cables and was cured under the same conditions as the actual coil. Multiple loading up to 130 MPa was applied.

C. Further Plans

The test coil winding of the 2-m-long model will be started in August 2014, followed by the 20-cm-long mechanical cross section model study using the cut coil. Fabrication of the 2-m model coils will be started in December 2014. Procurement of the fine-blanking dies for the collars and the yokes is underway and the production is planned in January 2015. Assembly of the short model magnet will be completed in spring of 2015, followed by an excitation test at 1.9 K in the vertical cryostat at KEK.

IV. Summary

The 2-m-long model magnet development for the beam separation dipole for the HL-LHC is underway at KEK. Following the conceptual design study, the engineering design to realize the model magnet has been started since May 2013. Design highlights are the tight control of the field quality notwithstanding the large iron saturation, and the accommodation for the heat load and the radiation dose. The fabrication of the model magnet is in progress and the excitation test is expected in 2015.

Acknowledgment

The authors would like to express their gratitude to Profs. K. Tokushuku, K. Oide at KEK and L. Rossi at CERN for their strong supports for this project. The authors are really grateful to the colleagues at KEK and CERN, in particular, B. Auchmann, A. Ballarino, L. Bottura, P. Fessia, P. P. Granieri, G. Kirby, G. de Rijk, F. Savary, R. van Weelderen for their kind suggestions and fruitful discussions. The authors also thank O. Kobayashi, T. Kawashima for their technical supports.

平成 27 年度	34,900,000	10,470,000	45,370,000
総計	181,600,000	54,480,000	236,080,000

研究成果

1．研究開始当初の背景

(1) 素粒子標準模型は、過去 30 年間の加速器実験により、高い精度で検証されてきた。しかし、模型の重要なキーとなるヒッグス粒子が発見されていなかった。さらに、テラスケール（TeV のエネルギースケール）において、標準模型を超えた新しい素粒子現象の存在が大いに期待されていた。

(2) 2010 年 3 月より大型陽子・陽子衝突型加速器（LHC）は重心系 7TeV での実験を開始した。LHC によって実現する世界最高エネルギーの陽子・陽子衝突からは、高いエネルギーのジェット及び W、Z 粒子等の重い粒子が数多く生成され、テラスケールの素粒子物理反応の研究が可能になった。

2．研究の目的

(1)アトラス検出器を用い、高統計のデータで測定することによって、未踏のエネルギー領域における標準模型の精密検証を行う。本計画研究及びヒッグス（A01)、トップクォーク(A04）に関する計画研究による結果を合わせることで、標準模型の破れを明らかにし、標準模型を超えた新現象の発見を目指す。これら W/Z を伴うジェット事象、特にボトムクォークの生成事象は、超対称性粒子をはじめとした新粒子直接探査時の背景事象となるため、この研究の結果は新粒子発見の

感度を向上に必須である。
(2)次世代素粒子実験では高いルミノシティ環境での高精度測定が行なわれる。ミューオンは、透過性が高いレプトンであり、膨大な背景事象からの効率的な選別が可能で、精密測定の鍵となる。そこで、新しい技術を応用したミューオン検出器、およびフロントエンド・エレクトロニクスを含めた高度なミューオン・トリガーの技術的開発研究を行い、次世代実験への応用へと繋げる。

3．研究の方法

(1) 質量が重く、LHC のエネルギー領域では直接生成できない粒子でも、測定結果と理論予想のズレから 10TeV 付近までの範囲で新現象を間接的に探索できる。間接探索と直接探索（A02）の結果を統合することで、新粒子・新現象を多角的に研究する。特にミューオンへの崩壊チャンネルをもちいて、W/Z 粒子の生成断面積、異常 3 点ゲージ結合の測定を行う。
(2) 標準模型の検証を可能にするには、陽子内部のパートン分布(PDF)が重要となる。HERA 実験等から数%の精度で PDF が分かってきているが、高いエネルギー領域での不定性は大きく、高運動量ジェット生成、W/Z 粒子生成等高い Q^2 領域の素粒子反応から PDF の決定精度を向上させる。
(3)将来の高ルミノシティ LHC 実験のために、マイクロパターンガスチェンバー等の新しい検出器技術を応用したミューオン検出器の開発研究を行う。同時に、読出エレクトロニクスの開発・実用化のための研究を進める。

4．研究成果

(1)LHC 加速器は陽子･陽子衝突実験を順調に行い、重心系 7TeV/8TeV で約 27fb-1、重心系 13TeV で約 4fb-1 の積分ルミノシティのデータを取得した。本計画研究では、このデータを用いて、標準模型を高い精度で検証し、以下のような研究成果を得た。
①W/Z および WW,WZ,ZZ,2 光子生成断面積測定を約 10%の精度で行い、理論予想値と矛盾しない結果を得た。これらの測定結果から、異常 3 点ゲージ結合カップリングとして、Tevatron/LEP の測定より 1 桁以上小さい上限値を得た。
②b-tagging の改良により、高 Pt を持つ Z
粒子の b 崩壊過程や、B_c^+稀崩壊過程の測定を行った。
③ジェット生成反応の断面積測定を行い、QCD Next Leading Order プロセスの計算結果との比較よって、PDF 決定につなげた。低 Pt ジェット生成反応の解析も並行して行い、'Underlying event'の性質について明らかにした。
(2) ミューオン検出器開発については、LHC フェーズ 1 ・アップグレードで計画されている ATLAS ミューオン・スモール・ウィールでの Micromegas 検出器開発を中心に行った。
①Micromegas 検出器の電極の構造・製造方法の開発を行い、アノードに高抵抗電極を用いるこ

とで、中性子による大きな電離損失に起因する放電を大幅に押さえられることがわかり、プロトタイプの製作を行った
②スモール・ウィール検出器を用いたトリガーのための、トリガーアルゴリズム及びトリガープロセッサーの開発を行った。
③LHC フェーズ 2・アップグレードで計画されている高ルミノシティ運転におけるミューオン・トリガーの為に、ドリフトチューブを用いたアルゴリズムについて検討を行い、トリガーレートを削減できることを明らかにした。また、そのための高精度 TDC など放射線耐性をもつフロントエンド・エレクトロニクスの開発を行った。

Measurement of the ZZ Production Cross Section in pp Collisions at $\sqrt{s} = 13$ TeV with the ATLAS Detector

G. Aad *et al.*[*]
(ATLAS Collaboration)

(Received 17 December 2015; published 10 March 2016)

The ZZ production cross section in proton-proton collisions at 13 TeV center-of-mass energy is measured using 3.2 fb^{-1} of data recorded with the ATLAS detector at the Large Hadron Collider. The considered Z boson candidates decay to an electron or muon pair of mass 66–116 GeV. The cross section is measured in a fiducial phase space reflecting the detector acceptance. It is also extrapolated to a total phase space for Z bosons in the same mass range and of all decay modes, giving $16.7^{+2.2}_{-2.0}\,(\text{stat})\,^{+0.9}_{-0.7}\,(\text{syst})\,^{+1.0}_{-0.7}\,(\text{lumi})$ pb. The results agree with standard model predictions.

DOI: 10.1103/PhysRevLett.116.101801

Studying the production of pairs of Z bosons in proton-proton (pp) interactions at the Large Hadron Collider (LHC) tests the electroweak sector of the standard model (SM) at the highest available energies. In pp collisions at a center-of-mass energy of $\sqrt{s} = 13$ TeV, ZZ production is dominated by quark-antiquark ($q\bar{q}$) interactions, with an $\mathcal{O}(10\%)$ contribution from loop-induced gluon-gluon (gg) interactions [1,2]. The SM ZZ production can proceed via a Higgs boson propagator, although this contribution is suppressed in the region where both Z bosons are produced on-shell. As such, non-Higgs ZZ production is an important background in studies of the Higgs boson [3–5]. It is also a background in searches for new physics producing pairs of Z bosons at high invariant mass [6,7] and sensitive to triple neutral-gauge-boson couplings, which are not allowed in the SM [8].

This Letter presents the first measurement of the ZZ production cross section in pp interactions at $\sqrt{s} = 13$ TeV. Throughout it, "Z boson" refers to the superposition of a Z boson and virtual photon with mass in the range 66–116 GeV. The analyzed data correspond to an integrated luminosity of 3.2 ± 0.2 fb^{-1}, collected with the ATLAS detector [9]. The uncertainty of the integrated luminosity is derived, following a methodology similar to that detailed in Ref. [10], from a preliminary calibration of the luminosity scale using a pair of x-y beam-separation scans performed in June 2015. The ZZ production cross section was previously measured at $\sqrt{s} = 7$ and 8 TeV by the ATLAS and CMS Collaborations [11–13] and found to be consistent with SM predictions.

Candidate events are reconstructed in the fully leptonic $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ decay channel where ℓ and ℓ' can be an electron or a muon. The cross section $\sigma^{\text{fid}}_{ZZ\to\ell^+\ell^-\ell'^+\ell'^-}$ is found by counting candidate events, subtracting the expected contribution from background events, correcting for detector effects, and dividing by the integrated luminosity. It is measured in a fiducial phase space that corresponds closely to the experimental acceptance. In addition, an extrapolation of the cross section to a total phase space for Z bosons, σ^{tot}_{ZZ}, is performed. The presented cross-section measurements are inclusive with respect to additional jets. Small contributions from triboson production with two leptonically decaying Z bosons and a third hadronically decaying weak boson and contributions from double parton scattering are included in the measurement.

The fiducial phase space, which is designed to reflect the acceptance of the ATLAS detector (described below), is defined for simulated events by applying the following criteria to the final-state particle-level objects. Final-state electrons and muons are required to be prompt (i.e., to not originate from hadron or τ decay) and their kinematics are computed including the contributions from prompt photons with a distance in η-ϕ coordinates of $\Delta R_{\ell,\gamma} = \sqrt{(\Delta\eta_{\ell,\gamma})^2 + (\Delta\phi_{\ell,\gamma})^2} < 0.1$ between the charged lepton and the photon, as motivated in Ref. [14]. (ATLAS uses a right-handed coordinate system with its origin at the nominal interaction point in the center of the detector and the z axis along the beam pipe. The x axis points to the center of the LHC ring, and the y axis points upward. Cylindrical coordinates (r, ϕ) are used in the transverse plane, ϕ being the azimuthal angle around the z axis. The pseudorapidity is defined in terms of the polar angle θ as $\eta = -\ln[\tan(\theta/2)]$.) The leptons are required to be well separated with $\Delta R_{\ell,\ell'} > 0.2$ between any two leptons. Each lepton must have a momentum component transverse to the beam direction $p_T > 20$ GeV and pseudorapidity $|\eta| < 2.7$. Events must have exactly four leptons satisfying the above

criteria forming two pairs of leptons of the same flavor and oppositely charged ($\mu^+\mu^-$ or e^+e^-). This gives rise to three signal channels: $4e$, 4μ, and $2e2\mu$. Each lepton pair must have an invariant mass in the range 66–116 GeV. In the $4e$ and 4μ channels, where there are two possible ways to form same-flavor oppositely charged lepton pairs, the combination that minimizes $|m_{\ell\ell,a} - m_Z| + |m_{\ell\ell,b} - m_Z|$ is chosen, where $m_{\ell\ell,a}$ and $m_{\ell\ell,b}$ are the invariant masses of the lepton pairs and m_Z is the mass of the Z boson.

The ATLAS detector is a multipurpose particle detector with a cylindrical geometry. It consists of layers of inner tracking detectors, calorimeters, and muon chambers. The inner detector (ID) covers the pseudorapidity range $|\eta| < 2.5$. The calorimeter covers the pseudorapidity range $|\eta| < 4.9$. Within $|\eta| < 2.47$ the finely segmented electromagnetic calorimeter identifies electromagnetic showers and measures their energy and position, providing electron identification together with the ID. The muon spectrometer (MS) surrounds the calorimeters and provides muon identification and measurement in the region $|\eta| < 2.7$ and triggering in the region $|\eta| < 2.4$.

A muon is reconstructed by matching a track (or track segment) reconstructed in the MS to a track reconstructed in the ID. Its momentum is calculated by combining the information from the two systems and correcting for energy deposited in the calorimeters. In regions of limited coverage of the MS ($|\eta| < 0.1$) or outside the ID acceptance ($2.5 < |\eta| < 2.7$), muons can also be reconstructed by matching calorimeter signals consistent with muons to ID tracks (calorimeter-tagged muons) or standalone in the MS [15], respectively.

An electron is reconstructed from an energy deposit (cluster) in the electromagnetic calorimeter matched to a track in the ID. Its momentum is computed from the cluster energy and the direction of the track. Electrons are distinguished from other particles using several identification criteria that rely on the shapes of electromagnetic showers as well as tracking and track-to-cluster matching quantities. The output of a likelihood function taking these quantities as input, similar to that described in Ref. [16], is used to identify electrons. Electrons sharing an ID track with a selected muon are ignored.

The leptons are required to be isolated from other particles using ID track information, and for muons using calorimeter information also (since standalone muons are outside the ID acceptance). The exact requirements depend on the lepton p_T and η and are designed to give a uniform 99% efficiency.

Leptons are required to originate from the primary vertex, defined as the reconstructed vertex with the largest sum of the p_T^2 of the associated tracks. To this end, the longitudinal impact parameter of each lepton track, calculated with respect to the vertex and multiplied by $\sin\theta$ of the track, is required to be less than 0.5 mm. Furthermore, the significance of the transverse impact parameter calculated with respect to the beam line is required to be less than 3 (5) for muons (electrons). Standalone muons are exempt from both impact parameter requirements, as they do not have an ID track.

Candidate events are preselected by either a single-muon or dielectron trigger. As in the fiducial phase space described above, leptons must have $p_T > 20$ GeV. There are slight differences from the fiducial phase space: electrons must satisfy $|\eta| < 2.47$ due to the limited experimental acceptance, and at least one muon in the 4μ channel must satisfy $|\eta| < 2.4$, corresponding to the acceptance of the muon trigger. The other muons must satisfy $|\eta| < 2.7$. Events are ignored if more than one selected muon is calorimeter tagged or standalone. Apart from the above differences, reconstructed candidate events are selected using exactly the same criteria that define the fiducial phase space. A total of 63 events are observed, of which 15, 30, and 18 are in the $4e$, $2e2\mu$, and 4μ channels, respectively.

Monte Carlo (MC)-simulated event samples are used to obtain corrections for detector effects and to estimate background contributions. The principal signal sample is generated with the POWHEG method and framework [17–19], with a diboson event generator [20,21] used to simulate the ZZ production process at next-to-leading order (NLO). (Throughout this Letter, orders of calculations refer to perturbative expansions in the strong coupling constant α_S unless stated otherwise). The simulation of parton showering, of the underlying event, and of hadronization is performed with PYTHIA8 [22,23] using the AZNLO set of tuned parameters (tune) [24]. SHERPA [25–31] is used to generate a sample with the $q\bar{q}$-initiated process simulated at NLO for ZZ plus zero or one additional jet and at leading order (LO) for two or three additional jets, as well as a sample with the loop-induced gg-initiated process simulated at LO with zero or one additional jet. These are used to include the loop-induced gg-initiated production, which is not included in the POWHEG+PYTHIA8 sample, as well as to estimate, by comparison of the various samples, a systematic uncertainty due to the choice of event generator. The CT10 NLO [32] parton distribution functions (PDFs) are used in the event generation for all samples above. Additional samples are generated to estimate the contribution from background events. Triboson events are simulated with SHERPA, using CT10 PDFs, and $t\bar{t}Z$ events are simulated with MADGRAPH [33] interfaced with PYTHIA8 using the NNPDF 2.3 LO PDFs [34] and the A14 tune [35].

In all MC samples, additional pp interactions occurring in the same bunch crossing as the ZZ production, or in nearby ones, are simulated with PYTHIA8 with MSTW 2008 LO PDFs [36] and the A2 tune [37]. The samples are then passed through a simulation of the ATLAS detector [38] based on GEANT4 [39]. Scale factors are applied to the simulated events to correct for the small differences from data in the trigger, reconstruction, identification, isolation,

and impact parameter efficiencies for electrons and muons [15,16]. Furthermore, the lepton momentum scales and resolutions are adjusted to match the data.

Background events from processes with at least four prompt leptons in the final state are estimated with the MC samples described above, including uncertainties from the cross-section values, luminosity, and reconstruction effects. Contributions of 0.07 ± 0.02 events from ZZ processes where at least one Z boson decays to τ leptons, 0.17 ± 0.05 events from nonhadronic triboson processes, and 0.30 ± 0.09 events from all-leptonic $t\bar{t}Z$ processes are predicted. Events from processes with two or three prompt leptons, e.g., Z, WW, WZ, $t\bar{t}$, and ZZ events where one Z boson decays hadronically, where associated jets or photons contain or fake a nonprompt lepton, can pass the event selection. This background contribution is estimated to be $0.09^{+1.08}_{-0.04}$ events, using control samples and a data-driven technique described in Ref. [11]. The uncertainty is dominated by the small number of events in the control samples. It can be asymmetric due to truncation, as background contributions cannot be negative. Background from two single Z bosons produced in different pp collisions in the same bunch crossing is estimated to be negligible. The total expected number of background events is 0.20 ± 0.05 ($0.25^{+0.40}_{-0.05}$, $0.17^{+1.00}_{-0.04}$) in the $4e$ ($2e2\mu$, 4μ) channel, giving a total of $0.62^{+1.08}_{-0.11}$ events.

A factor C_{ZZ} is applied to correct for detector inefficiencies and resolution effects. It relates the background-subtracted number of selected events to the number in the fiducial phase space, and is defined as the ratio of generated signal events passing the selection criteria using reconstructed objects to the number passing the fiducial criteria using generator-level objects. C_{ZZ} is determined with a combination of the POWHEG ZZ MC sample and the SHERPA loop-induced gg-initiated sample. The normalization of the latter is scaled to $\mathcal{O}(\alpha_S^3)$ accuracy [2] in order to improve the model used to correct the measurement. The C_{ZZ} value and its total uncertainty is determined to be 0.55 ± 0.02 ($0.63 \pm 0.02, 0.81 \pm 0.03$) in the $4e$ ($2e2\mu$, 4μ) channel. The dominant systematic uncertainties come from the uncertainties of the scale factors used to correct lepton reconstruction and identification efficiencies in the simulation and the choice of MC generator. Other smaller uncertainties come from the scale and resolution of the lepton momenta, PDFs, and statistical fluctuations in the MC sample. Table I gives a breakdown of the systematic uncertainties.

Figure 1 shows the invariant mass of the leading-$p_{T,\ell\ell}$ and the subleading-$p_{T,\ell\ell}$ lepton pair ($\ell\ell$), as well as the invariant mass, transverse momentum, and rapidity of the four-lepton system. Distributions from data are compared to the signal and background expectations, with good agreement in general.

The fiducial cross section is determined using a maximum-likelihood fit to the event counts in the three signal channels. A Poisson probability function is used to parametrize the number of expected events, multiplied by Gaussian distributions that model the nuisance parameters representing systematic uncertainties. This procedure can lead to asymmetric uncertainties as Poisson-distributed variables cannot be negative.

TABLE I. Relative uncertainties of the correction factor C_{ZZ} by signal channel, expressed in percent.

Source	$4e$	$2e2\mu$	4μ
Statistical (signal samples)	0.7	0.5	0.5
Theoretical (generator, PDFs)	2.5	2.5	2.5
Experimental efficiencies	2.3	2.2	2.0
Momentum scales and resolutions	0.4	0.2	0.1
Total	3.5	3.3	3.2

The cross section measured in the fiducial phase space is also extrapolated to the total phase space, which includes a correction for QED final-state radiation effects. The extrapolation factor is obtained from the same combination of MC samples as used in the C_{ZZ} determination. The ratio of the fiducial to full phase-space cross section is 0.39 ± 0.02, in all three channels. It is corrected for the $\sim$3% increase bias introduced by the pairing algorithm in the $4e$ and 4μ channels. The dominant systematic uncertainty comes from the difference between the nominal value and that obtained using the SHERPA samples. Smaller uncertainties are derived from PDF variations in the CT10 error set, differences between using PYTHIA8 and HERWIG++ [40] for simulating the rest of the event, and varying the QCD renormalization and factorization scales independently by a factor of 2. In order to extrapolate to the total cross section, the fiducial cross sections are divided by the ratio 0.39 ± 0.02 and corrected for the leptonic branching fraction $(3.3658\%)^2$ [41] (this value excludes γ^* contributions; including these, the branching fraction $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ is about 1.01–1.02 times larger).

The measured fiducial cross sections are shown in Table II and Fig. 2(a) along with a comparison to $\mathcal{O}(\alpha_S^2)$ calculations [1]. Table II also shows the total combined cross section. The CT10 next-to-next-to-leading order PDFs [45] and a dynamic scale equal to the mass of the four-lepton system are used in the calculation. The loop-induced gg-initiated process is included, and contributes 7.0% (5.8%) of the cross section in the fiducial (total) phase space. The predicted cross sections in the fiducial phase space are corrected for QED final-state radiation effects, which amount to a 4% reduction. The measurements agree with the SM predictions.

The theoretical predictions do not include the following effects. The loop-induced gg-initiated process calculated at $\mathcal{O}(\alpha_S^2)$ could receive large corrections at $\mathcal{O}(\alpha_S^3)$ of 70% [2], which would increase the prediction by 4%–5%. Electroweak corrections at next-to-leading order [46,47]

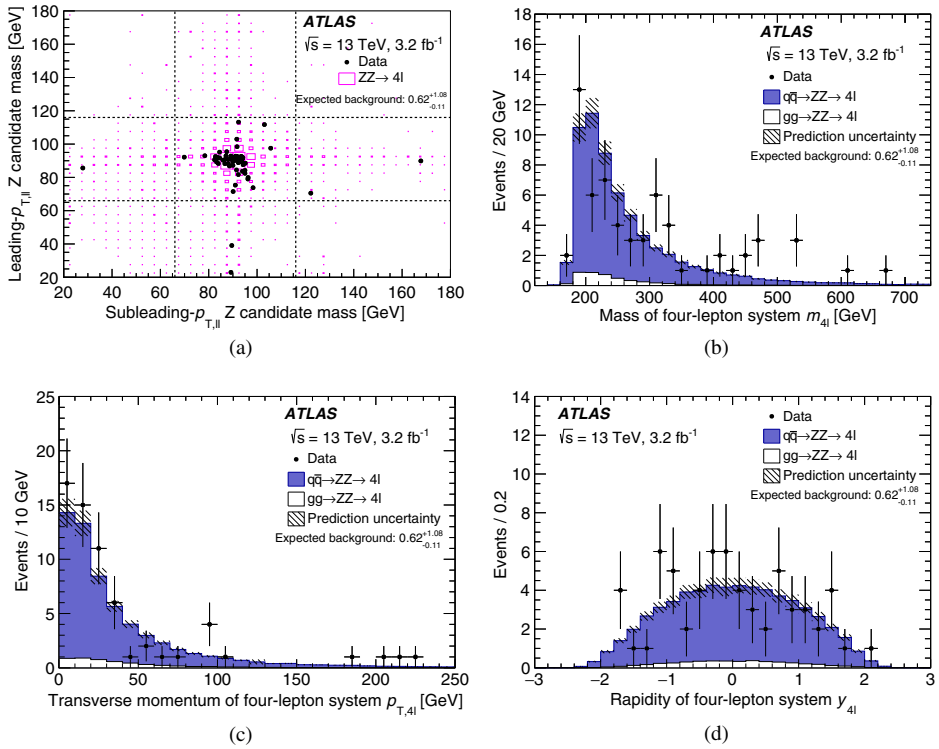

FIG. 1. (a) Invariant mass $m_{\ell\ell}$ of the leading-$p_{T,\ell\ell}$ vs the subleading-$p_{T,\ell\ell}$ lepton pair ($\ell\ell$), before the requirement 66 GeV $< m_{\ell\ell} <$ 116 GeV is applied. The dashed lines indicate this requirement. (b) Invariant mass, (c) transverse momentum, and (d) rapidity of the four-lepton system in selected events. The points represent experimental data. The filled histograms show the signal prediction from simulation, including the $q\bar{q}$ and loop-induced gg-initiated process. The contributions are stacked. In the simulation, the prediction from POWHEG+PYTHIA8 combined with SHERPA is scaled to the $\mathcal{O}(\alpha_S^2)$ prediction. The uncertainties in the simulation are from the same sources as the C_{ZZ} uncertainty. In addition, 6% ZZ cross-section uncertainty and 5% integrated-luminosity uncertainty are included. The expected background of $0.62^{+1.08}_{-0.11}$ events is not shown as a histogram due to its small size.

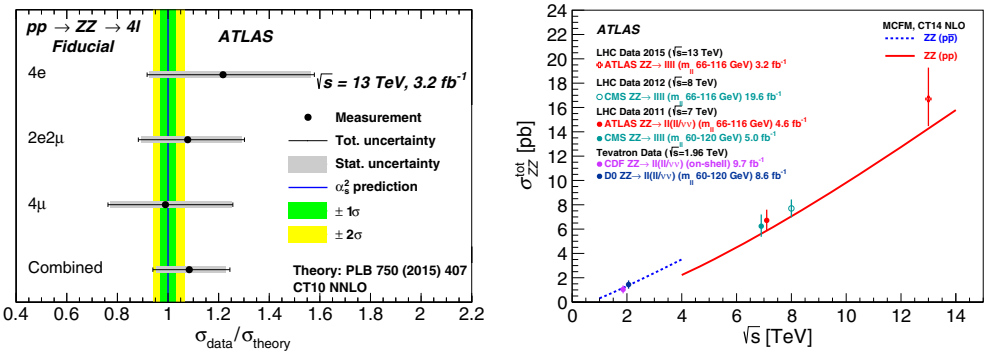

are expected to reduce the cross section by 7%–8% [47]. Furthermore, the contribution from double parton scattering is not accounted for, but is expected to be an effect of less than 1% [48].

The measured total cross section is compared to measurements at lower center-of-mass energies and to a prediction from MCFM [49] with the CT14 NLO PDFs [50], which is calculated at $\mathcal{O}(\alpha_S^1)$ accuracy for the $q\bar{q}$-initiated process and at $\mathcal{O}(\alpha_S^2)$ accuracy for the loop-induced gg-initiated process and is shown vs center-of-mass energy in Fig. 2(b). The cross section increases by a factor of more than 2 with a center-of-mass energy increase from 8 TeV to 13 TeV.

In summary, ATLAS has measured the ZZ production cross section in 3.2 fb^{-1} of 13 TeV pp collisions at the LHC using the fully leptonic decay channel $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$. Fiducial cross sections as well as a total cross section for Z bosons with mass 66–116 GeV have been measured and agree well with $\mathcal{O}(\alpha_S^2)$ SM predictions.

TABLE II. Cross-section measurement results compared to the $\mathcal{O}(\alpha_S^2)$ standard model predictions. The per-channel and combined fiducial cross sections are shown along with the combined total cross section. For experimental results, the statistical, systematic, and luminosity uncertainties are shown. For theoretical predictions, the PDF and renormalization and factorization scale uncertainties added in quadrature are shown.

(a) (b)

FIG. 2. (a) Comparison between measured fiducial cross sections and $\mathcal{O}(\alpha_S^2)$ predictions. (b) Total cross section compared to measurements at lower center-of-mass energies by ATLAS, CMS, CDF, and D0 [11–13,42,43], and to a prediction from MCFM at $\mathcal{O}(\alpha_S^1)$ accuracy for the $q\bar{q}$-initiated process and at $\mathcal{O}(\alpha_S^2)$ accuracy for the loop-induced gg-initiated process. A full $\mathcal{O}(\alpha_S^2)$ prediction (known to improve agreement at $\sqrt{s} = 13$ TeV) was not yet available for all the different center-of-mass energies. Some data points are shifted horizontally to improve readability. The ZZ cross section as function of $\sqrt{s}$ in the range 130–209 GeV was also measured at the LEP 2 e^+e^- collider [44].

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently. We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWFW and FWF, Austria; ANAS, Azerbaijan; SSTC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR and VSC CR, Czech Republic; DNRF, DNSRC and Lundbeck Foundation, Denmark; IN2P3-CNRS, CEA-DSM/IRFU, France; GNSF, Georgia; BMBF, HGF, and MPG, Germany; GSRT, Greece; RGC, Hong Kong SAR, China; ISF, I-CORE and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; RCN, Norway; MNiSW and NCN, Poland; FCT, Portugal; MNE/IFA, Romania; MES of Russia and NRC KI, Russian Federation; JINR; MSTD, Serbia; MSSR, Slovakia; ARRS and MIZŠ, Slovenia; DST/NRF, South Africa; MINECO, Spain; SRC and Wallenberg Foundation, Sweden; SERI, SNSF and Cantons of Bern and Geneva, Switzerland; MOST, Taiwan; TAEK, Turkey; STFC, United Kingdom; DOE and NSF, United States of America. In addition, individual groups and members have received support from BCKDF, the Canada Council, CANARIE, CRC, Compute Canada, FQRNT, and the Ontario Innovation Trust, Canada; EPLANET, ERC, FP7, Horizon 2020 and Marie Skłodowska-Curie Actions, European Union; Investissements d'Avenir Labex and Idex, ANR, Region Auvergne and Fondation Partager le Savoir, France; DFG and AvH Foundation, Germany; Herakleitos, Thales and Aristeia programmes co-financed by EU-ESF and the Greek NSRF; BSF, GIF and Minerva, Israel; BRF, Norway; the Royal Society, and Leverhulme Trust, United Kingdom. The crucial computing support from all WLCG partners is acknowledged gratefully, in particular from CERN and the ATLAS Tier-1 facilities at TRIUMF (Canada), NDGF (Denmark, Norway, Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy), NL-T1 (Netherlands), PIC (Spain), ASGC (Taiwan), RAL (UK), and BNL (USA) and in the Tier-2 facilities worldwide.

Measurement of four-jet differential cross sections in $\sqrt{s} = 8$ TeV proton-proton collisions using the ATLAS detector

The ATLAS collaboration

E-mail: atlas.publications@cern.ch

Abstract: Differential cross sections for the production of at least four jets have been measured in proton-proton collisions at $\sqrt{s} = 8$ TeV at the Large Hadron Collider using the ATLAS detector. Events are selected if the four anti-k_t $R = 0.4$ jets with the largest transverse momentum (p_{T}) within the rapidity range $|y| < 2.8$ are well separated ($\Delta R_{4\mathrm{j}}^{\mathrm{min}} > 0.65$), all have $p_{\mathrm{T}} > 64$ GeV, and include at least one jet with $p_{\mathrm{T}} > 100$ GeV. The dataset corresponds to an integrated luminosity of 20.3 fb^{-1}. The cross sections, corrected for detector effects, are compared to leading-order and next-to-leading-order calculations as a function of the jet momenta, invariant masses, minimum and maximum opening angles and other kinematic variables.

1 Introduction

The production of particle jets at hadron colliders such as the Large Hadron Collider (LHC) [1] provides a fertile testing ground for the theory describing strong interactions, Quantum Chromodynamics (QCD). In QCD, jet production is interpreted as the fragmentation of quarks and gluons produced in the scattering process followed by their subsequent hadronisation. At high transverse momenta (p_{T}) the scattering of partons can be calculated using perturbative QCD (pQCD) and experimental jet measurements are directly related to the scattering of quarks and gluons. The large cross sections for such processes allow for differential measurements in a wide kinematic range and stringent testing of the underlying theory.

JHEP12(2015)105

This analysis studies events where at least four jets are produced in a hard-scatter process. These events are of particular interest as the corresponding Feynman diagrams require several vertices even at leading-order (LO) in the strong coupling constant α_S. The current state-of-the-art theoretical predictions for such processes are at next-to-leading-order in α_S (next-to-leading-order perturbative QCD, NLO pQCD) [2, 3],[1] and they have recently been combined with parton shower (PS) simulations [4]. An alternative approach is taken by generators which provide a matrix element (ME) for the hardest $2 \to 2$ process while the rest of the jets are provided by a PS model, which implements a resummation of the leading-logarithmic terms (e.g. Pythia 8 [5] and Herwig++ [6]). It is also interesting to test multi-leg (i.e., $2 \to n$) LO pQCD generators (e.g. Sherpa [7] or MadGraph [8]), since they may provide adequate descriptions of the data in specific kinematic regions and have the advantage of being less computationally expensive than NLO calculations.

It is interesting to note that the previous ATLAS measurement of multi-jet production at $\sqrt{s} = 7\,\text{TeV}$ [9] indicates that predictions may differ from data by $\sim 30\%$ even at NLO [10]. This work explores a variety of kinematic regimes and topological distributions to test the validity of QCD calculations, including the PS approximation and the necessity of higher-order ME in Monte Carlo (MC) generators.

Additionally, four-jet events represent a background to many other processes at hadron colliders. Hence, the predictive power of the QCD calculations, in particular their ability to reproduce the shapes of the distributions studied in this analysis, is of general interest. While searches for new phenomena in multi-jet events use data-driven techniques to estimate the contribution from QCD events, as was done for example in ref. [11], these methods are tested in MC simulations. The accuracy of the theoretical predictions remains therefore important.

Three-jet events have been measured differentially by many experiments. Indeed it was observations of such events that heralded the discovery of the gluon [12–15]. More recently, at the LHC, ATLAS has measured the three-jet cross section differentially [16] and CMS has used the ratio of three to two jet events to measure α_S [17]. Event shape variables have also been measured, showing sensitivity to higher-order pQCD effects [18, 19]. Multi-jet cross sections have been measured previously at CMS [20], ATLAS [9], CDF [21, 22] and D0 [23, 24], although with smaller datasets and/or lower energy, and generally focussed on different observables.

This paper presents the differential cross sections for events with at least four jets, studied as a function of a variety of kinematic and topological variables which include momenta, masses and angles. Events are selected if the four anti-k_t $R = 0.4$ jets with the largest transverse momentum within the rapidity range $|y| < 2.8$ are well separated, all have $p_T > 64\,\text{GeV}$, and include at least one jet with $p_T > 100\,\text{GeV}$. The measurements are corrected for detector effects. The variables are binned in the leading jet p_T and the total invariant mass, such that different regimes and configurations can be tested. The measurements are sensitive to the various mass scales in an event, the presence of forward

[1] We thank Dr D. Maître (Durham University, U.K.) for providing the BlackHat histograms that were compared with the data.

JHEP12(2015)105

jets, or the azimuthal configuration of the jets — that is, one jet recoiling against three, or two recoiling against two.

The structure of the paper is as follows. Section 2 introduces the ATLAS detector. The observables and phase space of interest are defined in section 3. The MC simulation samples studied in this work are summarised in section 4, while the theory predictions and their uncertainties are described in section 5. The trigger, jet calibration and data cleaning are presented in section 6. The unfolding of detector effects is detailed in section 7. Section 8 provides the experimental uncertainties included in the final distributions. Finally, the results are shown in section 9 and the conclusions are drawn in section 10.

2 The ATLAS detector

The ATLAS experiment [25] is a multi-purpose particle physics detector with a forward-backward symmetric cylindrical geometry and nearly 4π coverage in solid angle, with instrumentation up to $|\eta| = 4.9$.[2]

The layout of the detector is based on four superconducting magnet systems, which comprise a thin solenoid surrounding the inner tracking detectors (ID) and a barrel and two end-cap toroids generating the magnetic field for a large muon spectrometer. The calorimeters are located between the ID and the muon system. The lead/liquid-argon (LAr) electromagnetic (EM) calorimeter is split into two regions: the barrel ($|\eta| < 1.475$) and the end-cap ($1.375 < |\eta| < 3.2$). The hadronic calorimeter is divided into four regions: the barrel ($|\eta| < 0.8$) and the extended barrel ($0.8 < |\eta| < 1.7$) made of scintillator/steel, the end-cap ($1.5 < |\eta| < 3.2$) with LAr/copper modules, and the forward calorimeter ($3.1 < |\eta| < 4.9$) composed of LAr/copper and LAr/tungsten modules.

A three-level trigger system [26] is used to select events for further analysis. The first level (L1) of the trigger reduces the event rate to less than 75 kHz using hardware-based trigger algorithms acting on a subset of detector information. The second level (L2) uses fast online algorithms, while the final trigger stage, called the Event Filter (EF), uses reconstruction software with algorithms similar to the offline versions. The last two software-based trigger levels, referred to collectively as the High-Level Trigger (HLT), further reduce the event rate to about 400 Hz.

3 Cross-section definition

This measurement uses jets reconstructed with the anti-k_t algorithm [27] with four-momentum recombination as implemented in the FastJet package [28]. The radius parameter is $R = 0.4$.

Cross sections are calculated for events with at least four jets within the rapidity range $|y| < 2.8$. Out of those four jets, the leading one must have $p_{\mathrm{T}} > 100$ GeV, while

[2] ATLAS uses a right-handed Cartesian coordinate system with its origin at the nominal interaction point (IP) in the centre of the detector. The z-axis is taken along the beam pipe, and the x-axis points from the IP to the centre of the LHC ring. Cylindrical coordinates (r, ϕ) are used in the transverse plane, ϕ being the azimuthal angle around the beam pipe. The rapidity y is defined by $\frac{1}{2} \ln \frac{E+p_z}{E-p_z}$, the pseudorapidity in terms of the polar angle θ as $\eta = -\ln \tan(\theta/2)$.

Name	Definition	Comment
$p_{\mathrm{T}}^{(i)}$	Transverse momentum of the ith jet	Sorted descending in p_{T}
H_{T}	$\sum_{i=1}^{4} p_{\mathrm{T}}^{(i)}$	Scalar sum of the p_{T} of the four jets
$m_{4\mathrm{j}}$	$\left(\left(\sum_{i=1}^{4} E_i\right)^2 - \left(\sum_{i=1}^{4} \mathbf{p}_i\right)^2\right)^{1/2}$	Invariant mass of the four jets
$m_{2\mathrm{j}}^{\mathrm{min}}/m_{4\mathrm{j}}$	$\min_{\substack{i,j\in[1,4]\\ i\neq j}} \left((E_i+E_j)^2 - (\mathbf{p}_i+\mathbf{p}_j)^2\right)^{1/2} \Big/ m_{4\mathrm{j}}$	Minimum invariant mass of two jets relative to invariant mass of four jets
$\Delta\phi_{2\mathrm{j}}^{\mathrm{min}}$	$\min_{\substack{i,j\in[1,4]\\ i\neq j}} (\lvert\phi_i - \phi_j\rvert)$	Minimum azimuthal separation of two jets
$\Delta y_{2\mathrm{j}}^{\mathrm{min}}$	$\min_{\substack{i,j\in[1,4]\\ i\neq j}} (\lvert y_i - y_j\rvert)$	Minimum rapidity separation of two jets
$\Delta\phi_{3\mathrm{j}}^{\mathrm{min}}$	$\min_{\substack{i,j,k\in[1,4]\\ i\neq j\neq k}} (\lvert\phi_i - \phi_j\rvert + \lvert\phi_j - \phi_k\rvert)$	Minimum azimuthal separation between any three jets
$\Delta y_{3\mathrm{j}}^{\mathrm{min}}$	$\min_{\substack{i,j,k\in[1,4]\\ i\neq j\neq k}} (\lvert y_i - y_j\rvert + \lvert y_j - y_k\rvert)$	Minimum rapidity separation between any three jets
$\Delta y_{2\mathrm{j}}^{\mathrm{max}}$	$\Delta y_{ij}^{\mathrm{max}} = \max_{i,j\in[1,4]} (\lvert y_i - y_j\rvert)$	Maximum rapidity difference between two jets
$\Sigma p_{\mathrm{T}}^{\mathrm{central}}$	$\lvert p_{\mathrm{T}}^{c}\rvert + \lvert p_{\mathrm{T}}^{d}\rvert$	If $\Delta y_{2\mathrm{j}}^{\mathrm{max}}$ is defined by jets a and b, this is the scalar sum of the p_{T} of the other two jets, c and d ('central' jets)

Table 1. Definitions of the various kinematic variables measured. Only the four jets with the largest p_{T} are considered in all cases.

the next three must have $p_{\mathrm{T}} > 64\,\mathrm{GeV}$. In addition, these four jets must be well separated from one another by $\Delta R_{4\mathrm{j}}^{\mathrm{min}} > 0.65$, where $\Delta R_{4\mathrm{j}}^{\mathrm{min}} = \min_{\substack{i,j\in[1,4]\\ i\neq j}}(\Delta R_{ij})$, and $\Delta R_{ij} = (|y_i - y_j|^2 + |\phi_i - \phi_j|^2)^{1/2}$. This set of criteria is also referred to as the 'inclusive analysis cuts' to differentiate them from the cases where additional requirements are made, for example on the invariant mass of the four leading jets. The inclusive analysis cuts are mainly motivated by the triggers used to select events, described in section 6.1.

Cross sections are measured differentially as a function of the kinematic variables defined in table 1; the list includes momentum variables, mass variables and angular variables. The only jets used in all cases are the four leading ones in p_{T}. The observables were selected for their sensitivity to differences between different Monte Carlo models of QCD processes and their ability to describe the dynamics of the events. For example, the H_{T} variable is often used to set the scale of multi-jet processes. The four-jet invariant mass $m_{4\mathrm{j}}$ is representative of the largest energy scale in the event whereas $m_{2\mathrm{j}}^{\mathrm{min}}$, the minimum dijet invariant mass, probes the smallest jet-splitting scale. The ratio $m_{2\mathrm{j}}^{\mathrm{min}}/m_{4\mathrm{j}}$ therefore provides information about the range of energy scales relevant to the QCD calculation. The $\Delta\phi_{2\mathrm{j}}^{\mathrm{min}}$ and $\Delta y_{2\mathrm{j}}^{\mathrm{min}}$ variables quantify the minimum angular separation between any two jets. The azimuthal variable $\Delta\phi_{3\mathrm{j}}^{\mathrm{min}}$ distinguishes events with pairs of nearby jets (which

Table 2. Summary of the analysed phase-space regions, including the $p_T^{(1)}$, m_{4j} and Δy_{2j}^{max} bins into which each of the differential cross-section measurements is split (a dash indicates when the cut is not applied on a variable). The ΔR_{4j}^{min} and $p_T^{(4)}$ requirements, specified in the second and third columns respectively, apply to all variables. The observables are defined in table 1.

have large $\Delta\phi_{3j}^{min}$) from the recoil of three jets against one (leading to small $\Delta\phi_{3j}^{min}$ values). The rapidity variable Δy_{3j}^{min} works in a similar way. The Δy_{2j}^{max} and $\Sigma p_T^{central}$ variables are designed to be sensitive to events with forward jets. In order to build $\Sigma p_T^{central}$, first the two jets with the largest rapidity interval in the event are identified, and then the scalar sum of the p_T of the remaining two jets is calculated.

Different phase-space regions are probed by binning the variables in regions defined by a lower bound on $p_T^{(1)}$ and m_{4j}. This allows one to distinguish between the two types of topologies characterised by $\Delta\phi_{3j}^{min}$, or to track the position of the leading jet with respect to the forward-backward pair in the $\Sigma p_T^{central}$ variables. Table 2 summarises all the phase-space regions considered in the analysis for each of the variables.

The resulting differential cross-section distributions are corrected for detector effects (*unfolding*) and taken to the so-called particle-jet level, or simply 'particle level'. In the MC simulations used in the unfolding procedure, particle jets are built from particles with a proper lifetime τ satisfying $c\tau > 10$ mm, including muons and neutrinos from hadron decays. The event selection described above is applied to particle jets to define the phase space of the unfolded results.

Double parton interactions have not been investigated independently, so the measurement is inclusive in this respect. They are expected to contribute 1% or less to the results.

4 Monte Carlo samples

Monte Carlo samples are used to estimate experimental systematic uncertainties, deconvolve detector effects, and provide predictions to be compared with the data. Leading-order Monte Carlo samples are used for all three purposes. A set of theoretical calculations at higher orders, described in section 5, are also compared to the data. The full list of generators is shown in table 3.

[†]The HEJ sample is based on an approximation to all orders in α_S.

Table 3. The generators used for comparison against the data are listed, together with the parton distribution functions (PDFs), PS algorithms, underlying event (UE) and parameter tunes. Each MC prediction is multiplied by a normalisation factor (last column) as described in section 5.1, except BlackHat/Sherpa and NJet/Sherpa.

The samples used in the experimental studies comprise two LO $2 \to 2$ generators, Pythia 8.160 [5] and Herwig++ 2.5.2 [6], and the LO multi-leg generator MadGraph5 v1.5.12 [8]. As described in the introduction, LO generators are still widely used in searches for new physics, which motivates the comparison of their predictions to the data.

Both Pythia and Herwig++ employ leading-logarithmic PS models matched to LO ME calculations. Pythia uses a PS algorithm based on p_T ordering, while the PS model implemented in Herwig++ follows an angular ordering. The ME calculation provided by MadGraph contains up to four outgoing partons in the ME. It is matched to a PS generated with Pythia 6.427 [29] using the shower k_t-jet MLM matching [30], where the jet-parton matching scale is set to 20 GeV. Hadronisation effects are included via the string model in the case of the Pythia and MadGraph samples [29], or the cluster model [31] in events simulated with Herwig++. The parton distribution functions (PDFs) used are the NLO CT10 [32] or the LO distributions of CTEQ6L1 [33] as shown in table 3.

Simulations of the underlying event, including multiple parton interactions, are included in all three LO samples. The parameter tunes employed are the ATLAS tunes AU2 [34] and AUET2B [35] for Pythia and MadGraph respectively, and the Herwig++ tune UE-EE-3 [36].

The multiple pp collisions within the same and neighbouring bunch crossings (pile-up) are simulated as additional inelastic pp collisions using Pythia 8. Finally, the interaction of particles with the ATLAS detector is simulated using a GEANT4-based program [37, 38].

5 Theoretical predictions

The results of the measurement are compared to NLO predictions, in addition to the LO samples described in section 4. These are calculated using BlackHat/Sherpa [2, 3] and NJet/Sherpa [39, 40], and have been provided by their authors. They are both fixed-order calculations with no PS and no hadronisation. Therefore, the results are presented at the parton-jet level, that is, using jets built from partons instead of hadrons. For the high-

JHEP12(2015)105

p_{T} phase space covered in this analysis, non-perturbative corrections are expected to be small [41, 42]. BlackHat performs one-loop virtual corrections using the unitarity method and on-shell recursion. The remaining terms of the full NLO computation are obtained with AMEGIC++ [43, 44], part of Sherpa. NJet makes a numerical evaluation of the one-loop virtual corrections to multi-jet production in massless QCD. The Born matrix elements are evaluated with the Comix generator [45, 46] within Sherpa. Sherpa also performs the phase-space integration and infra-red subtraction via the Catani-Seymour dipole formalism. Both the BlackHat/Sherpa and NJet/Sherpa predictions use the CT10 PDFs.

The results are also compared to predictions provided by HEJ [47–49].[3] HEJ is a fully exclusive Monte Carlo event generator based on a perturbative cross-section calculation which approximates the hard-scattering ME to all orders in the strong coupling constant α_{S} for jet multiplicities of two or greater. The approximation is exact in the limit of large separation in rapidity between partons. The calculation uses the CT10 PDFs. As in the case of the NLO predictions, no PS or hadronisation are included.

The different predictions tested are expected to display various levels of agreement in different kinematic configurations. The generators which combine $2 \to 2$ parton matrix elements (MEs) with parton showers (PSs) are in principle not expected to provide a good description of the data, particularly in regions where the additional jets are neither soft nor collinear. A previous measurement of multi-jet cross sections at 7 TeV by the ATLAS Collaboration [9] found that the cross section predicted by MC models typically disagreed with the data by $\mathcal{O}(40\%)$. It also found disagreements of up to 50% in the shape of the differential cross section measured as a function of $p_{\mathrm{T}}^{(1)}$ or H_{T}. Nevertheless, there are also examples of exceptional cases where these calculations perform well, which adds interest to the measurement; for example, the same 7 TeV ATLAS paper observed that the shape of the $p_{\mathrm{T}}^{(4)}$ distribution was described by Pythia within just 10%. It is also interesting to test whether PSs based on an angular ordering perform better in angular variables such as $\Delta\phi_{2\mathrm{j}}^{\mathrm{min}}$ or $\Delta\phi_{3\mathrm{j}}^{\mathrm{min}}$ than those using momentum ordering. In contrast to PS predictions, multi-leg matrix element calculations matched to parton showers (ME+PS) were seen at 7 TeV to significantly improve the accuracy of the cross-section calculation and the shapes of the momentum observables. In the present analysis, such calculations are expected to perform better in events with additional high-p_{T} jets and/or large combined invariant masses of jets. This is also the type of scenario where HEJ is expected to perform well, since it provides an all-order description of processes with more than two hard jets, and it is designed to capture the hard, wide-angle emissions which a standalone PS approach would miss. Variables such as $\Delta y_{2\mathrm{j}}^{\mathrm{max}}$, $\Delta y_{3\mathrm{j}}^{\mathrm{min}}$ or $\Sigma p_{\mathrm{T}}^{\mathrm{central}}$ were included in the analysis with this purpose in mind. Finally, the fixed-order, four-jet NLO predictions are expected to provide a better estimation of the cross sections than the LO calculations. Interestingly, studies at 7 TeV found that the NLO cross section for four-jet events was $\sim 30\%$ higher than the data [10].

[3] We thank Dr J. Andersen and Dr T. Hapola (Durham University, U.K.) for providing the histograms for the HEJ predictions.

JHEP12(2015)105

5.1 Normalisation

To facilitate comparison with the data, the cross sections predicted by the LO generators as well as HEJ are multiplied by a scale factor. The factor is such that the integrated number of events in the region $500\,\text{GeV} < p_{\text{T}}^{(1)} < 1.5\,\text{TeV}$ which satisfy the inclusive analysis cuts in section 3 is equal to the corresponding number in data. The full set of normalisation factors is shown in table 3. No scale factor is ascribed to BlackHat/Sherpa and NJet/Sherpa such that the level of agreement with data can be assessed in light of the theoretical uncertainties, as discussed in section 5.2.

5.2 Theoretical uncertainties

Theoretical uncertainties have been computed for HEJ and the NLO predictions. The sensitivity of the HEJ calculation to higher-order corrections was determined by the authors of the calculation by varying independently the renormalisation and factorisation scales by factors of $\sqrt{2}$, 2, $1/\sqrt{2}$ and 1/2 around the central value of $H_{\text{T}}/2$. The total uncertainty is the result of taking the envelope of all the variations. The typical size of the uncertainty is $^{+50\%}_{-30\%}$, and it is not drawn on the figures for clarity.

The central value of the renormalisation and factorisation scales used in the NJet/Sherpa and BlackHat/Sherpa samples is also $H_{\text{T}}/2$. Scale uncertainties are evaluated for NJet/Sherpa by simultaneously varying both scales by factors of 1/2 and 2. PDF uncertainties are obtained by reweighting the distributions for all the PDF error sets using LHAPDF [50], following the recommendations from ref. [51]. The additional PDF sets include variations in the value of α_{S}. The sum in quadrature of the resulting scale and PDF variations defines the NLO theoretical uncertainty included in the result figures in section 9. The uncertainty is dominated by the scale component due to the rapid drop of the cross section with decreasing values of the renormalisation and factorisation scales. As a result, the uncertainty is significantly asymmetric.

6 Data selection and calibration

The data sample used was taken during the period from March to December 2012 with the LHC operating at a pp centre-of-mass energy of $\sqrt{s} = 8\,\text{TeV}$. The application of data-quality requirements results in an integrated luminosity of $20.3\,\text{fb}^{-1}$.

6.1 Trigger

The events used in this analysis are selected by a combination of four jet triggers, consisting of the three usual levels and defined in terms of the jets produced in the event. The hardware-based L1 trigger provides a fast decision based on the energy measured by the calorimeter. The L2 trigger performs a simple jet reconstruction procedure in the geometric regions identified by the L1 trigger. The final decision taken by the EF trigger is made using jets from the region of $|\eta| < 3.2$, and reconstructed from topological clusters [52] using the anti-k_t algorithm with $R = 0.4$.

The four different triggers used in this paper are shown in figure 1. Two of the triggers select events with at least four jets, while the remaining two select events with at least

JHEP12(2015)105

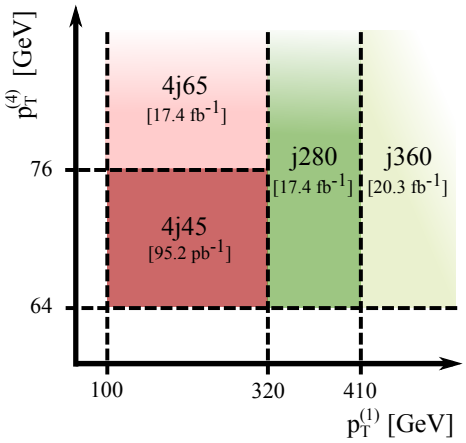

Figure 1. Schematic of the kinematic regions in which the four different jet triggers are used, including the total luminosity that each of them recorded. The term 4j45 (4j65) refers to a trigger requiring at least four jets with $p_{\mathrm{T}} > 45\,\mathrm{GeV}$ (65 GeV), where the p_{T} is measured at the EF level of the triggering system. The term j280 (j360) refers to a trigger requiring at least one jet with $p_{\mathrm{T}} > 280\,\mathrm{GeV}$ (360 GeV) at the EF level. The horizontal and vertical axes correspond to $p_{\mathrm{T}}^{(1)}$ and $p_{\mathrm{T}}^{(4)}$ respectively, both calculated at the offline level (i.e., including the full object calibration).

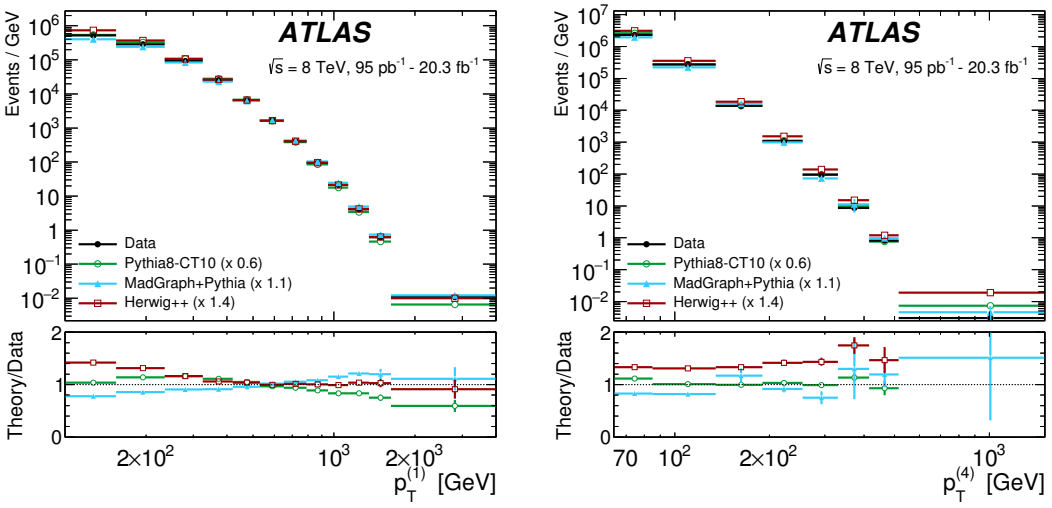
one jet at a higher p_{T} threshold. Events are split into the four non-overlapping kinematic regions shown in figure 1, requiring at least four well-separated jets with varying p_{T} thresholds in order to apply the corresponding trigger. This ensures trigger efficiencies greater than 99% for any event passing the inclusive analysis cuts. The small residual loss of data due to trigger inefficiency is corrected as a function of jet p_{T} using the techniques described in section 7.

As noted in figure 1, three out of the four triggers only recorded a fraction of the total dataset. The contributions from the events selected by those three triggers are scaled by the inverse of the corresponding fraction.



6.2 Jet reconstruction and calibration

Jets are reconstructed using the anti-k_t jet algorithm [27] with four-momentum recombination and radius parameter $R = 0.4$. The inputs to the jet algorithm are locally-calibrated topological clusters of calorimeter cells [52], which reconstruct the three-dimensional shower topology of each particle entering the calorimeter.

ATLAS has developed several jet calibration schemes [53] with different levels of complexity and different sensitivities to systematic effects. In this analysis the local cluster weighting (LCW) calibration [52] method is used, which classifies topological clusters as either being of electromagnetic or hadronic origin. Based on this classification, specific energy corrections are applied, improving the jet energy resolution. The final jet energy calibration, generally referred to as the jet energy scale, corrects the average calorimeter response to reproduce the energy of the true particle jet.

The jet energy scale and resolution have been measured in pp collision data using techniques described in references [54–56]. The effects of pile-up on jet energies are accounted

JHEP12(2015)105

(a) $p_{\mathrm{T}}^{(1)}$. **(b)** $p_{\mathrm{T}}^{(4)}$.

Figure 2. Detector-level distributions of (a) $p_{\mathrm{T}}^{(1)}$ and (b) $p_{\mathrm{T}}^{(4)}$ for data and for example MC predictions. The MC predictions have passed through detector simulation. The lower panel in each plot shows the ratios of the MC predictions to data. For better comparison, the predictions are multiplied by the factors indicated in the legend.

for by a jet-area-based correction [57] prior to the final calibration, where the area of the jet is defined in η–ϕ space. Jets are then calibrated to the hadronic energy scale using p_{T}- and η-dependent calibration factors based on MC simulations, and their response is corrected based on several observables that are sensitive to fragmentation effects. A residual calibration is applied to take into account differences between data and MC simulation based on a combination of several in-situ techniques [54].

6.3 Data quality criteria

Before applying the selection that defines the kinematic region of interest, events are required to pass the trigger, as described in section 6.1, and to contain a primary vertex with at least two tracks. Events which contain energy deposits in the calorimeter consistent with noise, or with incomplete event data, are rejected. In addition, events containing jets pointing to problematic calorimeter regions, or originating from non-collision background, cosmic rays or detector effects, are vetoed. These cleaning procedures are emulated in the MC simulation used to correct for experimental effects, as is discussed in detail in section 7.

No attempt is made to exclude jets that result from photons or leptons impacting the calorimeter, nor are the contributions from such signatures corrected for. Events containing photons or τ leptons are expected to contribute less than 0.1% to the cross sections under study.

Distributions of two example variables ($p_{\mathrm{T}}^{(1)}$ and $p_{\mathrm{T}}^{(4)}$) can be seen at the detector level (i.e. prior to unfolding detector effects) in figure 2. Different sets of points correspond to the data and the different MC generators, which are normalised to data with the scale

JHEP12(2015)105

factors indicated in table 3. These are constant factors used to facilitate the comparison with data, as described in section 5.1. Given that the generators have only LO or even only leading-logarithmic accuracy, the observed agreement is reasonable.

7 Data unfolding

Cross sections are measured differentially in several variables, each of which is binned in $p_{\mathrm{T}}^{(1)}$ or $m_{4\mathrm{j}}$. Each of the corresponding distributions is individually unfolded to deconvolve detector effects such as inefficiencies and resolutions. The unfolding is performed using the Bayesian Iterative method [58, 59], as implemented in the `RooUnfold` package [60]. The algorithm builds an unfolding matrix starting with an initial prior probability distribution taken from MC simulation, and improves it iteratively. The method takes into account migrations between bins. It also corrects the results for the presence of events which pass the selection at reconstructed-level but not at the particle level; and for detector inefficiencies, which have the opposite effect. The number of iterations is optimised in order to minimise the size of the statistical and systematic uncertainties. A lower number of iterations results in a higher dependence on the MC simulation, whereas higher values give larger statistical uncertainties. For the analysis presented in this paper, two iterations are used.

The data are unfolded to the particle-jet level using the Pythia MC simulation to build the unfolding matrix. In order to construct the matrix, events are required to pass the inclusive analysis cuts at both the reconstructed and particle levels. The cuts require that events have at least four jets within $|y| < 2.8$, with $p_{\mathrm{T}}^{(1)} > 100\,\mathrm{GeV}$ and $p_{\mathrm{T}}^{(2)}, p_{\mathrm{T}}^{(3)}, p_{\mathrm{T}}^{(4)} > 64\,\mathrm{GeV}$. The four leading jets must in addition be separated by $\Delta R_{4\mathrm{j}}^{\mathrm{min}} > 0.65$. For observables requiring additional kinematic cuts, these are also applied both at the reconstructed and particle levels. No spatial matching is performed between reconstructed-level and particle-level jets.

The correlation between the observables before and after the incorporation of experimental effects tends to be higher for p_{T}-based variables, such as H_{T}. In the case of angular variables, such as $\Delta\phi_{2\mathrm{j}}^{\mathrm{min}}$, the correlation is weakened due to cases where energy resolution effects lead to re-ordering of the jet p_{T}. Nevertheless, even in the case of such angular variables the entries far from the diagonal of the correlation matrix are significantly smaller than the diagonal elements. The binning is derived from an optimisation procedure such that the purity of the bins is between 70% and 90%, and the statistical uncertainty of the measurement is $\lesssim 10\%$. The purity is defined as the fractional number of events per bin which do not migrate to other bins after the detector simulation, calculated with respect to the number of events which pass the particle-level cuts.

The possible presence of biases in the unfolded spectra due to MC mismodelling of the reconstructed-level spectrum is evaluated using a data-driven closure test. In this study, the MC distributions are reweighted to match the shape of those obtained from the data, and then unfolded using the same unfolding matrix as for the data. A data-driven systematic uncertainty is computed by comparing the result obtained from this procedure and the

JHEP12(2015)105

original reweighted particle-level MC distributions. With two iterations of the unfolding algorithm, this systematic uncertainty is found to be negligible.

A second unfolding uncertainty is evaluated to account for the model dependence of the efficiency with which both the reconstructed- and particle-level cuts are satisfied in each MC event. The systematic uncertainty is derived from the differences between the efficiencies calculated with Herwig++ and those calculated using Pythia. The resulting uncertainty is found to be subdominant in most cases, with typical sizes of 2–10%. The uncertainty is rebinned and smoothed, such that its statistical uncertainty is smaller than 40%.

The statistical uncertainties are calculated with pseudo-experiments. For each pseudo-experiment, the data and MC distributions are reweighted event by event following a Poisson distribution centred at one. Each resulting Poisson replica of the data is unfolded using the corresponding fluctuated unfolding matrix. The random numbers for the pseudo-experiments are generated using unique seeds, following the same scheme used by the inclusive jet [42], dijet [61] and three-jet [16] measurements at $\sqrt{s} = 7\,\text{TeV}$, to allow for possible future combination of results with the same dataset used for this analysis.

The integral of the unfolded distributions, corresponding to the cross section in the fiducial range determined by the inclusive analysis cuts, was compared for all the variables defined in the same region of phase space and found to agree with each other within 0.5%.

8 Experimental uncertainties

Several sources of experimental uncertainty are considered in this analysis. Those arising from the unfolding procedure are described in section 7. This section presents the uncertainties which arise from the jet energy scale (JES), jet energy resolution (JER), jet angular resolution and integrated luminosity. The dominant source of uncertainty in this measurement is the JES.

The uncertainty in the JES calibration is determined in the central detector region by exploiting the transverse momentum balance in Z+jet, γ+jet or multi-jet events, which are measured in situ. The uncertainties in the energy of the reference object are propagated to the jet whose energy scale is being probed. The uncertainty in the central region is propagated to the forward region using dijet systems balanced in transverse momentum. The procedure is described in detail in ref. [54].

The total JES uncertainty is decomposed into eighteen components, which account for the uncertainty in the jet energy scale calibration itself, as well as uncertainties due to the pile-up subtraction procedure, parton flavour differences between samples, b-jet energy scale and punch-through. Each of these uncertainties is incorporated as a coherent shift of the scale of the jets in the MC simulation. The energies and transverse momenta of all jets with $p_{\text{T}} > 20\,\text{GeV}$ and $|y| < 2.8$ are varied up and down by one standard deviation of each uncertainty component; these components are asymmetric, i.e. the values of the upwards and downwards variations are different. The shifts are then propagated through the unfolding. The unfolded distributions corresponding to the systematically varied spectra are compared one by one to the nominal ones, and the difference taken as the unfolded-level uncertainty due to that JES uncertainty component. The total JES

JHEP12(2015)105

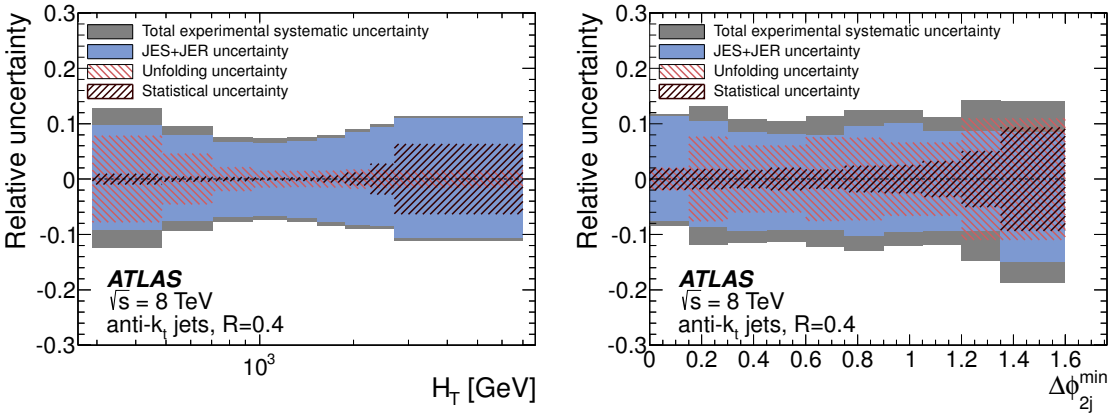
uncertainty is obtained by summing all such contributions quadratically, respecting the sign of the variations in the event yields; that is, positive and negative event yield variations are added independently.

Statistical uncertainties on each of the JES uncertainty components are obtained by creating Poisson replicas of the systematically varied spectra, obtained as explained in section 7. Such statistical uncertainties are used to evaluate the significance of the uncertainty for each component and for each bin of all the differential distributions. As in the case of the unfolding uncertainty, the unfolded-level uncertainty due to each JES component is then rebinned and smoothed using a Gaussian kernel regression in order to get statistical uncertainties smaller than 40% in all bins. The typical size of the JES uncertainty is 4–15%.

Jets may be affected by additional energy originating from pile-up interactions. This effect is corrected for as part of the jet energy calibration. The distributions were binned in different ranges of the average number of interactions per bunch crossing in order to test the possible presence of residual effects. No significant deviations were observed, therefore no uncertainty associated with pile-up mismodelling was considered beyond the pile-up uncertainty already included in the jet calibration procedure.

The JER has been measured in data using dijet events [62], and an uncertainty was derived from the differences seen between data and MC prediction. In general, the energy resolution observed in data is somewhat worse than that in MC simulations. The uncertainty on the observables can therefore be evaluated by smearing the energy of the reconstructed jets in the MC simulation. After applying this smearing to the jets, an alternative unfolding matrix is derived and used to unfold the nominal MC prediction. Then the MC distribution is unfolded using both the nominal and the smeared matrices, and the difference between the two is symmetrised and taken as the JER systematic uncertainty. The typical size of this uncertainty is 1–10% of the cross section.

The jet angular resolution was estimated in MC simulation for the pseudorapidity and ϕ by matching spatially jets at the reconstructed and particle level, and found to be $\lesssim 2\%$. This is in agreement with in-situ measurements, so no systematic uncertainty is assigned.



Finally, the uncertainty on the integrated luminosity is $\pm 2.8\%$. It is derived following the same methodology as that detailed in ref. [63].

Two examples of the values of the total experimental systematic uncertainty are shown in figure 3 for two representative variables, namely H_{T} and $\Delta\phi_{2\mathrm{j}}^{\mathrm{min}}$. The jet energy scale and resolution uncertainties dominate in the majority of bins, being larger at the high and low ends of the H_{T} spectrum. The unfolding uncertainty is nearly as large at low values of the jet momenta, and it is therefore an important contribution in most of the $\Delta\phi_{2\mathrm{j}}^{\mathrm{min}}$ bins.

9 Results

The various differential cross sections measured in events with at least four jets are shown in figures 4 to 19 for jets reconstructed with the anti-k_t algorithm with $R = 0.4$. The observables used for the measurements are defined in table 1. The measurements are performed for a wide range of jet transverse momenta from 64 GeV to several TeV, spanning

JHEP12(2015)105

(a) H_{T}. **(b)** $\Delta\phi_{2\mathrm{j}}^{\mathrm{min}}$.

Figure 3. Total systematic uncertainty in the four-jet cross section measurement for anti-k_t $R = 0.4$ jets as a function of (a) H_{T} and (b) $\Delta\phi_{2\mathrm{j}}^{\mathrm{min}}$. In both cases the event selection corresponds to the inclusive analysis cuts, namely $p_{\mathrm{T}}^{(4)} > 64\,\mathrm{GeV}$, $p_{\mathrm{T}}^{(1)} > 100\,\mathrm{GeV}$ and $\Delta R_{4\mathrm{j}}^{\mathrm{min}} > 0.65$. Separate bands show the jet energy scale (JES) and resolution (JER), and the unfolding uncertainty, as well as the combined total systematic uncertainty resulting from adding in quadrature all the components. The total statistical uncertainty of the unfolded data spectrum is also shown. The luminosity uncertainty is not shown separately but is included in the total uncertainty band.

two orders of magnitude in p_{T} and over seven orders of magnitude in cross section. The measured cross sections are corrected for all detector effects using the unfolding procedure described in section 7. The theoretical predictions described in sections 4 and 5 are compared to the unfolded results.

Summary of the results. The scale factors applied to LO generators (see section 5.1) are found to vary between 0.6 and 1.4, as shown previously in table 3. Not all generators describe the shape of $p_{\mathrm{T}}^{(1)}$ correctly, so these scale factors should not be seen as a measure of the level of agreement between MC simulation and data, which may vary as a function of the cuts in $p_{\mathrm{T}}^{(1)}$ and $m_{4\mathrm{j}}$. The cross section predicted by BlackHat/Sherpa and NJet/Sherpa is larger than that measured in data, but overall the difference is covered by the scale and PDF uncertainties evaluated using NJet/Sherpa, with only a few exceptions. BlackHat/Sherpa and NJet/Sherpa give identical results within statistical uncertainties; therefore only one of the two (NJet/Sherpa) is discussed in the following, for simplicity. It is nevertheless interesting to compare experimental results with two different implementations of the same NLO pQCD calculations as an additional cross-check.

In general, an excellent description of both the shape and the normalisation of the variables is given by NJet/Sherpa. The small differences found are covered by theoretical and statistical uncertainties in almost all cases; only the tails of $p_{\mathrm{T}}^{(4)}$ and $\Delta y_{2\mathrm{j}}^{\mathrm{max}}$ hint at deviations from the measured distribution. MadGraph+Pythia describes the data very well in most regions of phase space, the most significant discrepancy being in the slopes of $p_{\mathrm{T}}^{(1)}$ and $p_{\mathrm{T}}^{(2)}$and derived variables. HEJ also provides a good description of most variables;

JHEP12(2015)105

the most significant discrepancy occurs for the angular variables Δy_{2j}^{min} and Δy_{2j}^{max} when $p_T^{(1)}$ is small. However when $p_T^{(1)}$ is large, HEJ describes Δy_{2j}^{max} better than NJet/Sherpa, which highlights one of the strengths of this calculation. The $2 \to 2$ ME calculations matched to parton showers provide different levels of agreement depending on the variable studied; the only variable whose shape is reasonably well described by both Pythia and Herwig++ is H_T.

The following discussion is based on the results obtained after applying the particular choice of normalisation of the theoretical predictions as explained at the beginning of this section. NJet/Sherpa, which generally gives very good agreement with the data, is only discussed for those cases where some deviations are present.

Momentum variables. The momentum variables comprise the p_T of the four leading jets and H_T. Part of the importance of these variables lies in their wide use in analyses, alone or as inputs to more complex observables. They are also interesting in themselves: it has been shown that the ratio of the NLO to the LO predictions is relatively flat across the $p_T^{(1)}$ spectrum with a maximum variation of approximately 25% [10]. Perhaps surprisingly, the PS description of $p_T^{(4)}$ was found to be better than that of $p_T^{(1)}$ in the 7 TeV multi-jet measurement published by ATLAS [9].

Figures 4 to 7 show the p_T distributions of the leading four jets. All the LO generators show a slope with respect to the data in the leading jet p_T (figure 4). The ratios of Herwig++ and HEJ to data are remarkably flat above ~ 500 GeV and ~ 300 GeV respectively. MadGraph+Pythia is within the experimental uncertainties above ~ 300 GeV, and it is the only one with a positive slope in the ratio to data.

The subleading jet p_T (figure 5) is well described by HEJ, while the LO generators show similar trends to those in $p_T^{(1)}$. MadGraph+Pythia describes both $p_T^{(3)}$ and $p_T^{(4)}$ well, as shown in figures 6 and 7. As the 7 TeV results suggested, Pythia gives a good description of the distribution of $p_T^{(4)}$. HEJ and Herwig++ overestimate the number of events with high $p_T^{(4)}$. NJet/Sherpa shows a similar trend at high $p_T^{(4)}$, but the discrepancy is mostly covered by the theoretical uncertainties. H_T, shown in figure 8, exhibits features similar to those in $p_T^{(1)}$.

In summary, Pythia and Herwig++ tend to describe the p_T spectrum of the leading jets with similar levels of agreement, whereas Pythia is better at describing $p_T^{(4)}$. MadGraph+Pythia does a reasonable job for all of them, while HEJ and NJet/Sherpa are very good for the leading jets and less so for $p_T^{(4)}$. This could perhaps be improved by matching the calculations to PSs.

Mass variables. Mass variables are widely used in physics searches, and they are also sensitive to events with large separations between jets, which puts the HEJ and MadGraph+Pythia predictions to the test, as they are expected to be especially accurate in this regime.

The distribution of the total invariant mass m_{4j} is studied in figure 9. Pythia and MadGraph+Pythia describe the data very well. Herwig++ describes the shape of the data between 1 TeV and 3–6 TeV. HEJ is mostly compatible with the measurement, but

JHEP12(2015)105

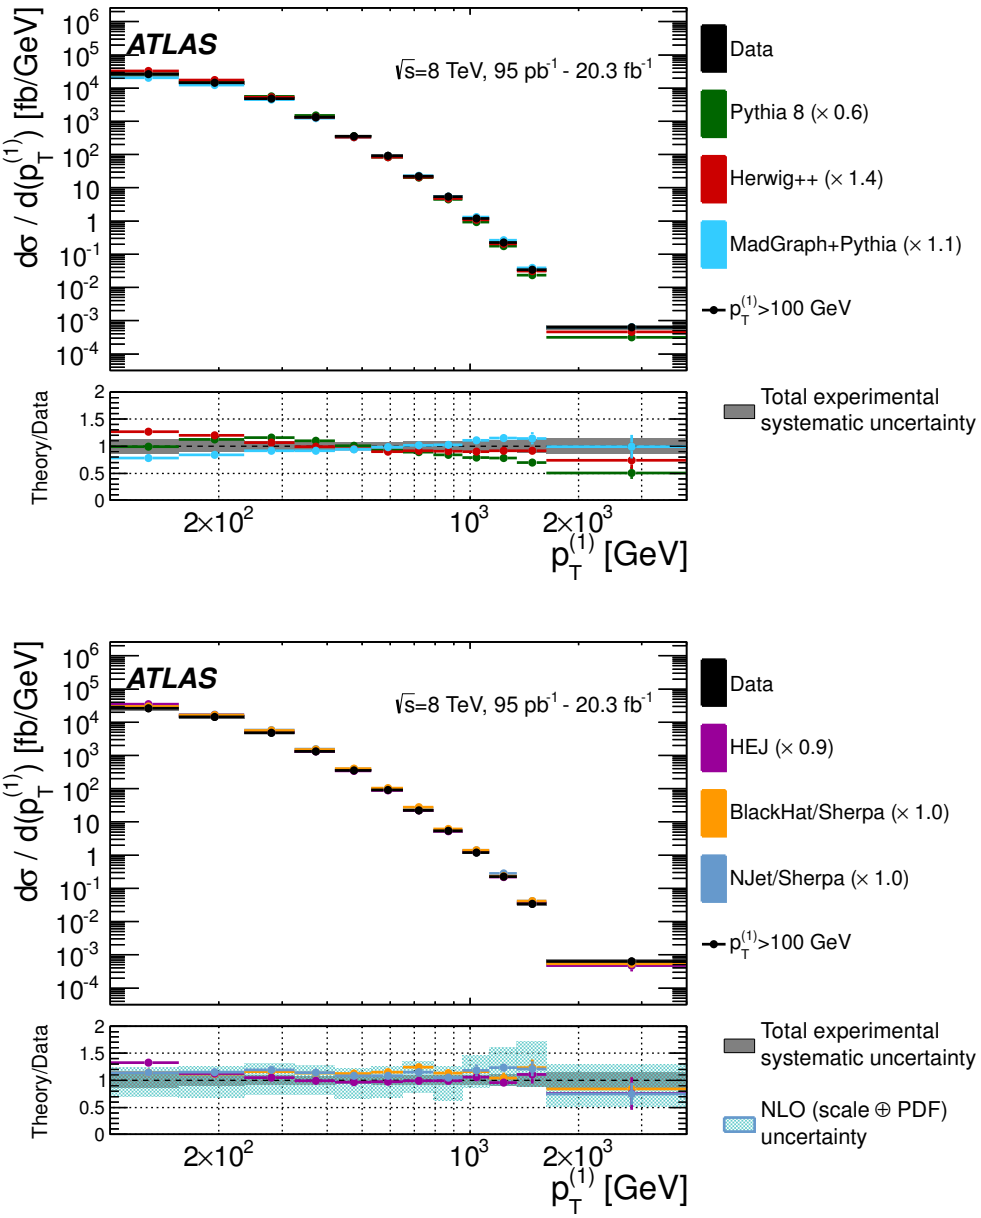


Figure 4. The four-jet differential cross section as a function of leading jet p_{T} ($p_{\mathrm{T}}^{(1)}$), compared to different theoretical predictions: Pythia, Herwig++ and MadGraph+Pythia (top), and HEJ, NJet/Sherpa and BlackHat/Sherpa (bottom). For better comparison, the predictions are multiplied by the factors indicated in the legend. In each figure, the top panel shows the full spectra and the bottom panel the ratios of the different predictions to the data. The solid band represents the total experimental systematic uncertainty centred at one. The patterned band represents the NLO scale and PDF uncertainties calculated from NJet/Sherpa centred at the nominal NJet/Sherpa values. The scale uncertainties for HEJ (not drawn) are typically $^{+50\%}_{-30\%}$. The ratio curves are formed by the central values with vertical uncertainty lines resulting from the propagation of the statistical uncertainties of the predictions and those of the unfolded data spectrum.

JHEP12(2015)105

the ratio to data has a bump structure in the region of approximately 1 to 2 TeV. This feature is also shared by NJet/Sherpa, but the differences with respect to the data are covered by the NLO uncertainties.

The description of different splitting scales is tested in figure 10 through the variable m_{2j}^{min}/m_{4j}. This distribution is well described by Pythia, whereas Herwig++ gets worse with increasing m_{4j}, consistently overestimating the two ends of the m_{2j}^{min}/m_{4j} spectrum. MadGraph+Pythia provides a very good description, with a flat ratio for all the m_{4j} cuts. The HEJ prediction shows trends similar to those of Herwig++ at higher values of m_{4j}. These differences are covered in all cases by the large associated scale uncertainty. NJet/Sherpa overestimates the number of events in the very first bin, possibly due to the lack of a PS, but otherwise agrees with the data within the theoretical uncertainties.

Overall, MadGraph+Pythia provides the best description of mass variables.

Angular variables. Similarly to mass variables, angular variables are able to test the description of events with small- and wide-angle radiation. In addition, they can also provide information on the global spatial distribution of the jets. High-p_T, large-angle radiation should be well captured by the ME+PS description of MadGraph+Pythia, or the all-orders approximation of HEJ — particularly the rapidity variables Δy_{2j}^{min}, Δy_{2j}^{max} and Δy_{3j}^{min}. PS generators are expected to perform poorly at large angles, given that they only contain two hard jets, and the rest is left to the soft- and collinear-enhanced PS. The fixed-order NLO prediction of NJet/Sherpa should provide a very good description of these variables too, as long as they are far from the infrared limit. This is indeed the case, and therefore no detailed comments about its performance are given here.

Figure 11 compares the distributions of $\Delta\phi_{2j}^{min}$ for different cuts in $p_T^{(1)}$. Pythia has a small downwards slope with respect to the data in all the $p_T^{(1)}$ ranges. MadGraph+Pythia also shows a small slope. The other generators, both LO and NLO, reproduce the data very well. Herwig++, in particular, provides a very good description of the data.

The $\Delta\phi_{3j}^{min}$ spectrum is shown in figure 12. The different $p_T^{(1)}$ cuts change the spatial distribution of the events, such that at low $p_T^{(1)}$ most events contain two jets recoiling against two, while at high $p_T^{(1)}$ the events where one jet recoils against three dominate. In general, the description of the data improves as $p_T^{(1)}$ increases. For Pythia, the number of events where one jet recoils against three (low $\Delta\phi_{3j}^{min}$) is significantly overestimated when $p_T^{(1)}$ is low; as $p_T^{(1)}$ increases, the agreement improves such that the $p_T^{(1)} > 1000\,\text{GeV}$ region is very well described. MadGraph+Pythia, Herwig++ and HEJ are mostly in good agreement with data.

Figure 13 compares the distributions of Δy_{2j}^{min} with data. This variable is remarkably well described by Pythia, showing no significant trend. MadGraph+Pythia mostly underestimates high Δy_{2j}^{min} values, while Herwig++ has a tendency to underestimate the low values. HEJ overestimates the number of events with high Δy_{2j}^{min} values at low $p_T^{(1)}$, but describes the data very well at larger values of $p_T^{(1)}$.

For the variable Δy_{3j}^{min}, presented in figure 14, the predictions provided by Pythia and Herwig++ show in general a positive slope with respect to the data. MadGraph+Pythia

JHEP12(2015)105

reproduces the shape of the data well, as does HEJ for $p_{\mathrm{T}}^{(1)} > 400\,\mathrm{GeV}$. However, for smaller values of $p_{\mathrm{T}}^{(1)}$ HEJ overestimates the number of events at the end of the spectrum, as was the case for $\Delta y_{2\mathrm{j}}^{\mathrm{min}}$.

The variable $\Delta y_{2\mathrm{j}}^{\mathrm{max}}$, shown in figure 15, is very well described by HEJ in events with $p_{\mathrm{T}}^{(1)} > 400\,\mathrm{GeV}$. The ratios to data in both Pythia and Herwig++ have upwards slopes in all $p_{\mathrm{T}}^{(1)}$ bins. MadGraph+Pythia provides mostly a good description of the data, with a tendency to underestimate the extremes of the distribution. Interestingly, NJet/Sherpa seems to overestimate the number of events in the tail, although it is a statistically limited region and the comparison with BlackHat/Sherpa is not conclusive.

In summary: NJet/Sherpa mostly agrees with the data within the uncertainties, but its ratio to data has an upwards trend in the tail of $\Delta y_{2\mathrm{j}}^{\mathrm{max}}$. HEJ provides a very good description of all angular variables for the region $p_{\mathrm{T}}^{(1)} > 400\,\mathrm{GeV}$, as expected, but shows significant discrepancies with respect to the data in all the rapidity variables for lower $p_{\mathrm{T}}^{(1)}$ values. It is important to keep in mind, though, that the associated scale uncertainties are large. MadGraph+Pythia describes all the data well, apart from the tail of $\Delta y_{2\mathrm{j}}^{\mathrm{min}}$ and the extreme values of $\Delta y_{2\mathrm{j}}^{\mathrm{max}}$, which it underestimates. Herwig++ gives good descriptions of the ϕ variables, but fails at describing the rapidity variables. Pythia has some problems describing both three-jet variables, as well as $\Delta y_{2\mathrm{j}}^{\mathrm{max}}$. These variables highlight the need to combine four-jet ME calculations with parton showers.

$\Sigma p_{\mathrm{T}}^{\mathrm{central}}$ variables. The variables setting a minimum forward-backward rapidity interval and measuring the total p_{T} of the central jets ($\Sigma p_{\mathrm{T}}^{\mathrm{central}}$) were defined to test the framework of HEJ. HEJ has been designed to describe events with two jets significantly separated in rapidity with additional, central, high-p_{T} radiation. These variables are also useful to describe the spatial configuration of the events, as they represent the forward-backward rapidity span of the jets, and whether the leading jet is among the two central ones or not. The NLO predictions and MadGraph+Pythia are also expected to be successful in this regime, whereas the $2 \to 2$ generators with PSs are expected to be less suitable.

The variable $\Sigma p_{\mathrm{T}}^{\mathrm{central}}$ is studied for values of $\Delta y_{2\mathrm{j}}^{\mathrm{max}}$ larger than 1, 2, 3 or 4, and for different cuts in $p_{\mathrm{T}}^{(1)}$. In most cases, the description of the observable worsens significantly with increasing $\Delta y_{2\mathrm{j}}^{\mathrm{max}}$ and $p_{\mathrm{T}}^{(1)}$. Figures 16 to 19 correspond to the results for $\Delta y_{2\mathrm{j}}^{\mathrm{max}} > 1, 2, 3, 4$.

The generators with $2 \to 2$ MEs have problems describing the data around the threshold values where the contribution from different jets changes, which results in kinks in the ratio distributions. One such transition occurs at the $\Sigma p_{\mathrm{T}}^{\mathrm{central}}$ value for which the leading jet is first allowed to be central. For $p_{\mathrm{T}}^{(1)} > 400\,\mathrm{GeV}$, this happens at $\Sigma p_{\mathrm{T}}^{\mathrm{central}} > 464\,\mathrm{GeV}$, at which point there is a major jump in Pythia in the second ratio plot of figure 16. Pythia gives in general the most discrepant prediction, with kinks in the ratio to data at the transition points that reach differences of 70% at high $p_{\mathrm{T}}^{(1)}$, as well as global slopes. Herwig++ describes the data very well at lower $\Delta y_{2\mathrm{j}}^{\mathrm{max}}$ values, but as $\Delta y_{2\mathrm{j}}^{\mathrm{max}}$ grows its normalisation worsens, as well as the shape — particularly at high $p_{\mathrm{T}}^{(1)}$.

JHEP12(2015)105

MadGraph+Pythia provides an excellent description of the $\Sigma p_{\mathrm{T}}^{\mathrm{central}}$ variables, especially at low $p_{\mathrm{T}}^{(1)}$. The agreement deteriorates at high $p_{\mathrm{T}}^{(1)}$, but it is not very much affected by the changes between different jet configurations, providing overall a very good description of the shapes. Most distributions are well described by HEJ, especially the high $\Sigma p_{\mathrm{T}}^{\mathrm{central}}$ region; the low $\Sigma p_{\mathrm{T}}^{\mathrm{central}}$ region shows more shape differences, which get worse at large $\Delta y_{2\mathrm{j}}^{\mathrm{max}}$. This is compatible with similar observations made in previous ATLAS measurements performed with 7 TeV data [64], where it was also shown that the agreement was significantly improved after interfacing HEJ with a PS generator. NJet/Sherpa has a tendency to overestimate the number of events with very low $\Sigma p_{\mathrm{T}}^{\mathrm{central}}$, which may be correlated with the $p_{\mathrm{T}}^{(4)}$ discrepancy discussed earlier. It provides a very good description of the data otherwise.

Tables 4 to 49 in appendix A contain the numerical values of the measured differential cross sections and their corresponding uncertainties. The quoted values correspond to the average differential cross sections over the bin ranges given

10 Conclusion

This paper presents unfolded differential cross sections of events with at least four jets in pp collisions at 8 TeV centre-of-mass energy. The cross sections are studied as a function of a variety of kinematic and topological variables which include momenta, masses and angles. Events are selected if the four anti-k_t $R = 0.4$ jets with the largest transverse momentum within the rapidity range $|y| < 2.8$ are well separated ($\Delta R_{4\mathrm{j}}^{\mathrm{min}} > 0.65$), all have $p_{\mathrm{T}} > 64$ GeV, and include at least one jet with $p_{\mathrm{T}} > 100$ GeV. The results are obtained from the analysis of the full dataset collected by the ATLAS detector at the LHC in 2012, which corresponds to a total integrated luminosity of 20.3 fb^{-1}. The total experimental systematic uncertainty is typically of the order of 10%, and it is dominated by the jet energy scale calibration uncertainty.

The measurements are compared to NLO pQCD predictions provided by BlackHat/Sherpa and NJet/Sherpa, as well as the all-orders calculation provided by HEJ. Three leading-order calculations are also considered, including two $2 \to 2$ PS samples (Pythia and Herwig++) and a multi-leg calculation with up to four partons in the ME matched to a PS generated by Pythia (MadGraph+Pythia).

The LO cross sections and HEJ are normalised by fixed factors to facilitate the comparison of the spectra in the kinematic regions of interest; these factors vary between 0.6 and 1.4 for the different samples, where the MadGraph+Pythia and HEJ samples are the ones that need the smallest corrections. The NLO predictions, BlackHat/Sherpa and NJet/Sherpa, are almost always compatible with the data within their theoretical uncertainties, which are found to be large ($\mathcal{O}(30\%)$ at low momenta) and asymmetric. Within the normalisation scheme used, MadGraph+Pythia also provides a good description of the data, as does HEJ, especially at high leading jet p_{T}. The $2 \to 2$ PS calculations generally describe the data relatively poorly, although they are found to provide good predictions in some particular cases: Pythia gives a very good prediction of $p_{\mathrm{T}}^{(4)}$ and $\Delta y_{2\mathrm{j}}^{\mathrm{min}}$, while Herwig++ performs well in the azimuthal angle variables.

JHEP12(2015)105

Looking at the individual distributions of the differential cross section, the description of the jet momenta is compatible with previous measurements of the multi-jet cross sections. It should be noted that HEJ, NJet/Sherpa and BlackHat/Sherpa give a very good description of the distributions of the leading jets but show some discrepancy with the data for $p_{\mathrm{T}}^{(4)}$. For variables that are particularly sensitive to wide-angle configurations and high-p_{T} radiation, such as masses or angles, BlackHat/Sherpa, NJet/Sherpa and MadGraph+Pythia do a remarkable job overall. HEJ also provides a good description of the data, the main exception being that it disagrees with the rapidity measurements in events with low $p_{\mathrm{T}}^{(1)}$. At high $p_{\mathrm{T}}^{(1)}$ the prediction is very good. These measurements expose the shortcomings of $2 \to 2$ parton ME+PS predictions in a variety of scenarios and highlight the importance of the more sophisticated calculations.

Acknowledgments

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently.

Study of the $B_c^+ \to J/\psi D_s^+$ and $B_c^+ \to J/\psi D_s^{*+}$ decays with the ATLAS detector

ATLAS Collaboration[⋆]

CERN, 1211 Geneva 23, Switzerland

Received: 27 July 2015 / Accepted: 19 October 2015 / Published online: 5 January 2016
© CERN for the benefit of the ATLAS collaboration 2015. This article is published with open access at Springerlink.com

Abstract The decays $B_c^+ \to J/\psi D_s^+$ and $B_c^+ \to J/\psi D_s^{*+}$ are studied with the ATLAS detector at the LHC using a dataset corresponding to integrated luminosities of 4.9 and 20.6 fb^{-1} of pp collisions collected at centre-of-mass energies $\sqrt{s} = 7$ TeV and 8 TeV, respectively. Signal candidates are identified through $J/\psi \to \mu^+\mu^-$ and $D_s^{(*)+} \to \phi\pi^+(\gamma/\pi^0)$ decays. With a two-dimensional likelihood fit involving the B_c^+ reconstructed invariant mass and an angle between the μ^+ and D_s^+ candidate momenta in the muon pair rest frame, the yields of $B_c^+ \to J/\psi D_s^+$ and $B_c^+ \to J/\psi D_s^{*+}$, and the transverse polarisation fraction in $B_c^+ \to J/\psi D_s^{*+}$ decay are measured. The transverse polarisation fraction is determined to be $\Gamma_{\pm\pm}(B_c^+ \to J/\psi D_s^{*+})/\Gamma(B_c^+ \to J/\psi D_s^{*+}) = 0.38 \pm 0.23 \pm 0.07$, and the derived ratio of the branching fractions of the two modes is $\mathcal{B}_{B_c^+\to J/\psi D_s^{*+}}/\mathcal{B}_{B_c^+\to J/\psi D_s^+} = 2.8^{+1.2}_{-0.8} \pm 0.3$, where the first error is statistical and the second is systematic. Finally, a sample of $B_c^+ \to J/\psi\pi^+$ decays is used to derive the ratios of branching fractions $\mathcal{B}_{B_c^+\to J/\psi D_s^+}/\mathcal{B}_{B_c^+\to J/\psi\pi^+} = 3.8 \pm 1.1 \pm 0.4 \pm 0.2$ and $\mathcal{B}_{B_c^+\to J/\psi D_s^{*+}}/\mathcal{B}_{B_c^+\to J/\psi\pi^+} = 10.4 \pm 3.1 \pm 1.5 \pm 0.6$, where the third error corresponds to the uncertainty of the branching fraction of $D_s^+ \to \phi(K^+K^-)\pi^+$ decay. The available theoretical predictions are generally consistent with the measurement.

1 Introduction

The B_c^+ meson[1] is the only known weakly decaying particle consisting of two heavy quarks. The ground $\bar{b}c$ state was first observed by CDF [1] via its semileptonic decay $B_c^+ \to J/\psi\ell^+\nu_\ell$. An excited $\bar{b}c$ state has been observed recently by ATLAS [2] using the B_c^+ decay mode $B_c^+ \to J/\psi\pi^+$. The presence of two heavy quarks, each of which can decay weakly, affects theoretical calculations of the decay properties of the B_c^+ meson. In the case of $\bar{b} \to \bar{c}c\bar{s}$ processes, decays to charmonium and a D_s^+ or a D_s^{*+} meson are predicted to occur via colour-suppressed and colour-favoured spectator diagrams as well as via the weak annihilation diagram (see Fig. 1). The latter, in contrast to decays of other B mesons, is not Cabibbo-suppressed and can contribute significantly to the decay amplitudes. The decay properties are addressed in various theoretical calculations [3–9] and can also be compared to the analogous properties in the lighter B meson systems such as $B_d^0 \to D^{*-}D_s^{(*)+}$ or $B^+ \to \bar{D}^{*0}D_s^{(*)+}$. The decays $B_c^+ \to J/\psi D_s^+$ and $B_c^+ \to J/\psi D_s^{*+}$, which have been observed recently by the LHCb experiment [10], provide a means to test these theoretical predictions.

This paper presents a measurement of the branching fractions of $B_c^+ \to J/\psi D_s^+$ and $B_c^+ \to J/\psi D_s^{*+}$ decays, normalised to that of $B_c^+ \to J/\psi\pi^+$ decay, and polarisation in $B_c^+ \to J/\psi D_s^{*+}$ decay performed with the ATLAS detector [11]. The D_s^+ meson is reconstructed via the $D_s^+ \to \phi\pi^+$ decay with the ϕ meson decaying into a pair of charged kaons. The D_s^{*+} meson decays into a D_s^+ meson and a soft photon or π^0. Detecting such soft neutral particles is very challenging, thus no attempt to reconstruct them is made in the analysis. The J/ψ meson is reconstructed via its decay into a muon pair.

The measurement presented in this paper allows an independent verification of the results of Ref. [10] with comparable statistical and systematic uncertainties. The following ratios are measured: $\mathcal{R}_{D_s^+/\pi^+} = \mathcal{B}_{B_c^+\to J/\psi D_s^+}/\mathcal{B}_{B_c^+\to J/\psi\pi^+}$, $\mathcal{R}_{D_s^{*+}/\pi^+} = \mathcal{B}_{B_c^+\to J/\psi D_s^{*+}}/\mathcal{B}_{B_c^+\to J/\psi\pi^+}$, and $\mathcal{R}_{D_s^{*+}/D_s^+} = \mathcal{B}_{B_c^+\to J/\psi D_s^{*+}}/\mathcal{B}_{B_c^+\to J/\psi D_s^+}$, where $\mathcal{B}_{B_c^+\to X}$ denotes the branching fraction of the $B_c^+ \to X$ decay. The decay $B_c^+ \to J/\psi D_s^{*+}$ is a transition of a pseudoscalar meson into a pair of vector states and is thus described by the three helicity amplitudes, A_{++}, A_{--}, and A_{00}, where the subscripts correspond to the helicities of J/ψ and D_s^{*+} mesons. The contribution of the A_{++} and A_{--} amplitudes, referred to as the $A_{\pm\pm}$ component, corresponds to the J/ψ and D_s^{*+} transverse polarisation. The fraction of transverse polarisation,

[1] Charge conjugate states are implied throughout the paper unless otherwise stated.

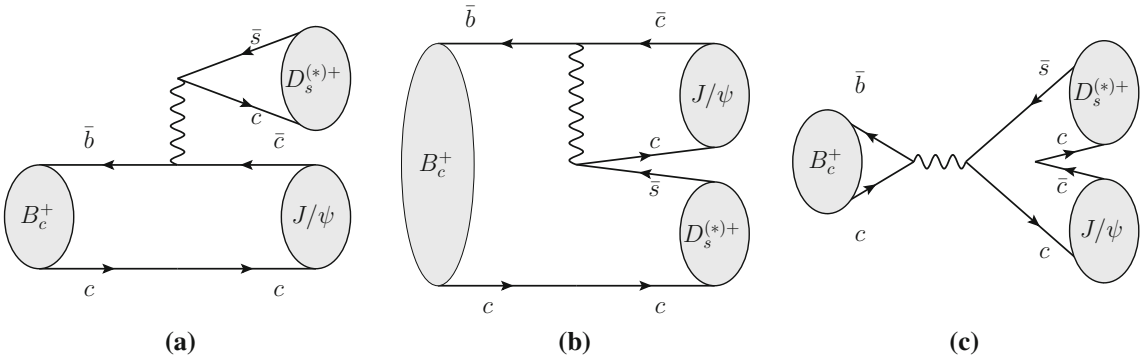

Fig. 1 Feynman diagrams for $B_c^+ \to J/\psi D_s^{(*)+}$ decays: **a** colour-favoured spectator, **b** colour-suppressed spectator, and **c** annihilation topology

$\Gamma_{\pm\pm}/\Gamma = \Gamma_{\pm\pm}(B_c^+ \to J/\psi D_s^{*+})/\Gamma(B_c^+ \to J/\psi D_s^{*+})$, is also measured. From a naive prediction by spin counting, one would expect this fraction to be 2/3, while calculations [8,9] predict values of 0.41–0.48.

This analysis is based on a combined sample of pp collision data collected by the ATLAS experiment at the LHC at centre-of-mass energies $\sqrt{s} = 7\,\text{TeV}$ and 8 TeV corresponding to integrated luminosities of 4.9 and 20.6 fb^{-1}, respectively.

2 The ATLAS detector, trigger selection and Monte Carlo samples

ATLAS is a general-purpose detector consisting of several subsystems including the inner detector (ID), calorimeters and the muon spectrometer (MS). Muon reconstruction makes use of both the ID and the MS. The ID comprises three types of detectors: a silicon pixel detector, a silicon microstrip semiconductor tracker (SCT) and a transition radiation tracker. The ID provides a pseudorapidity[2] coverage up to $|\eta| = 2.5$. Muons pass through the calorimeters and reach the MS if their transverse momentum, p_T, is above approximately 3 GeV.[3] Muon candidates are formed either from a stand-alone MS track matched to an ID track or, in case the MS stand-alone track is not reconstructed, from an ID track extrapolated to the MS and matched to track segments in the MS. Candidates of the latter type are referred to as segment-tagged muons while the former are called combined muons. Muon track parameters are taken from the ID measurement alone in this analysis, since the precision of the measured track parameters for muons in the p_T range of interest is dominated by the ID track reconstruction.

The ATLAS trigger system consists of a hardware-based Level-1 trigger and a two-stage high level trigger (HLT). At Level-1, the muon trigger uses dedicated MS chambers to search for patterns of hits satisfying different p_T thresholds. The region-of-interest around these hit patterns then serves as a seed for the HLT muon reconstruction, in which dedicated algorithms are used to incorporate information from both the MS and the ID, achieving a position and momentum resolution close to that provided by the offline muon reconstruction. Muons are efficiently triggered in the pseudorapidity range $|\eta| < 2.4$.

Triggers based on single-muon, dimuon, and three-muon signatures are used to select $J/\psi \to \mu^+\mu^-$ decays for the analysis. The third muon can be produced in the B_c^+ signal events in semileptonic decays of the two other heavy-flavour hadrons. The majority of events are collected by dimuon triggers requiring a vertex of two oppositely charged muons with an invariant mass between 2.5 and 4.3 GeV. During the data taking, the p_T threshold for muons in these triggers was either 4 or 6 GeV. Single-muon triggers additionally increase the acceptance for asymmetric J/ψ decays where one muon has $p_\text{T} < 4\,\text{GeV}$. Finally, three-muon triggers had a p_T threshold of 4 GeV, thus enhancing the acceptance during the periods of high luminosity when the p_T threshold for at least one muon in the dimuon triggers was 6 GeV.

Monte Carlo (MC) simulation is used for the event selection criteria optimisation and the calculation of the acceptance for the considered B_c^+ decay modes. The MC samples of the B_c^+ decays were generated with PYTHIA 6.4 [12] along with a dedicated extension for the B_c^+ production based on calculations from Refs. [13–16]. The decays of B_c^+ are then simulated with EVTGEN [17]. The generated events were passed through a full simulation of the detector using the ATLAS simulation framework [18] based on GEANT 4 [19,20] and processed with the same reconstruction algorithms as were used for the data.

[2] ATLAS uses a right-handed coordinate system with its origin at the nominal interaction point (IP) in the centre of the detector and the z-axis along the beam pipe. The x-axis points from the IP to the centre of the LHC ring, and the y-axis points upward. Cylindrical coordinates (r, ϕ) are used in the transverse plane, ϕ being the azimuthal angle around the beam pipe. The pseudorapidity is defined in terms of the polar angle θ as $\eta = -\ln\tan(\theta/2)$.

[3] Using a system of units with $c = 1$ is implied throughout the paper.

3 Reconstruction and event selection

The J/ψ candidates are reconstructed from pairs of oppositely charged muons. At least one of the two muons is required to be a combined muon. Each pair is fitted to a common vertex [21]. The quality of the vertex fit must satisfy $\chi^2/\text{ndf} < 15$, where the ndf stands for the number of degrees of freedom. The candidates in the invariant mass window $2800\,\text{MeV} < m(\mu^+\mu^-) < 3400\,\text{MeV}$ are retained.

For the $D_s^+ \to \phi(K^+K^-)\pi^+$ reconstruction, tracks of particles with opposite charges are assigned kaon mass hypotheses and combined in pairs to form ϕ candidates. An additional track is assigned a pion mass and combined with the ϕ candidate to form a D_s^+ candidate. To ensure good momentum resolution, all three tracks are required to have at least two hits in the silicon pixel detector and at least six hits in the SCT. Only three-track combinations successfully fitted to a common vertex with $\chi^2/\text{ndf} < 8$ are kept. The ϕ candidate invariant mass, $m(K^+K^-)$, and the D_s^+ candidate invariant mass, $m(K^+K^-\pi^+)$, are calculated using the track momenta refitted to the common vertex. Only candidates with $m(K^+K^-)$ within $\pm 7\,\text{MeV}$ around the ϕ mass, $m_\phi = 1019.461\,\text{MeV}$ [22], and with $1930\,\text{MeV} < m(K^+K^-\pi^+) < 2010\,\text{MeV}$ are retained.

The $B_c^+ \to J/\psi D_s^+$ candidates are built by combining the five tracks of the J/ψ and D_s^+ candidates. The J/ψ meson decays instantly at the same point as the B_c^+ does (secondary vertex) while the D_s^+ lives long enough to form a displaced tertiary vertex. Therefore the five-track combinations are refitted assuming this cascade topology [21]. The invariant mass of the muon pair is constrained to the J/ψ mass, $m_{J/\psi} = 3096.916\,\text{MeV}$ [22]. The three D_s^+ daughter tracks are constrained to a tertiary vertex and their invariant mass is fixed to the mass of D_s^+, $m_{D_s^+} = 1968.30\,\text{MeV}$ [22]. The combined momentum of the refitted D_s^+ decay tracks is constrained to point to the dimuon vertex. The quality of the cascade fit must satisfy $\chi^2/\text{ndf} < 3$.

The B_c^+ meson is reconstructed within the kinematic range $p_\text{T}(B_c^+) > 15\,\text{GeV}$ and $|\eta(B_c^+)| < 2.0$, where the detector acceptance is high and depends weakly on $p_\text{T}(B_c^+)$ and $\eta(B_c^+)$.

The refitted tracks of the D_s^+ daughter hadrons are required to have $|\eta| < 2.5$ and $p_\text{T} > 1\,\text{GeV}$, while the muons must have $|\eta| < 2.3$ and $p_\text{T} > 3\,\text{GeV}$. To further discriminate the sample of D_s^+ candidates from a large combinatorial background, the following requirements are applied:

- $\cos\theta^*(\pi) < 0.8$, where $\theta^*(\pi)$ is the angle between the pion momentum in the $K^+K^-\pi^+$ rest frame and the $K^+K^-\pi^+$ combined momentum in the laboratory frame;
- $|\cos^3\theta'(K)| > 0.15$, where $\theta'(K)$ is the angle between one of the kaons and the pion in the K^+K^- rest frame. The decay of the pseudoscalar D_s^+ meson to the ϕ (vector) plus π (pseudoscalar) final state results in an alignment of the spin of the ϕ meson perpendicularly to the direction of motion of the ϕ relative to D_s^+. Consequently, the distribution of $\cos\theta'(K)$ follows a $\cos^2\theta'(K)$ shape, implying a uniform distribution for $\cos^3\theta'(K)$. In contrast, the $\cos\theta'(K)$ distribution of the combinatorial background is uniform and its $\cos^3\theta'(K)$ distribution peaks at zero. The cut suppresses the background significantly while reducing the signal by 15 %.

The B_c^+ candidate is required to point back to a primary vertex such that $d_0^\text{PV}(B_c^+) < 0.1\,\text{mm}$ and $z_0^\text{PV}(B_c^+)\sin\theta(B_c^+) < 0.5\,\text{mm}$, where d_0^PV and z_0^PV are respectively the transverse and longitudinal impact parameters with respect to the primary vertex. All primary vertices in the event are considered. If there is more than one primary vertex satisfying these requirements (∼0.5 % events both in data and MC simulation), the one with the largest sum of squared transverse momenta of the tracks originating from it is chosen.

The transverse decay length[4] of the B_c^+ candidate is required to satisfy $L_{xy}(B_c^+) > 0.1\,\text{mm}$. The transverse decay length of the D_s^+ measured from the B_c^+ vertex must be $L_{xy}(D_s^+) > 0.15\,\text{mm}$. In order to remove fake candidates, both $L_{xy}(B_c^+)$ and $L_{xy}(D_s^+)$ are required not to exceed 10 mm.

Taking into account the characteristic hard fragmentation of b-quarks, a requirement $p_\text{T}(B_c^+)/\sum p_\text{T}(\text{trk}) > 0.1$ is applied, where the sum in the denominator is taken over all tracks originating from the primary vertex (tracks of the B_c^+ candidate are included in the sum if they are associated with the primary vertex). The requirement reduces a sizeable fraction of combinatorial background while having almost no effect on the signal.

The following angular selection requirements are introduced to further suppress the combinatorial background:

- $\cos\theta^*(D_s^+) > -0.8$, where $\theta^*(D_s^+)$ is the angle between the D_s^+ candidate momentum in the rest frame of the B_c^+ candidate, and the B_c^+ candidate line of flight in the laboratory frame. The distribution of $\cos\theta^*(D_s^+)$ is uniform for the decays of pseudoscalar B_c^+ meson before any kinematic selection while it tends to increase for negative values of $\cos\theta^*(D_s^+)$ for the background.
- $\cos\theta'(\pi) > -0.8$, where $\theta'(\pi)$ is the angle between the J/ψ candidate momentum and the pion momentum in the $K^+K^-\pi^+$ rest frame. Its distribution is nearly uniform for the signal processes but peaks towards -1 for the background.

[4] The transverse decay length of a particle is defined as the transverse distance between the production (primary) vertex and the particle decay (secondary) vertex projected along its transverse momentum.

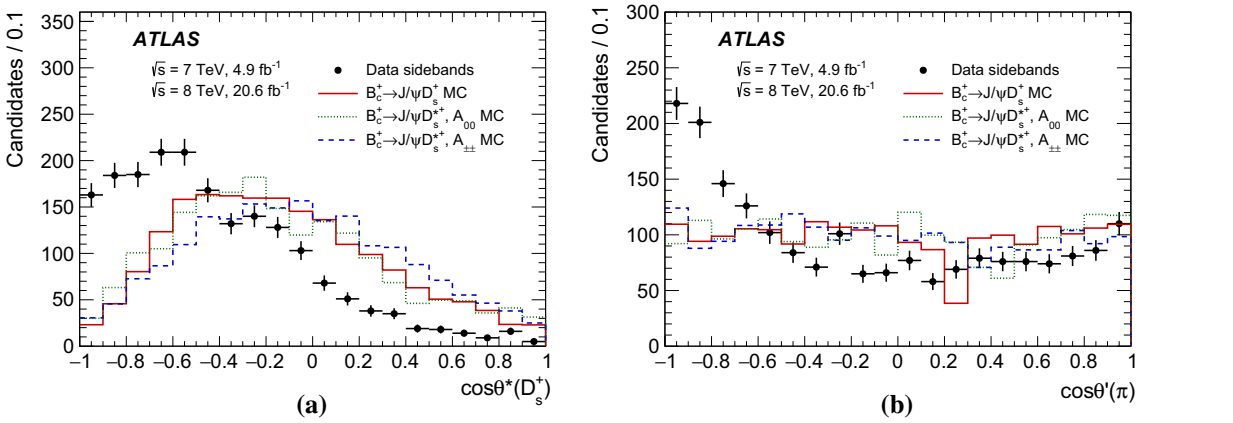

Fig. 2 Distributions of **a** $\cos\theta^*(D_s^+)$ and **b** $\cos\theta'(\pi)$, where $\theta^*(D_s^+)$ and $\theta'(\pi)$ are two angular variables defined in Sect. 3. The distributions are shown for data sidebands (*black dots*) and MC simulation of $B_c^+ \to J/\psi D_s^+$ signal (*red solid line*) and A_{00} (*green dotted line*) and $A_{\pm\pm}$ (*blue dashed line*) components of $B_c^+ \to J/\psi D_s^{*+}$ signal. The distributions are obtained after applying all selection criteria except the ones on the plotted variable. The MC distributions are normalised to data

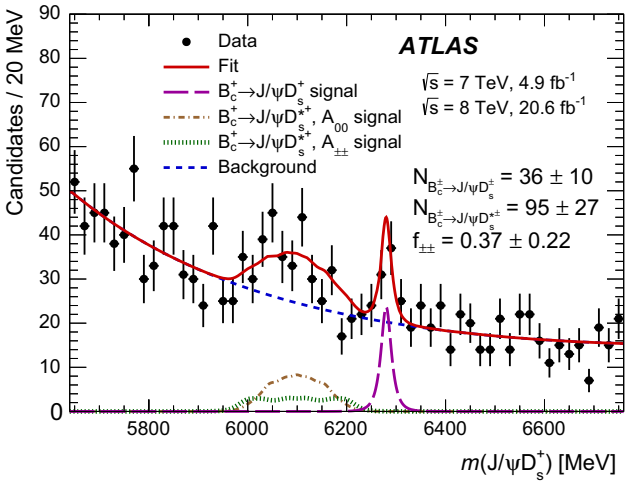
Distributions of these two variables after applying all other selection requirements described in this section are shown in Fig. 2. They are shown for the simulated signal samples, as well as for sidebands of the mass spectrum in data, defined as the regions 5640 MeV $< m(J/\psi D_s^+) <$ 5900 MeV (left sideband) and 6360 MeV $< m(J/\psi D_s^+) <$ 6760 MeV (right sideband). A dip in the $\cos\theta'(\pi)$ distribution for the $B_c^+ \to J/\psi D_s^+$ signal is caused by rejection of $B_s^0 \to J/\psi\phi$ candidates discussed below.

Various possible contributions of partially reconstructed $B \to J/\psi X$ decays were studied. The only significant one was found from the $B_s^0 \to J/\psi\phi$ decay process. This contribution arises when the combination of the tracks from a true $B_s^0 \to J/\psi(\mu^+\mu^-)\phi(K^+K^-)$ decay with a fifth random track results in a fake $B_c^+ \to J/\psi(\mu^+\mu^-)D_s^+(K^+K^-\pi^+)$ candidate. For each reconstructed B_c^+ candidate, an additional vertex fit is performed. The two muon tracks and the two kaon tracks are fitted to a common vertex, where the kaon tracks are assumed to be from $\phi \to K^+K^-$ and the muon pair is constrained to have the nominal J/ψ mass. The mass of the B_s^0 candidate, $m(\mu^+\mu^-K^+K^-)$, is then calculated from the refitted track parameters. Candidates with 5340 MeV $< m(\mu^+\mu^-K^+K^-) <$ 5400 MeV are rejected. This requirement suppresses the bulk of the B_s^0 events while rejecting only ∼4 % of the signal.

After applying the selection requirements described above, 1547 $J/\psi D_s^+$ candidates are selected in the mass range 5640–6760 MeV.

4 $B_c^+ \to J/\psi D_s^{(*)+}$ candidate fit

The mass distribution of the selected $B_c^+ \to J/\psi D_s^{(*)+}$ candidates is shown in Fig. 3. The peak near the B_c^+ mass, $m_{B_c^+} = 6275.6$ MeV [22], is attributed to the signal of



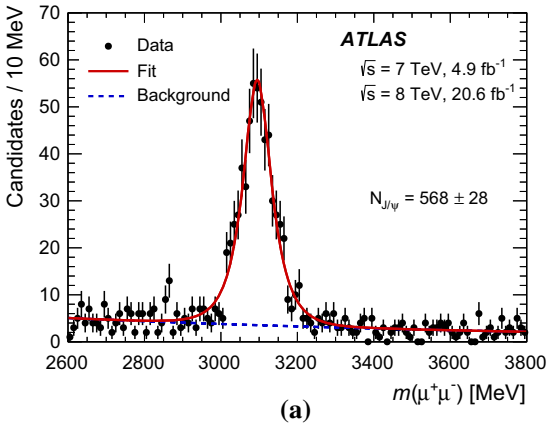


Fig. 3 The mass distribution for the selected $J/\psi D_s^+$ candidates. The *red solid line* represents the projection of the fit to the model described in the text. The contribution of the $B_c^+ \to J/\psi D_s^+$ decay is shown with the *magenta long-dashed line*; the *brown dash-dot* and *green dotted lines* show the $B_c^+ \to J/\psi D_s^{*+}$ A_{00} and $A_{\pm\pm}$ component contributions, respectively; the *blue dashed line* shows the background model. The uncertainties of the listed fit result values are statistical only

$B_c^+ \to J/\psi D_s^+$ decay while a wider structure between 5900 and 6200 MeV corresponds to $B_c^+ \to J/\psi D_s^{*+}$ with subsequent $D_s^{*+} \to D_s^+\gamma$ or $D_s^{*+} \to D_s^+\pi^0$ decays where the neutral particle is not reconstructed.

Mass distributions of the J/ψ and D_s^+ candidates corresponding to the $J/\psi D_s^+$ mass region of the observed $B_c^+ \to J/\psi D_s^{(*)+}$ signals are shown in Fig. 4. To obtain these plots, the B_c^+ candidates are built without the mass constraints in the cascade fit, with the mass of the candidate calculated as $m(J/\psi D_s^+) = m(\mu^+\mu^-K^+K^-\pi^+) - m(\mu^+\mu^-) + m_{J/\psi} - m(K^+K^-\pi^+) + m_{D_s^+}$, where $m_{J/\psi}$ and $m_{D_s^+}$ are the nominal masses of the respective par-

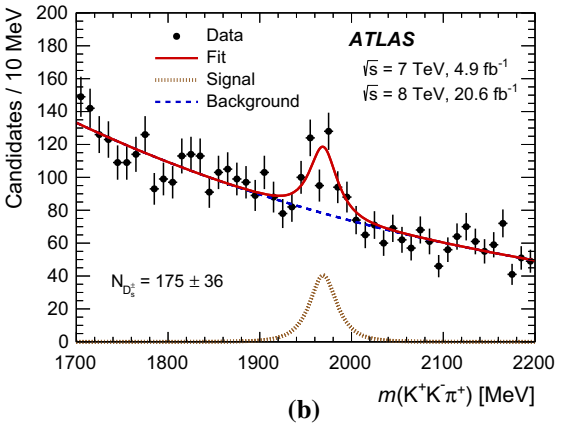

Fig. 4 Mass distribution of the **a** J/ψ and **b** D_s^+ candidates after the full $B_c^+ \to J/\psi D_s^{(*)+}$ selection (without mass constraints in the cascade fit) in the mass window of the B_c^+ candidate 5900 MeV $< m(J/\psi D_s^+) <$ 6400 MeV. The spectra are fitted with a sum of an exponential and a modified Gaussian function. The uncertainties of the shown J/ψ and D_s^+ yields are statistical only

ticles. The mass of the B_c^+ candidate is required to be 5900 MeV $< m(J/\psi D_s^+) <$ 6400 MeV while the mass windows for the corresponding intermediate resonances are widened to the plotting ranges. The J/ψ and D_s^+ mass distributions are fitted with a sum of an exponential function describing the background and a modified Gaussian function [23,24] describing the corresponding signal peak. The modified Gaussian function is defined as

$$\text{Gauss}^{\text{mod}} \sim \exp\left(-\frac{x^{1+\frac{1}{1+x/2}}}{2}\right), \tag{1}$$

where $x = |m_0 - m|/\sigma$ with the mean mass m_0 and width σ being free parameters. The fitted masses of J/ψ (3095.1 ± 2.4 MeV) and D_s (1969.0 ± 4.1 MeV) agree with their nominal masses, the widths are consistent with those in the simulated samples, and the signal yields are found to be $N_{J/\psi} = 568 \pm 28$ and $N_{D_s^\pm} = 175 \pm 36$.

The information about the helicity in $B_c^+ \to J/\psi D_s^{*+}$ decay is encoded both in the mass distribution of the $J/\psi D_s^+$ system and in the distribution of the helicity angle, $\theta'(\mu^+)$, which is defined in the rest frame of the muon pair as the angle between the μ^+ and the D_s^+ candidate momenta. Thus, a two-dimensional extended unbinned maximum-likelihood fit of the $m(J/\psi D_s^+)$ and $|\cos\theta'(\mu^+)|$ distributions is performed. The A_{++} and A_{--} helicity amplitude contributions are described by the same mass and angular shapes because of the parity symmetry of the J/ψ and D_s^{*+} decays. This is confirmed by the MC simulation. Thus these components are treated together as the $A_{\pm\pm}$ component, while the shape of the A_{00} component is different and is therefore treated separately. A simultaneous fit to the mass and angular distributions significantly improves the sensitivity to the contributions of the helicity amplitudes in $B_c^+ \to J/\psi D_s^{*+}$ decay with respect to a one-dimensional mass fit.

Four two-dimensional probability density functions (PDFs) are defined to describe the $B_c^+ \to J/\psi D_s^+$ signal, the $A_{\pm\pm}$ and A_{00} components of the $B_c^+ \to J/\psi D_s^{*+}$ signal, and the background. The signal PDFs are factorised into mass and angular components. The effect of correlations between their mass and angular shapes is found to be small and is accounted for as a systematic uncertainty.

The mass distribution of the $B_c^+ \to J/\psi D_s^+$ signal is described by a modified Gaussian function. For the $B_c^+ \to J/\psi D_s^{*+}$ signal components, the mass shape templates obtained from the simulation with the kernel estimation technique [25] are used. The branching fractions of $D_s^{*+} \to D_s^+\pi^0$ and $D_s^{*+} \to D_s^+\gamma$ decays for the simulation are set to the world average values [22]. The position of the templates along the mass axis is varied in the fit simultaneously with the position of the $B_c^+ \to J/\psi D_s^+$ signal peak. The background mass shape is described with a two-parameter exponential function, $\exp\left[a \cdot m(J/\psi D_s^+) + b \cdot m(J/\psi D_s^+)^2\right]$.

To describe the $|\cos\theta'(\mu^+)|$ shapes, templates from the kernel estimation are used. The templates for the signal angular PDFs are extracted from the simulated samples. Although their shapes are calculable analytically, using the templates allows the fit to account for detector effects. The background angular description is based on the $|\cos\theta'(\mu^+)|$ shape of the candidates in the sidebands of $J/\psi D_s^+$ mass spectra. Two templates are produced from the angular distributions of the candidates in the left and right mass sidebands as defined in Sect. 3. The angular PDF for the background is defined as a conditional PDF of $|\cos\theta'(\mu^+)|$ given the per-candidate $m(J/\psi D_s^+)$. For the candidates in the lower half of the left sideband (5640–5770 MeV), the template from the left sideband is used. Similarly, the template from the right sideband is used for the upper half of the right sideband (6560–6760 MeV). For the candidates in the middle part of the mass spectrum (5770–

Table 1 Parameters of the $B_c^+ \to J/\psi D_s^{(*)+}$ signals obtained with the unbinned extended maximum-likelihood fit. The width parameter of the modified Gaussian function is fixed to the MC value. Only statistical uncertainties are shown. No acceptance corrections are applied to the signal yields

Parameter	Value
$m_{B_c^+ \to J/\psi D_s^+}$ (MeV)	6279.9 ± 3.5
$N_{B_c^+ \to J/\psi D_s^+}$	36 ± 10
$N_{B_c^+ \to J/\psi D_s^{*+}}$	95 ± 27
$f_{\pm\pm}$	0.37 ± 0.22

6560 MeV), a linear interpolation between the two templates is used.

The fit has seven free parameters: the mass of the B_c^+ meson, $m_{B_c^+ \to J/\psi D_s^+}$; the relative contribution of the $A_{\pm\pm}$ component to the total $B_c^+ \to J/\psi D_s^{*+}$ decay rate in the selected sample, $f_{\pm\pm}$; the two parameters of the exponential background; the yields of the two signal modes, $N_{B_c^+ \to J/\psi D_s^+}$ and $N_{B_c^+ \to J/\psi D_s^{*+}}$, and the background yield. The width of the modified Gaussian function, $\sigma_{B_c^+ \to J/\psi D_s^+}$, is fixed to the value obtained from the fit to the simulated signal, $\sigma_{B_c^+ \to J/\psi D_s^+} = 9.95$ MeV. Leaving this parameter free in the data fit results in the value 7.9 ± 3.0 MeV, consistent with the simulation in the range of statistical uncertainty.

It was checked that the fit procedure provides unbiased values and correct statistical uncertainties for the extracted parameters using pseudo-experiments. The values of the relevant parameters obtained from the fit are given in Table 1. The fitted B_c^+ mass agrees with the world average value [22].

The mass and angular projections of the fit on the selected $J/\psi D_s^+$ candidate dataset are also shown in Figs. 3 and 5a, respectively. In order to illustrate the effect of the angular part of the fit in separating the helicity amplitudes, the $|\cos\theta'(\mu^+)|$ projection for the subset of candidates with the masses 5950 MeV $< m(J/\psi D_s^+) <$ 6250 MeV corresponding to the region of the observed $B_c^+ \to J/\psi D_s^{*+}$ signal is shown in Fig. 5b.

The statistical significance for the observed B_c^+ signal estimated from toy MC studies is 4.9 standard deviations.

5 $B_c^+ \to J/\psi\pi^+$ candidate reconstruction and fit

$B_c^+ \to J/\psi\pi^+$ candidates are reconstructed by fitting a common vertex of a pion candidate track and the two muons from a J/ψ candidate, selected as described in Sect. 3. For the pion candidate, tracks identified as muons are vetoed in order to suppress the substantial background from $B_c^+ \to J/\psi\mu^+\nu_\mu X$ decays. The invariant mass of the two muons in the vertex fit is constrained to the J/ψ nominal mass. The quality of the fit must satisfy $\chi^2/\text{ndf} < 3$. The following selection requirements applied to the $B_c^+ \to J/\psi\pi^+$ candidates are analogous to those for $B_c^+ \to J/\psi D_s^+$ candidates described in Sect. 3: the candidates must be within the kinematic range $p_T(B_c^+) > 15$ GeV, $|\eta(B_c^+)| < 2.0$; the refitted values of the transverse momenta and pseudorapidities of the muons are required to satisfy $p_T(\mu^\pm) > 3$ GeV, $|\eta(\mu^\pm)| < 2.3$; the same requirements on pointing to the primary vertex and the ratio $p_T(B_c^+)/\sum p_T(\text{trk})$ are applied. The refitted pion track kinematics must satisfy $p_T(\pi^+) > 5$ GeV and $|\eta(\pi^+)| < 2.5$. The transverse decay length

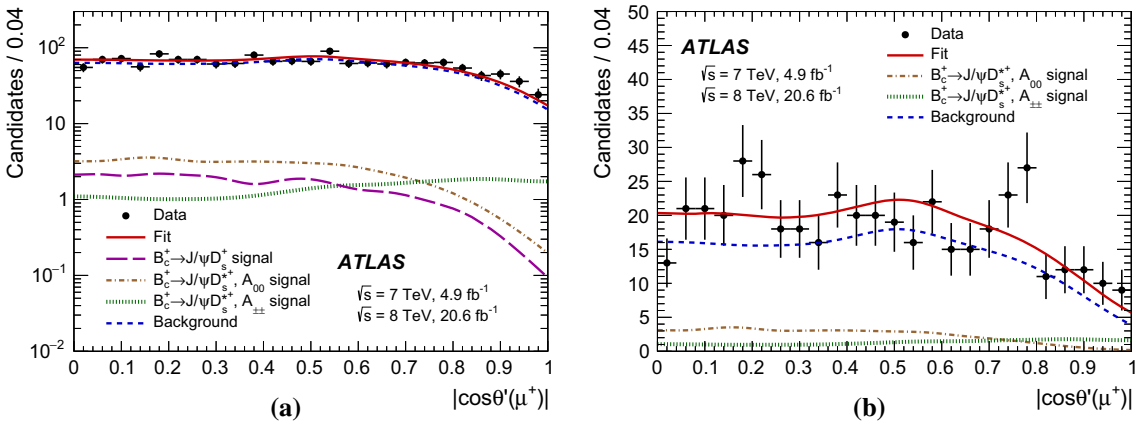

Fig. 5 The projection of the likelihood fit on the variable $|\cos\theta'(\mu^+)|$, where the helicity angle $\theta'(\mu^+)$ is the angle between the μ^+ and D_s^+ candidate momenta in the rest frame of the muon pair from J/ψ decay, for **a** the full selected $J/\psi D_s^+$ candidate dataset and **b** a subset of the candidates in a mass range 5950 MeV $< m(J/\psi D_s^+) <$ 6250 MeV corresponding to the observed signal of $B_c^+ \to J/\psi D_s^{*+}$ decay. The *red solid line* represents the full fit projection. The contribution of the $B_c^+ \to J/\psi D_s^+$ decay is shown with the *magenta long-dashed line* (it is not drawn in **b** because this contribution vanishes in that mass range); the *brown dash-dot* and *green dotted lines* show the $B_c^+ \to J/\psi D_s^{*+}$ A_{00} and $A_{\pm\pm}$ component contributions, respectively; the *blue dashed line* shows the background model

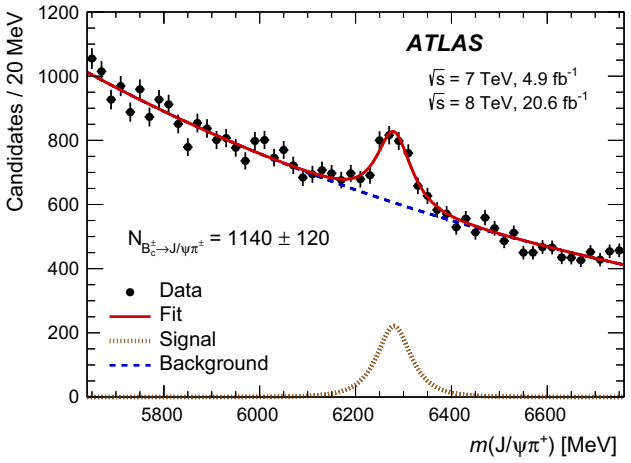

Fig. 6 The mass distribution for the selected $B_c^+ \to J/\psi\pi^+$ candidates. The *red solid line* represents the result of the fit to the model described in the text. The *brown dotted* and *blue dashed lines* show the signal and background component projections, respectively. The uncertainty of the shown signal yield is statistical only

is required to be $L_{xy}(B_c^+) > 0.2$ mm, and not to exceed 10 mm.

To further suppress combinatorial background, the following selection is applied:

- $\cos\theta^*(\pi) > -0.8$, where $\theta^*(\pi)$ is the angle between the pion momentum in the $\mu^+\mu^-\pi^+$ rest frame and the B_c^+ candidate line of flight in laboratory frame. This angular variable behaviour for the signal and the background is the same as that of $\cos\theta^*(D_s^+)$ used for $J/\psi D_s^+$ candidates selection.
- $|\cos\theta'(\mu^+)| < 0.8$, where $\theta'(\mu^+)$ is the angle between the μ^+ and π^+ momenta in the muon pair rest frame. The signal distribution follows a $\sin^2\theta'(\mu^+)$ shape, while the background is flat.

After applying the above-mentioned requirements, 38542 $J/\psi\pi^+$ candidates are selected in the mass range 5640–6760 MeV. Figure 6 shows the mass distribution of the selected candidates. An extended unbinned maximum-likelihood fit of the mass spectrum is performed to evaluate the $B_c^+ \to J/\psi\pi^+$ signal yield. The signal contribution is described with the modified Gaussian function while an exponential function is used for the background. The B_c^+ mass, $m_{B_c^+\to J/\psi\pi^+}$, the width of the modified Gaussian function, $\sigma_{B_c^+\to J/\psi\pi^+}$, the yields of the signal, $N_{B_c^+\to J/\psi\pi^+}$, and the background, and the slope of the exponential background are free parameters of the fit. The fit results are summarised in Table 2, and the fit projection is also shown in Fig. 6. The extracted B_c^+ mass value is consistent with the world average [22], and the signal peak width agrees with the simulation (37.4 MeV).

Table 2 Signal parameters of the $J/\psi\pi^+$ mass distribution obtained with the unbinned extended maximum-likelihood fit. Only statistical uncertainties are shown. No acceptance corrections are applied to the signal yields

Parameter	Value
$m_{B_c^+\to J/\psi\pi^+}$ (MeV)	6279.9 ± 3.9
$\sigma_{B_c^+\to J/\psi\pi^+}$ (MeV)	33.9 ± 4.2
$N_{B_c^+\to J/\psi\pi^+}$	1140 ± 120

6 Branching fractions and polarisation measurement

The ratios of the branching fractions $\mathcal{R}_{D_s^+/\pi^+}$ and $\mathcal{R}_{D_s^{*+}/\pi^+}$ are calculated as

$$\mathcal{R}_{D_s^{(*)+}/\pi^+} = \frac{\mathcal{B}_{B_c^+\to J/\psi D_s^{(*)+}}}{\mathcal{B}_{B_c^+\to J/\psi\pi^+}} = \frac{1}{\mathcal{B}_{D_s^+\to\phi(K^+K^-)\pi^+}} \times \frac{\mathcal{A}_{B_c^+\to J/\psi\pi^+}}{\mathcal{A}_{B_c^+\to J/\psi D_s^{(*)+}}} \times \frac{N_{B_c^+\to J/\psi D_s^{(*)+}}}{N_{B_c^+\to J/\psi\pi^+}}, \quad (2)$$

where $\mathcal{A}_{B_c^+\to X}$ and $N_{B_c^+\to X}$ are the total acceptance and the yield of the corresponding mode. For $\mathcal{B}_{D_s^+\to\phi(K^+K^-)\pi^+}$, the CLEO measurement [26] of the partial $D_s^+ \to K^+K^-\pi^+$ branching fractions, with a kaon-pair mass within various intervals around the nominal ϕ meson mass, is used. An interpolation between the partial branching fractions, measured for ± 5 and ± 10 MeV intervals, using a relativistic Breit–Wigner shape of the resonance yields the value $(1.85 \pm 0.11)\%$ for the ± 7 MeV interval which is used in the analysis. The effect of admixture of other D_s^+ decay modes with $(K^+K^-\pi^+)$ final state which are not present in the MC simulation is studied separately and accounted for as a systematic uncertainty.

The acceptance for the $B_c^+ \to J/\psi D_s^{*+}$ decay mode is different for the $A_{\pm\pm}$ and A_{00} components, thus the full acceptance for the mode is

$$\mathcal{A}_{B_c^+\to J/\psi D_s^{*+}} = \left(\frac{f_{\pm\pm}}{\mathcal{A}_{B_c^+\to J/\psi D_s^{*+},A_{\pm\pm}}} + \frac{1-f_{\pm\pm}}{\mathcal{A}_{B_c^+\to J/\psi D_s^{*+},A_{00}}} \right)^{-1}, \quad (3)$$

where the subscripts indicate the helicity state and $f_{\pm\pm}$ is the value extracted from the fit (Table 1). The acceptances are determined from the simulation and shown in Table 3.

The ratio $\mathcal{R}_{D_s^{*+}/D_s^+}$ is calculated as

$$\mathcal{R}_{D_s^{*+}/D_s^+} = \frac{\mathcal{B}_{B_c^+\to J/\psi D_s^{*+}}}{\mathcal{B}_{B_c^+\to J/\psi D_s^+}} = \frac{N_{B_c^+\to J/\psi D_s^{*+}}}{N_{B_c^+\to J/\psi D_s^+}} \times \frac{\mathcal{A}_{B_c^+\to J/\psi D_s^+}}{\mathcal{A}_{B_c^+\to J/\psi D_s^{*+}}}, \quad (4)$$

Table 3 The acceptance $\mathcal{A}_{B_c^+ \to X}$ for all decay modes studied. Only uncertainties due to MC statistics are shown

Mode	$\mathcal{A}_{B_c^+ \to X}$ (%)
$B_c^+ \to J/\psi\pi^+$	4.106 ± 0.056
$B_c^+ \to J/\psi D_s^+$	1.849 ± 0.034
$B_c^+ \to J/\psi D_s^{*+}$, A_{00}	1.829 ± 0.053
$B_c^+ \to J/\psi D_s^{*+}$, $A_{\pm\pm}$	1.712 ± 0.035

where the ratio of the yields $N_{B_c^+ \to J/\psi D_s^{*+}}/N_{B_c^+ \to J/\psi D_s^+}$ and its uncertainty is extracted from the fit as a parameter in order to account for correlations between the yields.

The fraction of the $A_{\pm\pm}$ component contribution in $B_c^+ \to J/\psi D_s^{*+}$ decay is calculated from the $f_{\pm\pm}$ value quoted in Table 1 by applying a correction to account for the different acceptances for the two component contributions:

$$\Gamma_{\pm\pm}/\Gamma = f_{\pm\pm} \times \frac{\mathcal{A}_{B_c^+ \to J/\psi D_s^{*+}}}{\mathcal{A}_{B_c^+ \to J/\psi D_s^{*+}}, \mathcal{A}_{\pm\pm}}. \quad (5)$$

7 Systematic uncertainties

The systematic uncertainties of the measured values are determined by varying the analysis procedure and repeating all calculations. Although some sources can have rather large effects on the individual decay rate measurements, they largely cancel in the ratios of the branching fractions due to correlation between the effects on the different decay modes. The following groups of systematic uncertainties are considered.

The first group of sources of systematic uncertainty relates to possible differences between the data and simulation affecting the acceptances for the decay modes. Thus, an effect of the B_c^+ production model is evaluated by varying the simulated p_{T} and $|\eta|$ spectra while preserving agreement with the data distributions obtained using the abundant $B_c^+ \to J/\psi\pi^+$ channel. These variations have very similar effects on the acceptances for the different decay modes, thus giving rather moderate estimates of the uncertainties, not exceeding 3 % in total, on the ratios of branching fractions. The effect of presence of other D_s^+ decay modes with $(K^+K^-\pi^+)$ final state on the calculated acceptances is studied with a separate MC simulation. Its conservative estimate yields 0.4 % which is assigned as $\mathcal{R}_{D_s^+/\pi^+}$ and $\mathcal{R}_{D_s^{*+}/\pi^+}$ uncertainties. An uncertainty on the tracking efficiency is dominated by the uncertainty of the detector material description in the MC simulation. Samples generated with distorted geometries and with increased material are used to estimate the effect on track reconstruction efficiencies. When propagated to the ratios of branching fractions, these estimates give 0.5 % uncertainty for $\mathcal{R}_{D_s^+/\pi^+}$ and $\mathcal{R}_{D_s^{*+}/\pi^+}$ due to the two extra tracks in $B_c^+ \to J/\psi D_s^{(*)+}$ modes. Limited knowledge of the B_c^+ and D_s^+ lifetimes leads to an additional systematic uncertainty. The simulated proper decay times are varied within one standard deviation from the world average values [22] resulting in uncertainties of ∼1 % assigned to $\mathcal{R}_{D_s^+/\pi^+}$ and $\mathcal{R}_{D_s^{*+}/\pi^+}$ due to the B_c^+ lifetime, and 0.3 % due to the D_s^+ lifetime. Removing the requirement on $p_{\mathrm{T}}(B_c^+)/\sum p_{\mathrm{T}}(\mathrm{trk})$ is found to produce no noticeable effect on the measured values.

The next group of uncertainties originates from the signal extraction procedure. These uncertainties are evaluated separately for $J/\psi D_s^+$ and $J/\psi\pi^+$ candidate fits. For the former, the following variations of the fit model are applied and the difference is treated as a systematic uncertainty:

- different background mass shape parametrisations (three-parameter exponential, second- and third-order polynomials), different fitted mass range (reduced by up to 40 MeV from each side independently);
- a double Gaussian or double-sided Crystal Ball function [27–29] for $B_c^+ \to J/\psi D_s^+$ signal description; variation of the modified Gaussian width within 10 % of the MC simulation value;
- variation of the smoothness of the $B_c^+ \to J/\psi D_s^{*+}$ signal mass templates, which is controlled by a parameter of the kernel estimation procedure [25];
- similar variation of the smoothness of the $B_c^+ \to J/\psi D_s^{(*)+}$ signal angular templates;
- variation of the smoothness of the sideband templates used for the background angular PDF construction; different ranges of the sidebands; different sideband interpolation procedure;
- modelling of the correlation between the mass and angular parts of the signal PDFs. This correlation takes place only at the detector level and manifests itself in degradation of the mass resolution for higher values of $|\cos\theta'(\mu^+)|$. A dedicated fit model accounting for this effect is used for the data fit. The impact on the result is found to be negligible compared to the total uncertainty.

The first two items give the dominant contributions to the uncertainties of the ratios of branching fractions while the transverse polarisation fraction measurement is mostly affected by the background angular modelling variations. For the normalisation channel fit model, the similar variations of the background and signal mass shape parametrisation are applied. The deviations produced by the variations of the fits reach values as high as 10–15 % thus making them the dominant sources of systematic uncertainty.

The branching fractions of D_s^{*+} [22] are varied in simulation within their uncertainties to estimate their effect on the measured quantities. Very small uncertainties are obtained

Table 4 Relative systematic uncertainties on the measured ratios of branching fractions $R_{D_s^+/\pi^+}$, $R_{D_s^{*+}/\pi^+}$, $R_{D_s^{*+}/D_s^+}$ and on the transverse polarisation fraction $\Gamma_{\pm\pm}/\Gamma$

Source	Uncertainty (%)			
	$R_{D_s^+/\pi^+}$	$R_{D_s^{*+}/\pi^+}$	$R_{D_s^{*+}/D_s^+}$	$\Gamma_{\pm\pm}/\Gamma$
Simulated $p_{\mathrm{T}}(B_c^+)$ spectrum	0.4	0.9	0.5	0.4
Simulated $\lvert\eta(B_c^+)\rvert$ spectrum	1.9	2.4	0.6	0.2
Other D_s^+ decay modes contribution	0.4	0.4	–	–
Tracking efficiency	0.5	0.5	<0.1	<0.1
B_c^+ lifetime	1.2	1.3	<0.1	<0.1
D_s^+ lifetime	0.3	0.3	<0.1	<0.1
$B_c^+ \to J/\psi D_s^{(*)+}$ signal extraction	4.4	10.5	10.7	17.4
$B_c^+ \to J/\psi\pi^+$ signal extraction	8.5	8.5	–	–
D_s^{*+} branching fractions	<0.1	<0.1	<0.1	1.1
MC sample sizes	2.3	2.4	2.7	2.2
Total	10.1	14.0	11.0	17.6
$\mathcal{B}_{D_s^+\to\phi(K^+K^-)\pi^+}$	5.9	5.9	–	–

for the $\mathcal{R}_{D_s^{*+}/\pi^+}$ and $\mathcal{R}_{D_s^{*+}/D_s^+}$, while for $\Gamma_{\pm\pm}/\Gamma$, the estimate is ∼1 %.

The statistical uncertainties on the acceptance values due to the MC sample sizes are also treated as a separate source of systematic uncertainty and estimated to be 2–3 %.

In order to check for a possible bias from using three-muon triggers, vetoing the D_s^+ meson daughter tracks identified as muons is tested and found not to affect the measurement.

Finally, since $\mathcal{B}_{D_s^+\to\phi(K^+K^-)\pi^+}$ enters Eq. (2), its uncertainty, evaluated from Ref. [26] as 5.9 %, is propagated to the final values of the relative branching fractions.

The systematic uncertainties on the measured quantities are summarised in Table 4.

8 Results

The following ratios of the branching fractions are measured:

$$\mathcal{R}_{D_s^+/\pi^+} = \frac{\mathcal{B}_{B_c^+\to J/\psi D_s^+}}{\mathcal{B}_{B_c^+\to J/\psi\pi^+}} = 3.8 \pm 1.1(\text{stat.}) \pm 0.4(\text{syst.}) \pm 0.2(\text{BF}), \quad (6)$$

$$\mathcal{R}_{D_s^{*+}/\pi^+} = \frac{\mathcal{B}_{B_c^+\to J/\psi D_s^{*+}}}{\mathcal{B}_{B_c^+\to J/\psi\pi^+}} = 10.4 \pm 3.1(\text{stat.}) \pm 1.5(\text{syst.}) \pm 0.6(\text{BF}), \quad (7)$$

$$\mathcal{R}_{D_s^{*+}/D_s^+} = \frac{\mathcal{B}_{B_c^+\to J/\psi D_s^{*+}}}{\mathcal{B}_{B_c^+\to J/\psi D_s^+}} = 2.8^{+1.2}_{-0.8}(\text{stat.}) \pm 0.3(\text{syst.}), \quad (8)$$

where the BF uncertainty corresponds to the knowledge of $\mathcal{B}_{D_s^+\to\phi(K^+K^-)\pi^+}$. The relative contribution of the $A_{\pm\pm}$ component in $B_c^+ \to J/\psi D_s^{*+}$ decay is measured to be

$$\Gamma_{\pm\pm}/\Gamma = 0.38 \pm 0.23(\text{stat.}) \pm 0.07(\text{syst.}) \quad (9)$$

These results are compared with those of the LHCb measurement [10] and to the expectations from various theoretical calculations in Table 5 and Fig. 7. The measurement agrees with the LHCb result. All ratios are well described by the recent perturbative QCD predictions [8]. The expectations from models in Refs. [3,5,7] as well as the sum-rules prediction [4] for the ratio $\mathcal{R}_{D_s^{*+}/D_s^+}$ are consistent with the measurement. The QCD relativistic potential model predictions [3] are consistent with the measured $\mathcal{R}_{D_s^+/\pi^+}$ ratio while the expectations from the sum rules [4] and models in Refs. [5–7] are somewhat smaller than the measured value. The predictions in Refs. [3–5,7] are also generally smaller than the measured ratio $\mathcal{R}_{D_s^{*+}/\pi^+}$; however, the discrepancies do not exceed two standard deviations when taking into account only the experimental uncertainty.

The measured fraction of the $A_{\pm\pm}$ component agrees well with the prediction of the relativistic independent quark model [9] and perturbative QCD [8].

9 Conclusion

A study of $B_c^+ \to J/\psi D_s^+$ and $B_c^+ \to J/\psi D_s^{*+}$ decays has been performed. The ratios of the branching fractions $\mathcal{B}_{B_c^+\to J/\psi D_s^+}/\mathcal{B}_{B_c^+\to J/\psi\pi^+}$, $\mathcal{B}_{B_c^+\to J/\psi D_s^{*+}}/\mathcal{B}_{B_c^+\to J/\psi\pi^+}$, $\mathcal{B}_{B_c^+\to J/\psi D_s^{*+}}/\mathcal{B}_{B_c^+\to J/\psi D_s^+}$ and the transverse polarisation fraction of $B_c^+ \to J/\psi D_s^{*+}$ decay have been measured by the ATLAS experiment at the LHC using pp collision data corresponding to an integrated luminosity of 4.9 fb^{-1} at 7 TeV centre-of-mass energy and 20.6 fb^{-1} at 8 TeV. The polarisation is found to be well described by the available

Table 5 Comparison of the results of this measurement with those of LHCb [10] and theoretical predictions based on a QCD relativistic potential model [3], QCD sum rules [4], relativistic constituent quark model (RCQM) [5], BSW relativistic quark model (with fixed average transverse quark momentum $\omega = 0.40\,\text{GeV}$) [6], light-front quark model (LFQM) [7], perturbative QCD (pQCD) [8], and relativistic independent quark model (RIQM) [9]. The uncertainties of the theoretical predictions are shown if they are explicitly quoted in the corresponding papers. Statistical and systematic uncertainties added in quadrature are shown for the results of ATLAS and LHCb

$3.45^{+0.49}_{-0.17}$	–	$2.54^{+0.07}_{-0.21}$	0.48 ± 0.04	pQCD [8]
–	–	–	0.410	RIQM [9]

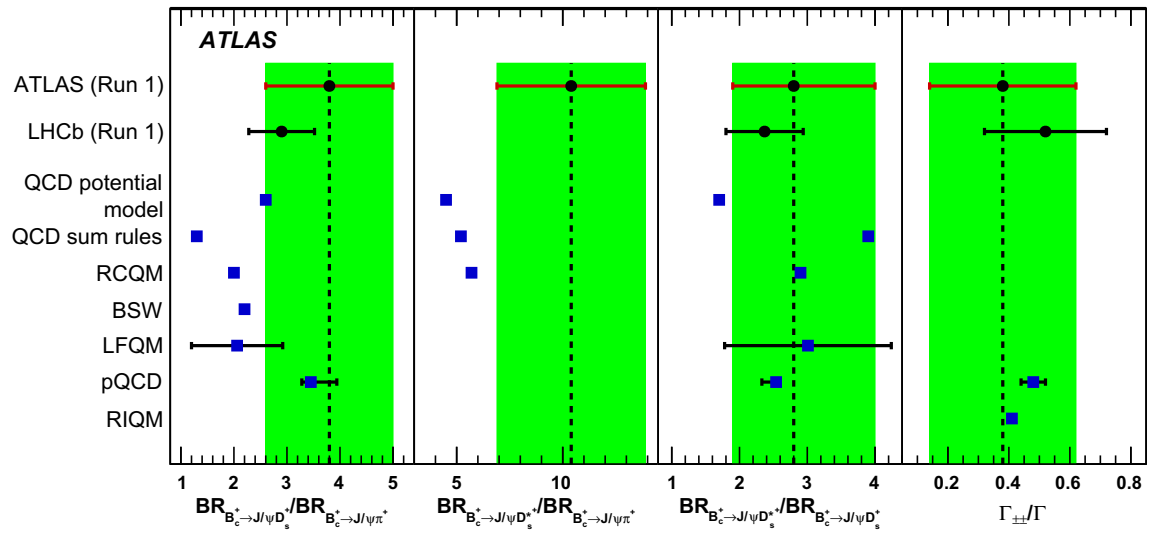

Fig. 7 Comparison of the results of this measurement with those of LHCb [10] and theoretical predictions based on a QCD relativistic potential model [3], QCD sum rules [4], relativistic constituent quark model (RCQM) [5], BSW relativistic quark model (with fixed average transverse quark momentum $\omega = 0.40\,\text{GeV}$) [6], light-front quark model (LFQM) [7], perturbative QCD (pQCD) [8], and relativistic independent quark model (RIQM) [9]. The uncertainties of the theoretical predictions are shown if they are explicitly quoted in the corresponding papers. Statistical and systematic uncertainties added in quadrature are quoted for the results of ATLAS and LHCb.

theoretical approaches. The measured ratios of the branching fraction are generally described by perturbative QCD, sum rules, and relativistic quark models. There is an indication of underestimation of the decay rates for the $B_c^+ \to J/\psi D_s^{(*)+}$ decays by some models, although the discrepancies do not exceed two standard deviations when taking into account only the experimental uncertainty. The measurement results agree with those published by the LHCb experiment.

Acknowledgments We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently. We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWFW and FWF, Austria; ANAS, Azerbaijan; SSTC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR and VSC CR, Czech Republic; DNRF, DNSRC and Lundbeck Foundation, Denmark; EPLANET, ERC and NSRF, European Union; IN2P3-CNRS, CEA-DSM/IRFU, France; GNSF, Georgia; BMBF, DFG, HGF, MPG and AvH Foundation, Germany; GSRT and NSRF, Greece; RGC, Hong Kong SAR, China; ISF, MINERVA, GIF, I-CORE and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; BRF and RCN, Norway; MNiSW and NCN, Poland; GRICES and FCT, Portugal; MNE/IFA, Romania; MES of Russia and NRC KI, Russian Federation; JINR; MSTD, Serbia; MSSR, Slovakia; ARRS and MIZŠ, Slovenia; DST/NRF, South Africa; MINECO, Spain; SRC and Wallenberg Foundation, Sweden; SER, SNSF and Cantons of Bern and

Geneva, Switzerland; NSC, Taiwan; TAEK, Turkey; STFC, the Royal Society and Leverhulme Trust, United Kingdom; DOE and NSF, United States of America. The crucial computing support from all WLCG partners is acknowledged gratefully, in particular from CERN and the ATLAS Tier-1 facilities at TRIUMF (Canada), NDGF (Denmark, Norway, Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy), NL-T1 (Netherlands), PIC (Spain), ASGC (Taiwan), RAL (UK) and BNL (USA) and in the Tier-2 facilities worldwide.

Evidence of $W\gamma\gamma$ Production in pp Collisions at $\sqrt{s} = 8$ TeV and Limits on Anomalous Quartic Gauge Couplings with the ATLAS Detector

G. Aad *et al.*[*]
(ATLAS Collaboration)

(Received 11 March 2015; published 16 July 2015)

This Letter reports evidence of triple gauge boson production $pp \to W(\ell\nu)\gamma\gamma + X$, which is accessible for the first time with the 8 TeV LHC data set. The fiducial cross section for this process is measured in a data sample corresponding to an integrated luminosity of 20.3 fb^{-1}, collected by the ATLAS detector in 2012. Events are selected using the W boson decay to $e\nu$ or $\mu\nu$ as well as requiring two isolated photons. The measured cross section is used to set limits on anomalous quartic gauge couplings in the high diphoton mass region.

DOI: 10.1103/PhysRevLett.115.031802 PACS numbers: 12.15.Ji, 13.85.Qk, 14.70.Bh, 14.70.Fm

In the standard model (SM), the self-couplings of the electroweak gauge bosons are specified by the non-Abelian $SU(2) \times U(1)$ structure of the electroweak sector. Since any deviation in the self-couplings from this expectation indicates the presence of new physics phenomena at unprobed energy scales, the measurement of the production of multiple electroweak gauge bosons represents an important test of the SM. This Letter presents a measurement of the triboson production cross section, discussed in Ref. [1], where the W boson decays into $e\nu$ or $\mu\nu$ [$W(\ell\nu)\gamma\gamma$], and its sensitivity to anomalous quartic gauge couplings (AQGCs) $WW\gamma\gamma$. Such final states mainly come from events where the W boson is produced in the hard interaction between the two partons, and the photons either originate from initial or final state radiation processes, or from triple or quartic gauge vertices together with the W boson. The inclusive and exclusive cross sections are both measured. The inclusive case has no restriction on the $W\gamma\gamma$ recoil system, whereas the exclusive case includes a veto on events containing one or more jets. Limits on AQGC parameters are set in the exclusive phase space with a diphoton mass larger than 300 GeV. Total and differential cross sections for the diboson production processes WW, WZ, ZZ, $W\gamma$, and $Z\gamma$ have been reported previously by the ATLAS [2–5], CMS [6–8], D0 [9–11], and CDF [12–14] Collaborations, including limits on anomalous triple gauge boson couplings. Limits have been set on AQGCs by ATLAS [15], CMS [16,17], the LEP experiments [18–21], and D0 [22].

ATLAS [23] is a multipurpose detector composed of an inner tracking detector (ID) surrounded by a thin superconducting solenoid providing a 2 T axial magnetic field, electromagnetic (EM) and hadronic calorimeters, and a muon spectrometer (MS) immersed in the magnetic field produced by a system of superconducting toroids. Events in this analysis are selected with triggers requiring the presence of one muon with a transverse momentum (p_T) of more than 18 GeV and two electromagnetic objects with a transverse energy (E_T) of more than 10 GeV each, with an efficiency of about 80% [24], or three $E_T > 15$ GeV electromagnetic objects with an efficiency of more than 95% [25,26]. After applying data quality requirements, the data set corresponds to a total integrated luminosity of 20.3 ± 0.6 fb^{-1} [27].

The main backgrounds to the $W(\ell\nu)\gamma\gamma$ process originate from processes with jets identified as photons or leptons, referred to as fakes hereafter. Data-driven techniques are used to estimate fakes, whereas Monte Carlo (MC) simulation is used to estimate background sources with prompt leptons and photons and for the signal. The SHERPA 1.4.1 generator [28–31] is used to model the signal with up to three partons in the final state. SHERPA was also used to simulate the $Z\gamma$, $Z\gamma\gamma$, WZ, and $W(\tau\nu)\gamma\gamma$ backgrounds. For the $Z\gamma$ background, the agreement between data and the MC prediction was assessed in Z-enriched control regions. The $t\bar{t}$, single top, and WW processes are modeled by MC@NLO 4.02 [32,33], interfaced to HERWIG 6.520 [34] for parton showering and fragmentation processes and to JIMMY 4.30 [35] for underlying event simulation. The POWHEG [36] generator is used to simulate ZZ production, interfaced to PYTHIA 8.163 [37] for parton showering and fragmentation. The CT10 parton distribution function (PDF) set [38] is used for all SHERPA, MC@NLO, and POWHEG samples. The standard ATLAS detector simulation [39] based on GEANT4 [40] is used. It includes multiple proton-proton interactions per bunch crossing (pileup) as observed in data.

The $W(\ell\nu)\gamma\gamma$ candidate events contain an isolated lepton and missing transverse momentum (E_T^{miss}) from the undetected neutrino of the leptonic W decay, and two isolated

photons (including also photons that have converted in electron-positron pairs within the ID volume). Muon candidates are identified, within pseudorapidity [26] $|\eta| < 2.4$, by associating complete tracks or track segments in the MS with tracks in the ID [41]. Electron candidates are reconstructed within $|\eta| < 2.47$ as electromagnetic clusters associated to a track [42], whereas photons are reconstructed as electromagnetic clusters with $|\eta| < 2.37$ [43]. The calorimeter transition regions at $1.37 < |\eta| < 1.52$ are excluded for electrons and photons. Identification criteria based on shower shapes in the EM calorimeter for photons, and additionally on tracking information for electrons, referred to as "tight" in Refs. [42,44], are used. The E_T^{miss} uses the energy deposits in the calorimeters within $|\eta| < 4.9$ and the muons identified in the MS, as described in Ref. [45]. Reconstructed muons, electrons, and photons are required to have $p_T^{\mu,e,\gamma} > 20$ GeV and to be isolated. Photons are considered isolated if the sum of calorimeter transverse energy deposits in a cone of size $\Delta R = 0.4$ around the candidate is smaller than 4 GeV. The isolation is corrected for photon energy leakage. The muon isolation is based on the sum of the transverse momenta of ID tracks in a cone of size $\Delta R = 0.2$ which must be below $0.15 \times p_T^{\mu}$. For electrons, the calorimeter transverse energy deposits and the sum of the transverse momenta of tracks in a cone of size $\Delta R = 0.2$ must be below $0.2 \times p_T^e$ and $0.15 \times p_T^e$, respectively. The lepton must also be compatible with originating from the primary vertex of the interaction, which is taken to be the vertex with the largest Σp_T^2 of associated tracks. E_T^{miss} is required to exceed 25 GeV. The transverse mass of the W boson [46] is required to be greater than 40 GeV. The two photons must be outside of their mutual isolation cones by requiring $\Delta R(\gamma,\gamma) > 0.4$. To suppress the contribution from final-state radiation, the lepton and photons are required to have $\Delta R(\ell,\gamma) > 0.7$. Events containing a second reconstructed lepton are rejected to reduce background from Drell-Yan events. In the electron channel, additional requirements are used to suppress events in which one electron is misidentified as a photon (mainly originated from the $Z\gamma$ process): the transverse momentum of the $e\gamma\gamma$ system is required to be greater than 30 GeV, and the invariant mass of the electron and the leading, subleading or both photons is required to be outside a 13, 8 or 15 GeV wide window around the Z boson mass, respectively. Exclusive events are defined with a veto on additional jets compared to the inclusive selection. Jets are reconstructed from clustered energy deposits in the calorimeter using the anti-k_t algorithm [47] with radius parameter $R = 0.4$ and are required to have $p_T > 30$ GeV and $|\eta| < 4.4$. Jets at $\Delta R < 0.3$ from the selected lepton and photons are rejected. In order to reduce pileup effects, for jets with $p_T < 50$ GeV and $|\eta| < 2.4$, more than 50% of the summed scalar p_T of tracks within $\Delta R = 0.4$ of the jet axis must be from tracks associated to the primary vertex.

Table I shows the expected background as well as the observation. The background expectation alone is not sufficient to describe the data indicating the presence of signal events. The fake-photon background from $W\gamma j + Wjj$ is estimated by performing a two-dimensional template fit to the isolation energy distributions of the leading and subleading photons, as described in Ref. [48]. Three background templates are obtained from data by reversing some of the photon identification requirements based on shower shape; the signal templates are taken from MC simulation. Contributions from events where a jet satisfies the electron identification criteria, or the muon originates from heavy-flavor decays, i.e. from $\gamma\gamma$ + jets processes, are estimated by using a two-dimensional sideband method constructed from the lepton isolation and E_T^{miss} variables, as described in Ref. [5]. The distribution of the diphoton invariant mass in the two channels is shown in Fig. 1. Alternative methods have been used to cross-check the estimate of the backgrounds coming from fakes, all of them provide consistent results. In the estimation of the fake-photon background, systematic uncertainties arise from the limited number of events in the control regions, the functional form used to describe the background isolation energy distribution, the definition of the control region, the modeling of the signal in the MC samples and the corresponding statistical uncertainty. In the estimate of the fake-lepton background, systematic uncertainties related to

TABLE I. The background composition in each channel is shown for the inclusive (left) and exclusive (right) cases. The $W\gamma j + Wjj$ and $\gamma\gamma$ + jets backgrounds are estimated using data-driven techniques, whereas the others are extracted from MC simulation. The number of candidate events in data passing the full selection is also shown.

	Electron channel	Muon channel	Electron channel	Muon channel

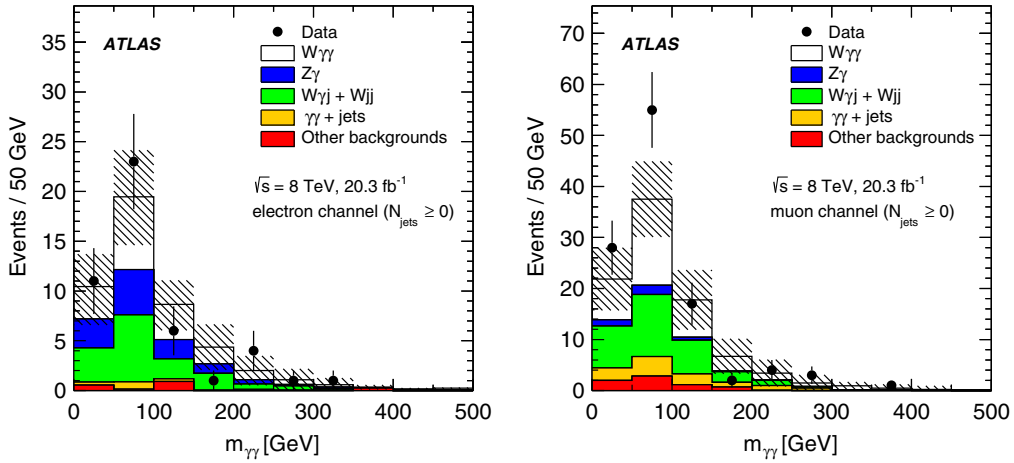

FIG. 1 (color online). Diphoton invariant mass distribution in the electron (left) and muon (right) channels. The expected signal based on the SHERPA prediction is shown. The hashed areas show the total systematic and statistical uncertainty on the background estimate.

the control region definitions and the residual correlation of the discriminating variables are considered.

The fiducial cross sections $\sigma^{\text{fid}}_{W\gamma\gamma}$ are obtained from a maximum-likelihood fit, similarly to Ref. [5], for the electron channel, the muon channel, and the combination of the two assuming lepton universality to determine the $W(\ell\nu)\gamma\gamma$ cross section for a single lepton flavor. They are measured in a phase space, defined in Table II, close to that of the experimentally selected region. Here p_T^{ν} is the transverse momentum of the neutrino and ϵ_h^p is the fractional energy carried by the closest particle-level jet in a cone of $\Delta R = 0.4$ around each photon direction.

The efficiency of the signal selection and the small acceptance correction due to the extrapolation over the calorimeter transition region and to $|\eta| = 2.5$ for the leptons are taken into account in the procedure. The acceptance correction factors are 0.83 and 0.90 in the electron and muon channel, respectively. The combined efficiency and acceptance correction amounts to $(19.6 \pm 0.5)\%$ and $(40.4 \pm 0.7)\%$ in the electron and muon channels in the inclusive case, and to $(15.1 \pm 0.7)\%$ and $(39.7 \pm 1.0)\%$ in the exclusive case. The given uncertainties are statistical only. Corrections are applied to account for small differences between data and MC simulation in lepton, photon, and jet efficiencies, momentum scale and resolution, additional pp interactions, and beam-spot position.

TABLE II. Definition of the fiducial region for which the cross section is evaluated.

Definition of the fiducial region
$p_T^{\ell} > 20$ GeV, $p_T^{\nu} > 25$ GeV, $\lvert\eta_{\ell}\rvert < 2.5$
$m_T > 40$ GeV
$E_T^{\gamma} > 20$ GeV, $\lvert\eta^{\gamma}\rvert < 2.37$, iso. fraction $\epsilon_h^p < 0.5$
$\Delta R(\ell,\gamma) > 0.7$, $\Delta R(\gamma,\gamma) > 0.4$, $\Delta R(\ell/\gamma,\text{jet}) > 0.3$
Exclusive: no anti-k_t jets with $p_T^{\text{jet}} > 30$ GeV, $\lvert\eta^{\text{jet}}\rvert < 4.4$

Systematic uncertainties on the cross section are accounted for by introducing nuisance parameters in the likelihood which modify the signal and background expected yields. Correlations between systematic uncertainties in the two channels are accounted for in the combined fit. When combining the two channels, the dominant systematic uncertainties in the inclusive and exclusive cross-section measurements are 14% and 23% from the data-driven background estimates, 5% to 7% from the jet energy scale, and 3% from the luminosity. Other systematic uncertainties considered stem from the electromagnetic and muonic energy scale and resolution, the object reconstruction, the pileup description, and the trigger efficiency. These are found to have a minor impact, below 3%. Theoretical uncertainties on the signal modeling, affecting only the acceptance extrapolation, are negligible. The measured cross sections are shown in Table III. The significance after combining the two channels is larger than 3σ in the inclusive case. The measurements in the electron and muon channels are compatible within 1σ.

The SM prediction for the $W(\ell\nu)\gamma\gamma$ cross section is calculated with the parton-level Monte Carlo program MCFM [49] at next-to-leading order (NLO). The

TABLE III. Measurement of the $pp \to \ell\nu\gamma\gamma + X$ inclusive and exclusive fiducial cross sections.

	σ^{fid} (fb)	σ^{MCFM} (fb)
Inclusive ($N_{\text{jet}} \geq 0$)		
$\mu\nu\gamma\gamma$	$7.1^{+1.3}_{-1.2}(\text{stat}) \pm 1.5(\text{syst}) \pm 0.2(\text{lumi})$	
$e\nu\gamma\gamma$	$4.3^{+1.8}_{-1.6}(\text{stat})^{+1.9}_{-1.8}(\text{syst}) \pm 0.2(\text{lumi})$	2.90 ± 0.16
$\ell\nu\gamma\gamma$	$6.1^{+1.1}_{-1.0}(\text{stat}) \pm 1.2(\text{syst}) \pm 0.2(\text{lumi})$	
Exclusive ($N_{\text{jet}} = 0$)		
$\mu\nu\gamma\gamma$	$3.5 \pm 0.9(\text{stat})^{+1.1}_{-1.0}(\text{syst}) \pm 0.1(\text{lumi})$	
$e\nu\gamma\gamma$	$1.9^{+1.4}_{-1.1}(\text{stat})^{+1.1}_{-1.2}(\text{syst}) \pm 0.1(\text{lumi})$	1.88 ± 0.20
$\ell\nu\gamma\gamma$	$2.9^{+0.8}_{-0.7}(\text{stat})^{+1.0}_{-0.9}(\text{syst}) \pm 0.1(\text{lumi})$	

calculations are performed using the MCFM default electroweak parameters [50] and the CT10 PDF set. The renormalization and factorization scales are set to the invariant mass of the $\ell\nu\gamma\gamma$ system. The fragmentation of quarks and gluons to photons is included using the fragmentation function GDRG_LO [51]. The kinematic requirements at parton level match the fiducial acceptance of Table II.

In addition to the inclusive prediction, an exclusive cross section is obtained by vetoing events with an additional jet emission. To account for the difference between jets defined at parton and particle levels, a correction factor of about 0.87 in the exclusive case is computed and applied to the prediction as documented in Ref. [5]. Uncertainties on the two predictions include the effect of varying independently the renormalization and factorization scales by factors of 0.5 and 2.0, evaluating the CT10 PDF error sets scaled to the 68% confidence level (C.L.), the uncertainties on quark or gluon fragmentation to a photon, and the parton to particle correction factors. The predictions for $W(\ell\nu)\gamma\gamma$ production are compared to the measured cross sections in Table III. The measured cross section is higher by 1.9σ in the inclusive case, while better agreement is seen in the exclusive case, similar to the measurement of $W\gamma$ and $Z\gamma$ in Ref. [5]. In the case of $Z\gamma$ and $W\gamma$, higher order corrections were calculated to be smaller for the exclusive compared to the inclusive case [52]. As the process $W\gamma\gamma$ has similar properties, the exclusive measurement is expected to be in better agreement with the theoretical prediction than the inclusive one. Therefore, in the following, the exclusive measurement will be used for the AQGC limits setting, as done in Ref. [5].

The AQGCs are introduced as dimension-8 operators following the formalism defined in the Appendix of Ref. [53]. While many operators give rise to anomalous couplings of the form $WW\gamma\gamma$, this study is restricted to f_{T0}/Λ^4, f_{M2}/Λ^4, and f_{M3}/Λ^4, where Λ represents the scale at which new physics appears, and f the coupling of the respective operator. The $W\gamma\gamma$ final state is expected to be particularly sensitive to the T0 operator, whereas the other two operators can be related to the parameters of the dimension-6 operators used at LEP [18–21] and by CMS [16] via the transformations described in Ref. [54]. To preserve unitarity up to high energy scales, a form factor is introduced which depends on the energy, the form factor scale Λ_{FF} and an exponent n, following the formalism described in Refs. [55,56]. The scale Λ_{FF} is independent of the new physics scale Λ [57]. The largest form factor scale ensuring unitarity for this process at $\sqrt{s} = 8$ TeV, calculated using the VBFNLO generator [58–61], is given by $n = 2$ and $\Lambda_{\mathrm{FF}} = 600$ GeV for f_{T0}/Λ^4, and $\Lambda_{\mathrm{FF}} = 500$ GeV for f_{M2}/Λ^4 and f_{M3}/Λ^4.

Deviations from the SM prediction for the AQGC parameters, which are predicted to be zero, lead to an excess of events with high diphoton invariant mass. The phase space to study AQGCs was optimized using the expected significance calculated on simulated events. The optimal phase space was found to be the exclusive selection with the additional requirement of $m_{\gamma\gamma} > 300$ GeV. The SM backgrounds in this region are determined from a fit to the observed $m_{\gamma\gamma}$ distribution. The expected SM background is $0.01 \pm 0.03(\mathrm{stat}) \pm 0.20(\mathrm{syst})$ $[0.02 \pm 0.05(\mathrm{stat}) \pm 0.46(\mathrm{syst})]$ events in the electron (muon) channel, where uncertainties include systematic effects due to the extrapolation procedure, depending on the modeling of the spectrum and on the initial background estimate used in the extrapolation. No events are observed in the high-mass region.

TABLE IV. Observed and expected 95% C.L. limits obtained for the f_{T0}/Λ^4, f_{M2}/Λ^4 and f_{M3}/Λ^4 AQGC parameters for the combination of the two channels. The values of $n = 0, 1, 2$ are the exponential choices of the form factor, Λ_{FF} is fixed to 600 GeV for f_{T0}/Λ^4 and to 500 GeV for the other parameters. The $n = 0$ choice produces the limits without the form factor applied.

		Observed (TeV^{-4})	Expected (TeV^{-4})
$n = 0$	f_{T0}/Λ^4	$[-0.9, 0.9] \times 10^2$	$[-1.2, 1.2] \times 10^2$
	f_{M2}/Λ^4	$[-0.8, 0.8] \times 10^4$	$[-1.1, 1.1] \times 10^4$
	f_{M3}/Λ^4	$[-1.5, 1.4] \times 10^4$	$[-1.9, 1.8] \times 10^4$
$n = 1$	f_{T0}/Λ^4	$[-7.6, 7.3] \times 10^2$	$[-9.6, 9.5] \times 10^2$
	f_{M2}/Λ^4	$[-4.4, 4.6] \times 10^4$	$[-5.7, 5.9] \times 10^4$
	f_{M3}/Λ^4	$[-8.9, 8.0] \times 10^4$	$[-11.0, 10.0] \times 10^4$
$n = 2$	f_{T0}/Λ^4	$[-2.7, 2.6] \times 10^3$	$[-3.5, 3.4] \times 10^3$
	f_{M2}/Λ^4	$[-1.3, 1.3] \times 10^5$	$[-1.6, 1.7] \times 10^5$
	f_{M3}/Λ^4	$[-2.9, 2.5] \times 10^5$	$[-3.7, 3.3] \times 10^5$

The cross-section prediction as a quadratic function of the AQGC parameters is obtained by using VBFNLO [58–61]. For SM couplings, VBFNLO agrees with MCFM. The limits on the AQGC parameters are extracted with a frequentist profile likelihood test [62], using the methodology of Ref. [5]. The expected and observed limits at 95% C.L. on the AQGC parameters are shown in Table IV for different values of n. The limits on f_{M2}/Λ^4 and f_{M3}/Λ^4 improve on the previous results from LEP [18–21] and D0 [22], but are less stringent than those from CMS [16,17]. The limit on f_{T0}/Λ^4 is tighter than the previous limit published by CMS [17,63]. This can be explained by the fact that f_{T0}/Λ^4 is especially sensitive to transversely polarized W bosons, which are favored in the present study [53].

In summary, evidence for the $W(\ell\nu)\gamma\gamma$ process is reported for the first time. The significance of the inclusive production cross section is larger than 3σ. The measured cross sections are in agreement within uncertainties with NLO SM predictions calculated with MCFM. Limits are set at 95% C.L. on the AQGC parameters, in particular improving the limit on f_{T0}/Λ^4.

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently. We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWFW and FWF, Austria; ANAS, Azerbaijan; SSTC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC, and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST, and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR, and VSC CR, Czech Republic; DNRF, DNSRC, and Lundbeck Foundation, Denmark; EPLANET, ERC, and NSRF, European Union; IN2P3-CNRS, CEA-DSM/IRFU, France; GNSF, Georgia; BMBF, DFG, HGF, MPG, and AvH Foundation, Germany; GSRT and NSRF, Greece; RGC, Hong Kong SAR, China; ISF, MINERVA, GIF, I-CORE, and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; BRF and RCN, Norway; MNiSW and NCN, Poland; GRICES and FCT, Portugal; MNE/IFA, Romania; MES of Russia and NRC KI, Russian Federation; JINR; MSTD, Serbia; MSSR, Slovakia; ARRS and MIZŠ, Slovenia; DST/NRF, South Africa; MINECO, Spain; SRC and Wallenberg Foundation, Sweden; SER, SNSF, and Cantons of Bern and Geneva, Switzerland; NSC, Taiwan; TAEK, Turkey; STFC, the Royal Society, and Leverhulme Trust, United Kingdom; DOE and NSF, United States of America. The crucial computing support from all WLCG partners is acknowledged gratefully, in particular from CERN and the ATLAS Tier-1 facilities at TRIUMF (Canada), NDGF (Denmark, Norway, Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy), NL-T1 (Netherlands), PIC (Spain), ASGC (Taiwan), RAL (UK), and BNL (USA) and in the Tier-2 facilities worldwide.

[26] ATLAS uses a right-handed coordinate system with its origin at the nominal interaction point (IP) in the center of the detector and the z axis along the beam pipe. The x axis points from the IP to the center of the LHC ring, and the y axis points upward. Cylindrical coordinates (r, ϕ) are used in the transverse (x, y) plane, ϕ being the azimuthal angle around the beam pipe. The pseudorapidity is defined in terms of the polar angle θ as $\eta = -\ln\tan(\theta/2)$. The distance ΔR in the (η, ϕ) space is defined as $\Delta R = \sqrt{(\Delta\eta)^2 + (\Delta\phi)^2}$.

[63] VBFNLO uses a slightly different definition of the field strength tensors than Ref. [53]. Therefore, the couplings f need to be scaled for comparison. In the case of f_{T0}, the scale factor is g^{-4}, where g is the $SU(2)$ gauge coupling [58].

Measurement of ZZ production in pp collisions at $\sqrt{s} = 7$ TeV and limits on anomalous ZZZ and $ZZ\gamma$ couplings with the ATLAS detector

The ATLAS collaboration

E-mail: atlas.publications@cern.ch

Abstract: A measurement of the ZZ production cross section in proton-proton collisions at $\sqrt{s} = 7$ TeV using data recorded by the ATLAS experiment at the Large Hadron Collider is presented. In a data sample corresponding to an integrated luminosity of 4.6 fb^{-1} collected in 2011, events are selected that are consistent either with two Z bosons decaying to electrons or muons or with one Z boson decaying to electrons or muons and a second Z boson decaying to neutrinos. The $ZZ^{(*)} \to \ell^+\ell^-\ell'^+\ell'^-$ and $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ cross sections are measured in restricted phase-space regions. These results are then used to derive the total cross section for ZZ events produced with both Z bosons in the mass range 66 to 116 GeV, $\sigma_{ZZ}^{\text{tot}} = 6.7 \pm 0.7$ (stat.) $^{+0.4}_{-0.3}$ (syst.) ± 0.3 (lumi.) pb, which is consistent with the Standard Model prediction of $5.89^{+0.22}_{-0.18}$ pb calculated at next-to-leading order in QCD. The normalized differential cross sections in bins of various kinematic variables are presented. Finally, the differential event yield as a function of the transverse momentum of the leading Z boson is used to set limits on anomalous neutral triple gauge boson couplings in ZZ production.

1 Introduction

The production of pairs of Z bosons at the Large Hadron Collider (LHC) provides an excellent opportunity to test the predictions of the electroweak sector of the Standard Model (SM) at the TeV energy scale. In the SM, Z boson pairs can be produced via non-resonant processes or in the decay of Higgs bosons. Deviations from SM expectations for the total or differential ZZ production cross sections could be indicative of the production of new resonances decaying to Z bosons or other non-SM contributions.

Non-resonant ZZ production proceeds at leading order (LO) via t- and u-channel quark-antiquark interactions, while about 6% of the production proceeds via gluon fusion. The ZZZ and $ZZ\gamma$ neutral triple gauge boson couplings (nTGCs) are absent in the SM, hence there is no contribution from s-channel $q\bar{q}$ annihilation at tree level. These different production processes are shown in figure 1. At the one-loop level, nTGCs generated by fermion triangles have a magnitude of the order of 10^{-4} [1]. Many models of physics beyond the Standard Model predict values of nTGCs at the level of 10^{-4} to 10^{-3} [2]. The primary signatures of non-zero nTGCs are an increase in the ZZ cross section at high ZZ invariant mass and high transverse momentum of the Z bosons [3]. ZZ production has been studied in e^+e^- collisions at LEP [4–8], in $p\bar{p}$ collisions at the Tevatron [9–12] and recently in pp collisions at the LHC [13, 14]. No deviation of the measured total cross section from the SM expectation has been observed, and limits on anomalous nTGCs have been set [8, 9, 13, 14]. In searching for the SM Higgs boson, the ATLAS and CMS collaborations observed recently a neutral boson resonance with a mass around 126 GeV [15–17]. A SM Higgs boson with that mass can decay to two Z bosons only when at least one Z boson is off-shell, and even in this case, the contribution is less than 3%. Searches for high-mass non-SM ZZ resonances have not resulted in any excess above the SM expectations [18].

This paper presents a measurement of ZZ production[1] in proton-proton collisions at a centre-of-mass energy $\sqrt{s} = 7$ TeV using 4.6 fb^{-1} of integrated luminosity collected by the ATLAS detector at the LHC. ZZ events are selected in two channels:[2] $\ell^+\ell^-\ell'^+\ell'^-$ and $\ell^+\ell^-\nu\bar{\nu}$. Two selections are used in the four-charged-lepton channel: an on-shell ZZ selection denoted by $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ where both Z bosons are required to be within the mass range 66-116 GeV[3] and a selection which includes an off-shell Z boson denoted by $ZZ^* \to \ell^+\ell^-\ell'^+\ell'^-$ where one Z boson is required to be within this mass range and the other can be off-shell and have any mass above 20 GeV. In the $\ell^+\ell^-\nu\bar{\nu}$ channel, the $\nu\bar{\nu}$ system is expected to be produced by an off-shell Z boson in 2.6% of the events. Since this fraction is small and only one event selection is used for this channel, it is referred to as $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ throughout the paper. The $ZZ^{(*)} \to \ell^+\ell^-\ell'^+\ell'^-$ channel has an excellent signal-to-background ratio, but it has a branching fraction six times lower than the $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ channel; the latter has higher background contributions with an expected

[1] Throughout this paper Z should be taken to mean Z/γ^* when referring to decays to charged leptons, and just Z when referring to decays to neutrinos.

[2] ℓ represents either electrons or muons. ℓ and ℓ' are used to denote leptons from a different Z parent, but not necessarily of different flavour. Decay modes mentioned with the use of ℓ indicate the sum of the decay modes with specific lepton flavours.

[3] Throughout this paper, the 66-116 GeV mass range is referred to as the Z mass window.

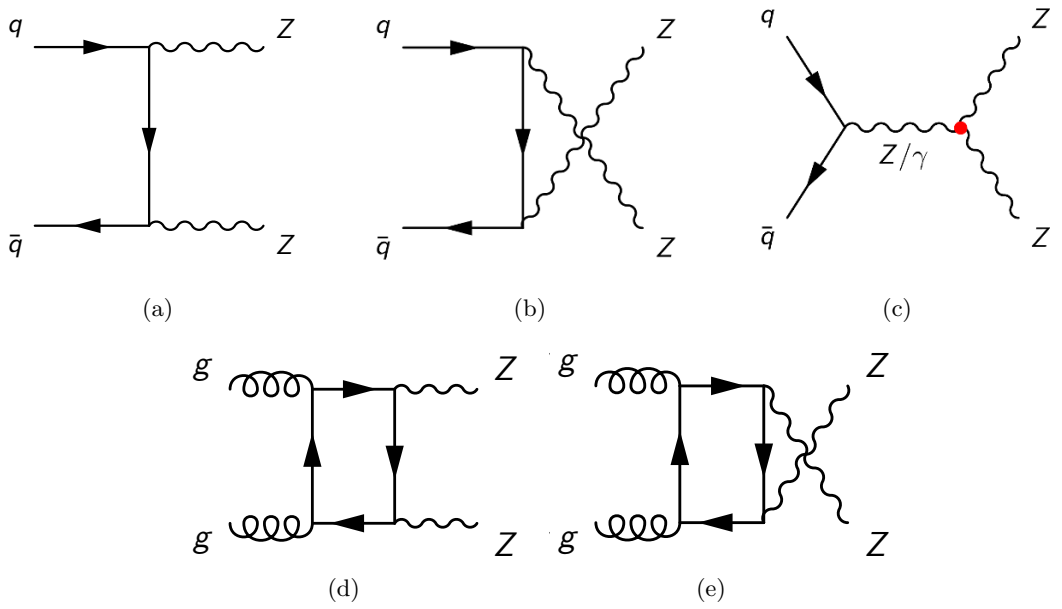

Figure 1. Leading order Feynman diagrams for ZZ production through the $q\bar{q}$ and gg initial state at hadron colliders. The s-channel diagram, (c), contains the ZZZ and $ZZ\gamma$ neutral TGC vertices which do not exist in the SM.

signal-to-background ratio around one (after applying the event selections described below). This paper presents the total ZZ production cross section, the fiducial cross section in a restricted phase space for each decay channel (integrated, and as a function of kinematic parameters for the ZZ selections) and limits on anomalous nTGCs using the observed ZZ event yields as a function of the transverse momentum of the leading Z boson.[4] The results presented in this paper supersede the previously published results [13] which were derived with the first 1.02 fb^{-1} of the dataset used here, only with the $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ decay channel and with the use of the total ZZ event count for the derivation of the limits on anomalous nTGCs.

The total cross section for non-resonant ZZ production is predicted at next-to-leading order (NLO) in QCD to be $6.18^{+0.25}_{-0.18}$ pb, where the quoted theoretical uncertainties result from varying the factorization and renormalization scales simultaneously by a factor of two whilst using the full CT10 parton distribution function (PDF) error set [19]. The cross section is calculated in the on-shell (zero-width) approximation using MCFM [20] with CT10; it includes a 5.8% contribution from gluon fusion. When the natural width of the Z boson is used and both Z bosons are required to be within the Z mass window, the NLO cross section is predicted to be $5.89^{+0.22}_{-0.18}$ pb. The cross sections given here are calculated at a renormalization and factorization scale equal to half the mass of the diboson system. The total cross section using the zero-width approximation was previously measured to be $8.5^{+2.7}_{-2.3}$ (stat.) $^{+0.4}_{-0.3}$ (syst.) $\pm$ 0.3 (lumi.) pb [13].

[4]Leading Z refers to the Z with the higher transverse momentum in $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ decays or to the Z boson decaying to a charged lepton pair in $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ decays.

JHEP03(2013)128

This paper is organized as follows: an overview of the ATLAS detector, data, signal and background Monte Carlo (MC) samples used for this analysis is given in section 2; section 3 describes the selection of the physics objects; section 4 describes the fiducial phase space of the measurement, the corresponding ZZ cross section definition and the acceptances of the event selection and fiducial phase space; section 5 explains how the backgrounds to the $\ell^+\ell^-\ell'^+\ell'^-$ and $\ell^+\ell^-\nu\bar{\nu}$ final states are estimated with a combination of simulation and data-driven techniques; section 6 presents the results: cross section, differential cross sections and nTGC limits; finally, a summary of the main results is given in section 7.

2 The ATLAS detector and data sample

The ATLAS detector [21] is a multipurpose particle detector with a cylindrical geometry. It consists of inner tracking devices surrounded by a superconducting solenoid, electromagnetic and hadronic calorimeters and a muon spectrometer with a toroidal magnetic field. The inner detector, in combination with the 2 T field from the solenoid, provides precision tracking of charged particles in the pseudorapidity range $|\eta| < 2.5$.[5] It consists of a silicon pixel detector, a silicon microstrip detector and a straw tube tracker that also provides transition radiation measurements for electron identification in the pseudorapidity range $|\eta| < 2.0$. The calorimeter system covers the pseudorapidity range $|\eta| < 4.9$. The electromagnetic calorimeter uses liquid argon (LAr) as the active material with lead as an absorber ($|\eta| < 3.2$). It identifies electromagnetic showers and measures their energy and position; in the region $|\eta| < 2.5$ it is finely segmented and provides electron identification in conjunction with the inner detector which covers the same η region. Hadronic showers are measured in the central rapidity range ($|\eta| < 1.7$) by scintillator tiles with iron absorber, while in the end-cap region ($1.5 < |\eta| < 3.2$) a LAr calorimeter with a copper absorber is used. In the forward region ($3.2 < |\eta| < 4.9$) a LAr calorimeter with a copper absorber for the first layer and tungsten for the last two layers is used for both electromagnetic and hadronic showers. All calorimeters are used to measure jets. The muon spectrometer surrounds the calorimeters; it consists of superconducting air-core toroid magnets, high-precision tracking chambers which provide muon identification and tracking measurement in the pseudorapidity range $|\eta| < 2.7$, and separate trigger chambers covering $|\eta| < 2.4$.

A three-level trigger system selects events to be recorded for offline analysis. The events used in this analysis were selected with single-lepton triggers with nominal transverse momentum (p_{T}) thresholds of 20 or 22 GeV (depending on the instantaneous luminosity of the LHC) for electrons and 18 GeV for muons. The efficiencies of the single-lepton triggers have been determined as a function of lepton pseudorapidity and transverse momentum using large samples of $Z \to \ell^+\ell^-$ events. The trigger efficiencies for events passing the offline selection described below are all greater than 98%.

[5] ATLAS uses a right-handed coordinate system with its origin at the nominal interaction point in the centre of the detector and the z-axis along the beam direction. The x-axis points from the interaction point to the centre of the LHC ring, and the y-axis points upwards. Cylindrical coordinates (r,ϕ) are used in the transverse plane, ϕ being the azimuthal angle around the beam direction. The pseudorapidity η is defined in terms of the polar angle θ as $\eta = -\ln\tan(\theta/2)$.

JHEP03(2013)128

The measurements presented here uses the full data sample of proton-proton collisions at $\sqrt{s} = 7$ TeV recorded in 2011. After data quality requirements, the total integrated luminosity used in the analysis is 4.6 fb^{-1} with an uncertainty of 3.9% [22].

2.1 Simulated data samples

Monte Carlo simulated samples cross-checked with data are used to calculate several quantities used in this measurement, including acceptance, efficiency and some of the background to the $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ decay channel. The NLO generator PowhegBox [23, 24] with the CT10 PDF set, interfaced to Pythia [25], is used to model the signal for both channels. The LO multi-leg generator Sherpa [26] with the CTEQ6L1 PDF set [27] in comparison with PowhegBox is used to evaluate systematic uncertainties. The contribution from $gg \to ZZ$ is modelled by the gg2zz generator [28] interfaced to Herwig [29] to model parton showers and to Jimmy [30] for multiparton interactions. In each case, the simulation includes the interference terms between the Z and γ^* diagrams. For both the $\ell^+\ell^-\ell'^+\ell'^-$ and $\ell^+\ell^-\nu\bar{\nu}$ final states, MCFM is used to calculate theoretical uncertainties, and Sherpa is used for the generation of signal samples with neutral triple gauge couplings.

The LO generator Alpgen [31] with CTEQ6L1 PDFs is used to simulate Z+jets, W+jets, $Z\gamma$ and $W\gamma$ background events with Jimmy used for multiparton interactions and Herwig for parton showers. The NLO generator MC@NLO [32] with CT10 PDFs is used to model $t\bar{t}$ background processes as well as WW production. The single-top Wt process is modelled with AcerMC [33] with the MSTW2008 PDFs [34]. The LO generator Herwig with MSTW2008 PDFs is used to model WZ production. The LO generator Madgraph [35] with CTEQ6L1 PDFs is also used to model $Z\gamma$ and $W\gamma^*$ events, where Pythia is used for hadronization and showering.

The detector response is simulated [36] with a program based on Geant4 [37]. Additional inelastic pp events are included in the simulation, distributed so as to reproduce the number of collisions per bunch-crossing in the data. The detector response to interactions in the out-of-time bunches from pile-up is also modelled in the simulation. The results of the simulation are corrected with scale factors determined by comparing efficiencies observed in data to those in the simulated events, and the lepton momentum scale and resolution are finely adjusted to match the observed dilepton spectra in $Z \to \ell\ell$ events using a sample of Z bosons.

3 Event reconstruction and selection

Events are required to contain a primary vertex formed from at least three associated tracks with $p_{\mathrm{T}} > 400$ MeV.

3.1 Leptons, jets and missing energy

3.1.1 Common lepton selection

Muons are identified by matching tracks (or track segments) reconstructed in the muon spectrometer to tracks reconstructed in the inner detector [38]. The momenta of these

JHEP03(2013)128

combined muons are calculated by combining the information from the two systems and correcting for the energy deposited in the calorimeters. The analyses of both decay channels use muons which have full tracks reconstructed in the muon spectrometer with $p_{\mathrm{T}} > 20$ GeV and $|\eta| < 2.5$. The $ZZ^{(*)} \to \ell^+\ell^-\ell'^+\ell'^-$ channel recovers additional ZZ acceptance with minimal additional background using a lower threshold of $p_{\mathrm{T}} > 7$ GeV and by accepting muons with segments reconstructed in the muon spectrometer (in this latter case, the muon spectrometer is used to identify the track as a muon, but its momentum is measured using the inner detector; for the purposes of the discussion below, these muons are also referred to as *combined* muons).

Electrons are reconstructed from an energy cluster in the electromagnetic calorimeter matched to a track in the inner detector [38]; the transverse momentum is computed from the calorimeter energy and the direction from the track parameters measured in the inner detector. The electron track parameters are corrected for bremsstrahlung energy loss using the Gaussian-sum filter algorithm [39]. Electron candidates in the $ZZ^{(*)} \to \ell^+\ell^-\ell'^+\ell'^-$ ($ZZ \to \ell^+\ell^-\nu\bar{\nu}$) channel are required to have longitudinal and transverse shower profiles consistent with those expected from electromagnetic showers, by satisfying the loose (medium) identification criteria described in ref. [40] reoptimized for the 2011 data-taking conditions. They are also required to have a transverse momentum of at least 7 (20) GeV and a pseudorapidity of $|\eta| < 2.47$.

In order to reject non-prompt leptons from the decay of heavy quarks and fake electrons from misidentified jets (charged hadrons or photon conversions), all selected leptons must satisfy isolation requirements based on calorimetric and tracking information and must be consistent with originating from the primary vertex. For the calorimetric isolation the scalar sum of the transverse energies, ΣE_{T}, of calorimeter deposits inside a cone around the lepton, corrected to remove the energy from the lepton and from additional interactions (pile-up), is formed. In the $ZZ^{(*)} \to \ell^+\ell^-\ell'^+\ell'^-$ ($ZZ \to \ell^+\ell^-\nu\bar{\nu}$) channel, the ΣE_{T} inside a cone of size $\Delta R = \sqrt{(\Delta\phi)^2 + (\Delta\eta)^2} = 0.2$ (0.3) around the lepton is required to be no more than 30% (15%) of the lepton p_{T}. For the track isolation, the scalar sum of the transverse momenta, Σp_{T}, of inner detector tracks inside a cone of size $\Delta R = 0.2$ (0.3) around the lepton is required to be no more than 15% of the lepton p_{T}. The wider cone size, in conjunction with the same or tighter requirements on the fraction of extra activity allowed in the cone, corresponds to more stringent isolation requirements applied to the $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ channel compared to the $ZZ^{(*)} \to \ell^+\ell^-\ell'^+\ell'^-$ channel. This reflects the need to reduce the much higher reducible background (predominantly from Z+jets, $t\bar{t}$ and WW). To ensure that the lepton originates from the primary vertex, its longitudinal impact parameter $|z_0|$ is required to be less than 2 mm, and its transverse impact parameter significance (the transverse impact parameter divided by its error), $|d_0/\sigma_{d_0}|$, is required to be less than 3.5 (6) for muons (electrons). Electrons have a worse impact parameter resolution than muons due to bremsstrahlung.

Since muons can radiate photons which may then convert to electron-positron pairs, electron candidates within $\Delta R = 0.1$ of any selected muon are not considered. If two electron candidates are within $\Delta R = 0.1$ of each other, the one with the lower p_{T} is removed.

JHEP03(2013)128

3.1.2 Extended-lepton selection

Two additional categories of muons are considered for the $ZZ^{(*)} \to \ell^+\ell^-\ell'^+\ell'^-$ channel: forward spectrometer muons with $2.5 < |\eta| < 2.7$ (in a region outside the nominal coverage of the inner detector) and calorimeter-tagged muons with $|\eta| < 0.1$ (where there is a limited geometric coverage in the muon spectrometer). Forward spectrometer muons are required to have a full track that is reconstructed in the muon spectrometer; if these muons are also measured in the inner detector, their momentum is measured using the combined information; otherwise, only the muon spectrometer information is used. In either case, such muons are required to have $p_{\mathrm{T}} > 10$ GeV and the ΣE_{T} of calorimeter deposits inside a cone of size $\Delta R = 0.2$ around the muon is required to be no more than 15% of the muon p_{T}, while no requirement is made on Σp_{T}. The same impact parameter requirements as for the combined muons are imposed for the forward muons measured in the inner detector; no such requirement is imposed on those measured in the muon spectrometer only. Calorimeter-tagged muons are reconstructed from calorimeter energy deposits consistent with a muon which are matched to an inner detector track with $p_{\mathrm{T}} > 20$ GeV and are required to satisfy the same impact parameter and isolation criteria as for the combined muons.

The $ZZ^{(*)} \to \ell^+\ell^-\ell'^+\ell'^-$ channel also uses calorimeter-only electrons with $2.5 < |\eta| < 3.16$ and $p_{\mathrm{T}} > 20$ GeV passing the tight identification requirements [40] for this forward η region, where only the longitudinal and transverse shower profiles in the calorimeters are used for their identification. Their transverse momentum is computed from the calorimeter energy and the electron direction, where the electron direction is computed using the primary vertex position and the shower barycentre position in the calorimeter. Being identified outside the acceptance of the inner detector, no impact parameter requirements can be applied to these calorimeter-only electron candidates, and their charge is not measured. Since only one such electron is allowed in the event, and since all other leptons have their charge measured, the calorimeter-only electron is assigned the charge needed to have two pairs of same-flavour opposite-sign leptons in the event. The requirements described above constrain the additional background introduced by the inclusion of calorimeter-only electrons, and no isolation requirements are imposed on such electrons.

The use of the extended-lepton selection increases the $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ and $ZZ^* \to \ell^+\ell^-\ell'^+\ell'^-$ acceptance by about 6% from the forward spectrometer muons, 4% from the calorimeter-tagged muons and 6% from the forward electrons. The expected background is kept small by requiring each event to have at most one lepton from each extended-lepton category, and each such lepton to be paired with a non-extended lepton.

3.1.3 Jets and missing transverse momentum

For the $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ selection, events which contain at least one well-reconstructed jet are vetoed to reduce background from top-quark production. Jets are reconstructed from topological clusters of energy in the calorimeter [41] using the anti-k_t algorithm [42] with radius parameter $R = 0.4$. The measured jet energy is corrected for detector inhomogeneities and for the non-compensating nature of the calorimeter using p_{T}- and η-dependent correction factors based on Monte Carlo simulations with adjustments from in-situ measure-

JHEP03(2013)128

ments [43, 44]. Jets are required to have $p_{\mathrm{T}} > 25$ GeV and $|\eta| < 4.5$. In order to minimize the impact of jets from pile-up at high luminosity, the jet vertex fraction is required to be at least 0.75; the jet vertex fraction is defined as the sum of the p_{T} of tracks associated to the jet and originating from the primary vertex, divided by the sum of the p_{T} of all the tracks associated to the jet. If a reconstructed jet and a lepton lie within $\Delta R = 0.3$ of each other, the jet is not considered in the analysis.

The missing transverse momentum $E_{\mathrm{T}}^{\mathrm{miss}}$ is the imbalance of transverse momentum in the event. A large imbalance in the transverse momentum is a signature of the $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ decay channel. The two-dimensional $E_{\mathrm{T}}^{\mathrm{miss}}$ vector is determined from the negative vectorial sum of reconstructed electron, muon and jet momenta together with calorimeter cells not associated to any object [45]. Calorimeter cells are calibrated to the jet energy scale if they are associated with a jet and to the electromagnetic energy scale otherwise. Using calorimeter timing and shower shape information, events that contain jets with $p_{\mathrm{T}} > 20\,\mathrm{GeV}$ and not originating from proton-proton collisions but from e.g. calorimeter signals due to noisy cells are rejected.

3.2 $ZZ^{(*)} \to \ell^+\ell^-\ell'^+\ell'^-$ selection

$ZZ^{(*)} \to \ell^+\ell^-\ell'^+\ell'^-$ events are characterized by four high-p_{T}, isolated electrons or muons, in three channels: $e^+e^-e^+e^-$, $\mu^+\mu^-\mu^+\mu^-$ and $e^+e^-\mu^+\mu^-$. Selected events are required to have exactly four leptons and to have passed at least a single-muon or single-electron trigger. Each combination of lepton pairs is required to satisfy $\Delta R(\ell_1, \ell_2) > 0.2$, where ℓ_1 and ℓ_2 are used hereafter to denote a pair of distinct leptons, independent of their Z parent assignment, flavour and charge. To ensure high and well-measured trigger efficiency, at least one lepton must have $p_{\mathrm{T}} > 20$ GeV (25 GeV) for the offline muon (electron) and be matched to a muon (electron) reconstructed online by the trigger system within $\Delta R = 0.1$ (0.15).

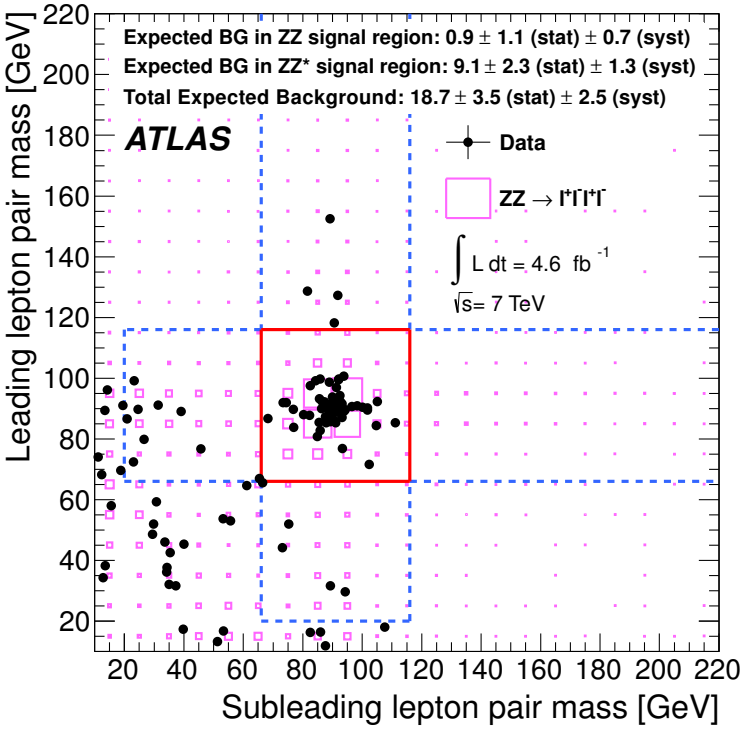
Same-flavour, oppositely-charged lepton pairs are combined to form Z candidates. An event must contain two such pairs. In the $e^+e^-e^+e^-$ and $\mu^+\mu^-\mu^+\mu^-$ channels, ambiguities are resolved by choosing the combination which results in the smaller value of the sum of $|m_{\ell^+\ell^-} - m_Z|$ for the two pairs, where $m_{\ell^+\ell^-}$ is the mass of the dilepton system and m_Z is the mass of the Z boson [46]. Figure 2 shows the correlation between the invariant mass of the leading (higher p_{T}) and the sub-leading (lower p_{T}) lepton pair. The events cluster in the region where both masses are around m_Z. At least one lepton pair is required to have invariant mass within the Z mass window, $66 < m_{\ell^+\ell^-} < 116\,\mathrm{GeV}$. If the second lepton pair satisfies this as well, the event is classified as a ZZ event; if the second pair satisfies $m_{\ell^+\ell^-} > 20\,\mathrm{GeV}$, the event is classified as a ZZ^* event.

With the selection described here, 84 $ZZ^* \to \ell^+\ell^-\ell'^+\ell'^-$ candidates are observed, out of which 66 are classified as $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ candidates. From the 84 (66) $ZZ^* \to \ell^+\ell^-\ell'^+\ell'^-$ ($ZZ \to \ell^+\ell^-\ell'^+\ell'^-$) candidates, 8 (7) candidates contain extended leptons.

3.3 $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ selection

$ZZ \to \ell^+\ell^-\nu\bar{\nu}$ events are characterized by large missing transverse momentum and two high-p_{T}, isolated electrons or muons. Selected events are required to have exactly two

JHEP03(2013)128



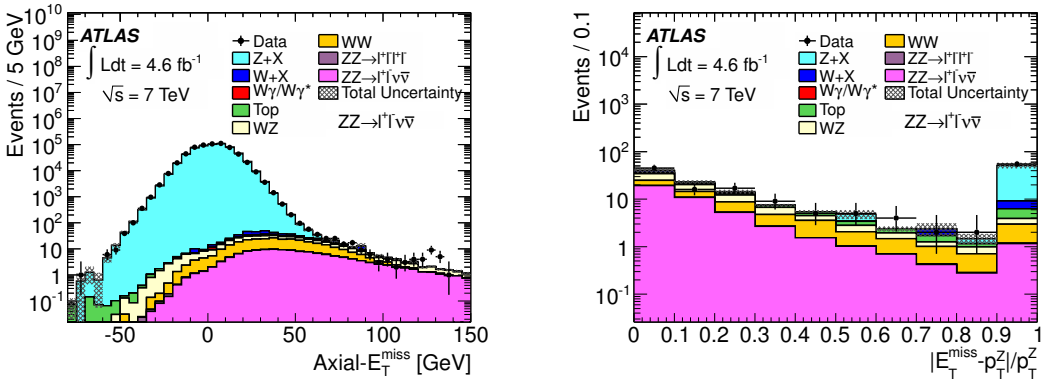


Figure 2. The mass of the leading lepton pair versus the mass of the sub-leading lepton pair. The events observed in the data are shown as solid circles and the $ZZ^{(*)} \to \ell^+\ell^-\ell'^+\ell'^-$ signal prediction from simulation as boxes. The size of each box is proportional to the number of events in each bin. The region enclosed by the solid (dashed) lines indicates the signal region defined by the requirements on the lepton-pair masses for ZZ (ZZ^*) events, as defined in the text.

leptons of the same flavour with $76 < m_{\ell^+\ell^-} < 106$ GeV and to have passed at least a single-muon or a single-electron trigger. The mass window is chosen to be tighter than the mass window used for the $ZZ^{(*)} \to \ell^+\ell^-\ell'^+\ell'^-$ channel in order to reduce the background from $t\bar{t}$ and WW. The lepton pair is required to have $\Delta R(\ell^+, \ell^-) > 0.3$. This requirement reflects the choice of the isolation cone for the leptons. The same trigger matching requirement as in the $ZZ^{(*)} \to \ell^+\ell^-\ell'^+\ell'^-$ channel is used.

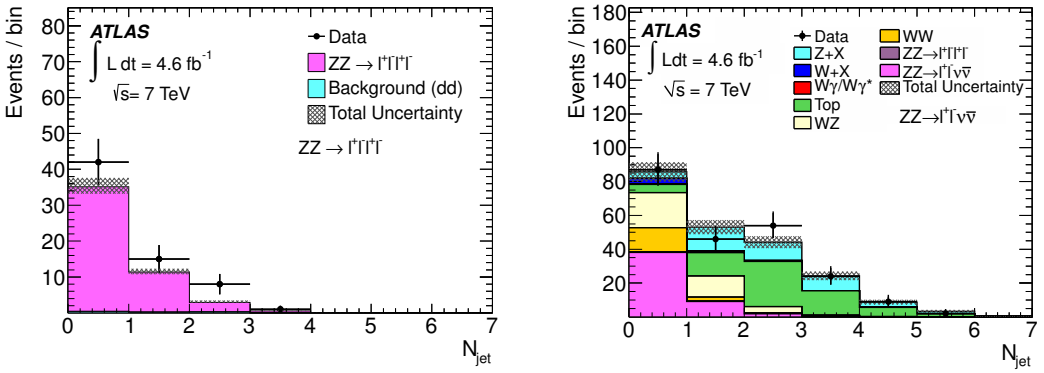
The $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ decay channel analysis makes use of several selections to reduce background. The largest background after the mass window requirement consists of Z+jets events, which are associated with non-zero missing transverse momentum when the $E_{\mathrm{T}}^{\mathrm{miss}}$ is mismeasured or when a b-quark decays to leptons and neutrinos inside of a jet. Since the Z bosons tend to be produced back-to-back, the axial-$E_{\mathrm{T}}^{\mathrm{miss}}$ (defined as the projection of the $E_{\mathrm{T}}^{\mathrm{miss}}$ along the direction opposite to the $Z \to \ell^+\ell^-$ candidate in the transverse plane) is a powerful variable to distinguish $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ decays from Z+jets. The axial-$E_{\mathrm{T}}^{\mathrm{miss}}$ is given by $-\vec{E}_{\mathrm{T}}^{\mathrm{miss}} \cdot \vec{p}^{Z}/p_{\mathrm{T}}^{Z}$, where p_{T}^{Z} is the magnitude of the transverse momentum of the Z candidate. Similarly, the fractional p_{T} difference, $|E_{\mathrm{T}}^{\mathrm{miss}} - p_{\mathrm{T}}^{Z}|/p_{\mathrm{T}}^{Z}$ is a good variable to distinguish the two. The axial-$E_{\mathrm{T}}^{\mathrm{miss}}$ and fractional p_{T} difference are shown in figure 3. In order to reduce Z+jets background, the axial-$E_{\mathrm{T}}^{\mathrm{miss}}$ must be greater than 75 GeV, and

JHEP03(2013)128

(a) (b)

Figure 3. For $\ell^+\ell^-\nu\bar{\nu}$ candidates in all channels figure (a) shows the axial-$E_{\mathrm{T}}^{\mathrm{miss}}$ after all selection requirements, except for the axial-$E_{\mathrm{T}}^{\mathrm{miss}}$, and figure (b) shows the fractional p_{T} difference between $E_{\mathrm{T}}^{\mathrm{miss}}$ and p_{T}^{Z} after all selection requirements, except for the fractional p_{T} difference (the last bin also contains events with fractional p_{T} difference greater than 1). In all plots, the points are data and the stacked histograms show the signal prediction from simulation. The shaded band shows the combined statistical and systematic uncertainties.

the fractional p_{T} difference must be less than 0.4. To reduce background from top-quark production, events which contain at least one reconstructed jet with $p_{\mathrm{T}} > 25\,\mathrm{GeV}$ and $|\eta| < 4.5$ are rejected.



To reduce background from WZ production, events with a third lepton (electron or muon) with p_{T} greater than 10 GeV are rejected. The shape of the jet multiplicity distribution is well modelled in Monte Carlo simulation as shown in figure 4 for the $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ and $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ selections, however, there is an overall excess of about 20% in the $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ selection. With this selection, 87 $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ candidates are observed in data.

4 Signal acceptance

The Z boson decays to hadrons, neutrinos and charged leptons with branching fractions of 69.9%, 20.0% and 10.1%, respectively [46]. The two ZZ decay channels considered in this paper, $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ and $ZZ \to \ell^+\ell^-\nu\bar{\nu}$, have branching fractions of 0.45% and 2.69%, respectively,[6] where decays involving τ leptons are not included in these branching fractions. Some of the ZZ decays produce one or more charged leptons which pass through the uninstrumented regions of the detector, and as such cannot be reconstructed. In order to measure the total ZZ cross section, the measured decays are extrapolated to non-measured parts of the phase-space; this results in the measurement being more dependent on theory predictions. Consequently, two types of cross sections are measured: fiducial and total. The fiducial cross section is the cross section measured within a restricted phase space, and the total cross section is the cross section extrapolated to the total phase space.

[6]The quoted branching fraction to four charged leptons is for the case where both Z bosons are within the mass window, so that the γ^* contribution can be neglected.

JHEP03(2013)128

(a) (b)

Figure 4. (a) Jet multiplicity for the $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ selection and (b) jet multiplicity for the $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ selection (with all selections applied but the jet veto). The points represent the observed data. In (a) the $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ background is normalized to the data-driven (dd) estimate, while in (b) the histograms show the prediction from simulation. The shaded band shows the combined statistical and systematic uncertainty on the prediction.

The total cross section calculation depends on the choice of Z mass range. The cross section is calculated using the Z boson natural width rather than the zero-width approximation, and includes the mass window requirement (66 to 116 GeV) to remove most of the γ^* contamination. The ratio of the total cross section calculated with both Z bosons within the mass window to the total cross section calculated using the zero-width approximation is 0.953, as the mass window requirement removes some of the Z bosons in the tails of the mass distribution.

4.1 Fiducial region definitions

The fiducial cross section is restricted to a region which is constructed to closely match the instrumented region and the event selection; for simplicity, only the most inclusive requirements on the lepton η and p_{T} are used for the definition of the fiducial phase space. The fiducial cross section $\sigma_{ZZ}^{\mathrm{fid}}$ is calculated as:

$$\sigma_{ZZ}^{\mathrm{fid}} = \frac{N_{\mathrm{obs}} - N_{\mathrm{bkg}}}{C_{ZZ} \times \mathcal{L}} \tag{4.1}$$

which depends on a correction factor given by the number of simulated $ZZ^{(*)}$ events which satisfy the full event selection divided by the number of $ZZ^{(*)}$ events generated in the fiducial region, C_{ZZ}; the integrated luminosity, $\mathcal{L}$; the number of selected events, N_{obs}; and the amount of estimated background, N_{bkg}. For the calculation of C_{ZZ}, final states including pairs of oppositely-charged leptons produced from decays of $Z \to \tau^+\tau^- \to \ell^+\ell^-\nu\bar{\nu}\nu\bar{\nu}$ are included in the number of selected events (numerator) since those decays have an identical final state to the signal and are not subtracted as background but are excluded from the fiducial region (denominator) because the fiducial regions are defined only with $ZZ^{(*)}$ decays directly to electrons, muons or neutrinos, depending on the channel. The contribution from such τ decays is estimated from Monte Carlo simulation to be < 0.1 % for the

Selection	C_{ZZ}
$ZZ \to \ell^+\ell^-\ell'^+\ell'^-$	$0.552 \pm 0.002 \pm 0.021$
$ZZ^* \to \ell^+\ell^-\ell'^+\ell'^-$	$0.542 \pm 0.002 \pm 0.022$
$ZZ \to \ell^+\ell^-\nu\bar{\nu}$	$0.679 \pm 0.004 \pm 0.014$

Table 1. Correction factors C_{ZZ} for each production and decay channel. The first uncertainty is statistical while the second is systematic.

$ZZ \to \ell^+\ell^-\nu\bar{\nu}$ selection, 0.24±0.01% for the $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ selection and 1.73±0.04% for the $ZZ^* \to \ell^+\ell^-\ell'^+\ell'^-$ selection. Fiducial requirements are applied at generator level. To reduce the dependence on QED radiation, the four-momentum assigned to each lepton includes the four-momentum of any neighbouring photon within $\Delta R \leq 0.1$.

The $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ fiducial region is defined using the following requirements: (i) two pairs of same-flavour opposite-sign electrons or muons, with each lepton satisfying $p_{\mathrm{T}}^{\ell} > 7\,\mathrm{GeV}$, $|\eta^{\ell}| < 3.16$ and at least a distance $\Delta R = 0.2$ from any other selected lepton, i.e., $\Delta R(\ell_1, \ell_2) > 0.2$, and (ii) both dilepton invariant masses within the Z mass window. A $ZZ^* \to \ell^+\ell^-\ell'^+\ell'^-$ fiducial region is defined with the same criteria as in the $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ case, except that one dilepton invariant mass requirement is relaxed to be greater than 20 GeV.

The $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ fiducial region is defined by requiring: (i) two same-flavour opposite-sign electrons or muons, each with $p_{\mathrm{T}}^{\ell} > 20\,\mathrm{GeV}$, $|\eta^{\ell}| < 2.5$, with $\Delta R(\ell^+, \ell^-) > 0.3$, (ii) dilepton invariant mass close to the Z boson mass: $76 < m_{\ell^+\ell^-} < 106\,\mathrm{GeV}$, (iii) dineutrino invariant mass close to the Z boson mass: $66 < m_{\nu\bar{\nu}} < 116\,\mathrm{GeV}$, (iv) no jet with $p_{\mathrm{T}}^{j} > 25\,\mathrm{GeV}$ and $|\eta^{j}| < 4.5$, and (v) $(|p_{\mathrm{T}}^{\nu\bar{\nu}} - p_{\mathrm{T}}^{Z}|)/p_{\mathrm{T}}^{Z} < 0.4$ and $-\vec{p}_{\mathrm{T}}^{\,\nu\bar{\nu}} \cdot \vec{p}^{\,Z}/p_{\mathrm{T}}^{Z} > 75\,\mathrm{GeV}$. Jets are defined at generator level using the same jet algorithm as used in reconstructed events and including all final state particles after parton showering and hadronization.

Fiducial cross sections are calculated using the $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$, $ZZ^* \to \ell^+\ell^-\ell'^+\ell'^-$ and $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ selections, integrated over the corresponding full fiducial phase space volumes. For the $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ and $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ selections the differential fiducial cross sections are derived in bins of the leading p_{T}^{Z}, $\Delta\phi(\ell^+, \ell^-)$ and the mass of the $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ system or the transverse mass of the $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ system.

The correction factor, C_{ZZ}, is determined from Monte Carlo simulations (PowhegBox for the $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ channel and PowhegBox and gg2zz for the $ZZ^{(*)} \to \ell^+\ell^-\ell'^+\ell'^-$ channel), after applying data-driven corrections as described in section 2.1. For the $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ ($ZZ^* \to \ell^+\ell^-\ell'^+\ell'^-$) selection it is 0.43 (0.41) for $e^+e^-e^+e^-$, 0.68 (0.69) for $\mu^+\mu^-\mu^+\mu^-$ and 0.55 (0.53) for $e^+e^-\mu^+\mu^-$ events. For the $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ selection the correction factor is 0.63 for $e^+e^-\nu\bar{\nu}$ and 0.76 for $\mu^+\mu^-\nu\bar{\nu}$ events. The correction factors combining all lepton categories within the fiducial region are given in table 1 for the three event selections in both decay channels.

Selection	A_{ZZ}
$ZZ \to \ell^+\ell^-\ell'^+\ell'^-$	$0.804 \pm 0.001 \pm 0.010$
$ZZ \to \ell^+\ell^-\nu\bar{\nu}$	$0.081 \pm 0.001 \pm 0.004$

Table 2. Acceptance A_{ZZ} for the two decay channels used for the measurement of the total ZZ production cross section. The first uncertainty is statistical while the second is systematic.

4.2 Extrapolation to the total phase space

The total ZZ cross section is measured using the $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ and $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ selections. The total cross section is calculated using the fiducial acceptance, A_{ZZ} (the fraction of ZZ events with Z bosons in the Z mass window that fall into the fiducial region) and the branching fraction, BF:

$$\sigma_{ZZ}^{\text{total}} = \frac{N_{\text{obs}} - N_{\text{bkg}}}{A_{ZZ} \times C_{ZZ} \times \mathcal{L} \times \text{BF}} \tag{4.2}$$

The fiducial acceptances A_{ZZ} are estimated from Monte Carlo simulation, using PowhegBox for the $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ channel and PowhegBox and gg2zz for the $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ channel. The fiducial acceptance of the $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ channel is much more constrained than the $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ channel in order to reduce background. Values are given in table 2.

4.3 Systematic uncertainties

Table 3 summarizes the systematic uncertainties on C_{ZZ} and A_{ZZ}. For C_{ZZ} in the $ZZ^{(*)} \to \ell^+\ell^-\ell'^+\ell'^-$ selections, the dominant systematic uncertainties arise from the lepton reconstruction efficiency, the efficiency of the isolation and impact parameter requirements, and the differences in C_{ZZ} estimated by Sherpa and PowhegBox; uncertainties on the trigger efficiency and the lepton energy scale and resolution are small. In the $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ channel the dominant C_{ZZ} uncertainties are from uncertainties on the lepton reconstruction efficiency, the lepton energy scale and resolution, and the missing transverse momentum modelling and jet veto uncertainty; uncertainties on the trigger efficiency and due to differences in C_{ZZ} estimated by Sherpa and PowhegBox also contribute.

The uncertainties on C_{ZZ} from the reconstruction efficiency, energy scale and resolution, isolation and impact parameter requirements and trigger efficiency are estimated by varying the data-driven correction factors applied to simulation by their systematic and statistical uncertainties. The systematic uncertainties on events with extended leptons used in the $ZZ^{(*)} \to \ell^+\ell^-\ell'^+\ell'^-$ channel are slightly higher than in events without them; nevertheless, since their relative contribution is small, the effect on the uncertainty of the combined channels is negligible. The generator systematic uncertainty for C_{ZZ} accounts for the effect of choosing a different renormalization and factorization scale and PDF set.

For A_{ZZ}, the systematic uncertainties are due to theoretical uncertainties which come from the PDFs, the choice of the renormalization and factorization scales, the modelling of the contribution from gg initial states and the parton shower model, as given in table 3. For the $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ channel, uncertainties in the efficiency of the jet veto are also taken into

JHEP03(2013)128

account through the calculation of a scale factor; the ratio of the jet veto efficiency in data to that in MC simulation is taken from a sample of single Z events and then applied to ZZ events [47]. The systematic uncertainties due to the PDFs and scales are evaluated with MCFM by taking the difference between the A_{ZZ} obtained using the CT10 and MSTW2008 PDF sets, as well as using the 44 CT10 error sets, and by shifting the factorization and renormalization scales up and down by a factor of two from the nominal value (half the mass of the diboson system). An additional uncertainty is assigned to account for the effect of different modelling at the generator level. Since the $ZZ^* \to \ell^+\ell^-\ell'^+\ell'^-$ measurement is not used for the total cross section, its A_{ZZ} acceptance is irrelevant and only uncertainty values related to C_{ZZ} are given.

The uncertainty on the integrated luminosity is 3.9% [22]. The uncertainty on the background estimates is discussed in the following sections.

5 Background estimation

5.1 $ZZ^{(*)} \to \ell^+\ell^-\ell'^+\ell'^-$ background

Background to the $ZZ^{(*)} \to \ell^+\ell^-\ell'^+\ell'^-$ signal originates from events with a Z (or W) boson decaying to leptons accompanied by additional jets or photons ($W/Z+X$), from top-quark production and from other diboson final states. Such events may contain electrons or muons from the decay of heavy-flavoured hadrons, muons from in-flight decay of pions and kaons, or jets and photons misidentified as electrons. The majority of these background leptons are rejected by the isolation requirements.

The background estimate follows a data-driven method in which a sample of events containing three leptons satisfying all selection criteria plus one 'lepton-like jet' is identified; such events are denoted as $\ell\ell\ell j$. For muons, the lepton-like jets are muon candidates that fail the isolation requirement or fail the impact parameter requirement but not both. For electrons with $|\eta| < 2.47$, the lepton-like jets are clusters in the electromagnetic

JHEP03(2013)128

calorimeter matched to inner detector tracks that fail either the full electron selection or the isolation requirement but not both. For electrons with $|\eta| > 2.5$, the lepton-like jets are electromagnetic clusters that are reconstructed as electrons but fail the tight identification requirements. The events are otherwise required to satisfy the full event selection, treating the lepton-like jet as if it were a fully identified lepton. The background is then estimated by weighting the $\ell\ell\ell j$ events by a measured factor f, which is the ratio of the probability for a non-lepton to satisfy the full lepton selection criteria to the probability of a non-lepton satisfying the lepton-like jet criteria. The background in which two selected leptons originate from jets is treated similarly, by identifying a data sample with two leptons and two lepton-like jets; such events are denoted as $\ell\ell jj$. The total number of expected background $\ell^+\ell^-\ell'^+\ell'^-$ events, $N(\mathrm{BG})$, is calculated as:

$$N(\mathrm{BG}) = [N(\ell\ell\ell j) - N(ZZ)] \times f - N(\ell\ell jj) \times f^2 \tag{5.1}$$

where double counting from $\ell\ell\ell j$ and $\ell\ell jj$ events is accounted for, and the term $N(ZZ)$ is a Monte Carlo estimate correcting for contributions from signal $ZZ^{(*)} \to \ell^+\ell^-\ell'^+\ell'^-$ events having a real lepton that is classified as a lepton-like jet (the equivalent correction to the term $N(\ell\ell jj)$ is negligible).

The factor f is measured in a sample of data selected with single-lepton triggers which contain a Z boson candidate: a pair of isolated same-flavour opposite-sign electrons or muons. In these selected events, f is measured, using the lepton and lepton-like jet candidates not assigned to the Z boson, as the ratio of the number of selected leptons to the number of lepton-like jets, after correcting for expected true lepton contributions from WZ and ZZ events using simulation. Independent values as a function of the η and p_{T} of the lepton-like jet are measured, which are then combined assuming they are uncorrelated. The factor f is found to vary from 0.33 ± 0.01 (0.26 ± 0.02) below $p_{\mathrm{T}} = 10$ GeV to 0.09 ± 0.02 (0.46 ± 0.20) above $p_{\mathrm{T}} = 50$ GeV for electrons (muons). The quoted uncertainties are statistical. Then, with the same procedure, a value for f is also derived using the simulated samples of background processes. The difference between the value of f derived in data and in simulation is assigned as a systematic uncertainty on f. The statistical and systematic uncertainties are then added in quadrature to derive a combined uncertainty on f, which varies as a function of p_{T} from 14% (19%) below 10 GeV to 22% (51%) above 50 GeV for electrons (muons). For the muons, the total uncertainty on f is dominated by its statistical uncertainty. The background estimates for the $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ and $ZZ^* \to \ell^+\ell^-\ell'^+\ell'^-$ selections are $0.9^{+1.1}_{-0.9}(\mathrm{stat.}) \pm 0.7(\mathrm{syst.})$ and $9.1 \pm 2.3(\mathrm{stat.}) \pm 1.3(\mathrm{syst.})$ events, respectively, as shown in tables 4 and 5. The statistical uncertainty on the background estimate comes from the statistical uncertainty on the numbers of $\ell\ell\ell j$, $\ell\ell jj$ and $ZZ^{(*)} \to \ell^+\ell^-\ell'^+\ell'^-$ events used in eq. 5.1. The systematic uncertainty results from the combined uncertainty on f. In cases where the overall estimate is negative, the background estimate is described using a truncated Gaussian with mean at zero and standard deviation equal to the estimated statistical and systematic uncertainties added in quadrature.

The extra background induced by the use of the extended leptons in the $ZZ^{(*)} \to \ell^+\ell^-\ell'^+\ell'^-$ channel is estimated to be negligible in the $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ selection, and about 20% (2 events out of the 9.1 estimated, compared to a signal gain of about 10.6 events out of the 64.4 expected) in the $ZZ^* \to \ell^+\ell^-\ell'^+\ell'^-$ selection.

Background estimate, N(BG)	4.3 ± 1.4(stat.) ± 0.6(syst.)	< 0.91	5.8 ± 1.6(stat.) ± 0.9 (syst.)	9.1 ± 2.3(stat.) ± 1.3(syst.)

Table 5. Expected number of background events for the $ZZ^* \to \ell^+\ell^-\ell'^+\ell'^-$ selection in 4.6 fb^{-1} of data, for the individual decay modes (columns 2, 3 and 4) and for their combination (last column). If the central value of the estimate is negative, the upper bound on the number of events in that channel is derived as detailed in section 5.1.

The background is also estimated purely from the simulated samples of background processes, and is predicted to be 1.5 ± 0.4 events for the $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ selection and 8.3 ± 1.3 events for the $ZZ^* \to \ell^+\ell^-\ell'^+\ell'^-$ selection, with uncertainties being statistical only. These estimates compare well with the data-driven results given in tables 4 and 5. According to the estimate from simulation, the dominant source of background is Z+jets events, with only about a 10% to 20% contribution from other diboson channels (WZ and WW), and a negligible contribution from events with top quarks.

Differential background distributions are determined by first deriving the shape of the distributions from the background MC samples. This is achieved by selecting events where one Z candidate is required to satisfy the nominal lepton selection, while the other Z candidate is formed by leptons satisfying relaxed criteria for the isolation requirements and transverse impact parameter significance. The shape determined in this way is then scaled such that the total number of events in the distribution is equal to the data-driven background estimate shown in tables 4 and 5.

5.2 $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ background

There are several sources of background to the $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ channel. Processes such as $t\bar{t}$, WW, Wt or $Z \to \tau^+\tau^-$ production give two true isolated leptons with missing transverse momentum. Diboson WZ events in which both bosons decay leptonically have

Process	$e^+e^-E_{\mathrm{T}}^{\mathrm{miss}}$	$\mu^+\mu^-E_{\mathrm{T}}^{\mathrm{miss}}$	$\ell^+\ell^-E_{\mathrm{T}}^{\mathrm{miss}}$
$t\bar{t}$, Wt, WW, $Z \to \tau^+\tau^-$	$8.5 \pm 2.1 \pm 0.5$	$10.6 \pm 2.6 \pm 0.6$	$19.1 \pm 2.3 \pm 1.0$
WZ	$8.9 \pm 0.5 \pm 0.4$	$11.9 \pm 0.5 \pm 0.3$	$20.8 \pm 0.7 \pm 0.5$
$Z \to \mu^+\mu^-, e^+e^-$+jets	$2.6 \pm 0.7 \pm 1.0$	$2.7 \pm 0.8 \pm 1.2$	$5.3 \pm 1.1 \pm 1.6$
W+ jets	$0.7 \pm 0.3 \pm 0.3$	$0.7 \pm 0.2 \pm 0.2$	$1.5 \pm 0.4 \pm 0.4$
$W\gamma$	$0.1 \pm 0.1 \pm 0.0$	$0.2 \pm 0.1 \pm 0.0$	$0.3 \pm 0.1 \pm 0.0$
Total	$20.8 \pm 2.3 \pm 1.2$	$26.1 \pm 2.8 \pm 1.4$	$46.9 \pm 4.8 \pm 1.9$

Table 6. Expected number of background events to the $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ channel in 4.6 fb^{-1} of data, for the individual decay modes (columns 2 and 3) and for their combination (last column). The first uncertainty is statistical while the second is systematic.

three charged leptons, but if one lepton from a W or Z boson decay is not identified, the event has the same signature as the signal. Production of a Z boson in association with jets gives two isolated leptons from the Z boson decay and may have missing transverse momentum if the jet momenta are mismeasured. Finally, production of a W boson in association with jets or photons may satisfy the selection requirements when one of the jets or photons is misidentified as an isolated lepton. All of the backgrounds are measured with data-driven techniques except for WZ and $W\gamma$. The total background is estimated to be $46.9 \pm 4.8 \pm 1.9$ events as summarized in table 6.

5.2.1 Backgrounds from $t\bar{t}$, Wt, WW and $Z \to \tau^+\tau^-$

The contributions from $t\bar{t}$, Wt, WW and $Z \to \tau^+\tau^-$ processes are measured by extrapolating from a control sample of events with one electron and one muon (instead of two electrons or two muons), which otherwise satisfy the full $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ selection. This sample is free from signal events. The extrapolation from the $e\mu$ channel to the ee or $\mu\mu$ channel uses the relative branching fractions ($2:1:1$ for $e\mu : ee : \mu\mu$) as well as the ratio of the efficiencies ϵ_{ee} or $\epsilon_{\mu\mu}$ of the ee or $\mu\mu$ selections to the efficiency $\epsilon_{e\mu}$ of the $e\mu$ selection, which differs from unity due to differences in the electron and muon efficiencies.

For the electron channel, this is represented by the equation:

$$N_{ee}^{\mathrm{bkg}} = (N_{e\mu}^{\mathrm{data}} - N_{e\mu}^{\mathrm{sim}}) \times \frac{1}{2} \times \frac{\epsilon_{ee}}{\epsilon_{e\mu}} \tag{5.2}$$

where $N_{e\mu}^{\mathrm{data}}$ is the number of observed $e\mu$ events and $N_{e\mu}^{\mathrm{sim}}$ is the number expected events from processes other than $t\bar{t}$, Wt, WW and $Z \to \tau^+\tau^-$ (WZ, ZZ, W+jet, Z+jet and W/γ). Therefore, $(N_{e\mu}^{\mathrm{data}} - N_{e\mu}^{\mathrm{sim}})$ is the estimate of $t\bar{t}$, Wt, WW and $Z \to \tau^+\tau^-$ production in the control sample. The efficiency correction factor, $\epsilon_{ee}/\epsilon_{e\mu}$, corrects for the difference between electron and muon efficiency. The efficiency correction factor is measured in data using reconstructed $Z \to \ell^+\ell^-$ events, as

$$\frac{\epsilon_{ee}}{\epsilon_{e\mu}} = \frac{\epsilon_e^2}{\epsilon_e\epsilon_\mu} = \frac{\epsilon_e}{\epsilon_\mu} = \sqrt{\frac{N_{ee}^{\mathrm{data}}}{N_{\mu\mu}^{\mathrm{data}}}} \tag{5.3}$$

JHEP03(2013)128

where N_{ee}^{data} and $N_{\mu\mu}^{\text{data}}$ are the number of observed ee or $\mu\mu$ events in the Z boson mass window, respectively, after all lepton selection requirements and the Z boson mass window requirement are applied. A parallel argument gives $N_{\mu\mu}^{\text{bkg}}$. This procedure is repeated in bins of p_{T}^{Z} in order to obtain the p_{T} distribution of the $t\bar{t}$, Wt, WW and $Z \to \tau^{+}\tau^{-}$ background.

The dominant uncertainty is statistical (25%), due to the limited number of events in the control samples. Additional uncertainties are due to systematic uncertainties in the normalization of the simulated samples used to correct the $e\mu$ contribution (5.5%) and the systematic uncertainty in the efficiency correction factor (4.5%).

5.2.2 Background from WZ production with leptonic decays

Events from leptonic WZ decays may result in an $\ell^{+}\ell^{-}E_{\text{T}}^{\text{miss}}$ signature when one lepton from the W or Z boson is not reconstructed. The contribution from this process is estimated using the simulated samples described in section 2.1. The estimate is checked using a control region with three high-p_{T} isolated leptons. The two dominant processes that contribute to this control region are WZ and Z+jets production, where the WZ boson pair decays to three leptons and a neutrino and the Z+jets contribution has two real leptons from the Z decay and a misidentified lepton from the jet. The technique used to estimate the background in the $ZZ^{(*)} \to \ell^{+}\ell^{-}\ell'^{+}\ell'^{-}$ channel is also used to normalize the contribution from Z+jets in the three-lepton control region. The WZ Monte Carlo expectation is consistent with the data. The systematic uncertainties are estimated in the same way as for signal Monte Carlo events.

5.2.3 Background from Z bosons with associated jets

Occasionally events with a Z boson produced in association with jets may have large amounts of missing transverse momentum due to mismeasurement of the momenta of the jets. This background is estimated using events with a high-p_{T} photon and jets as a template, since the mechanism for large missing transverse momentum is the same as in Z+jets events. The events are reweighted such that the photon E_{T} matches the observed Z boson p_{T} and are normalized to the observed Z + jets yield. The procedure is repeated in bins of p_{T}^{Z} in order to obtain the p_{T} distribution of the Z+jets backgrounds. The largest systematic uncertainty is due to the subtraction of $W\gamma$, $Z\gamma$, $t\bar{t}$ and $W \to e\nu$ contributions to the γ+jets sample, which is 33% in the ee channel and 37% in the $\mu\mu$ channel.

5.2.4 Background from events with a misidentified lepton

A small contribution to the selected sample is due to events in which one of the two leptons comes from the decay of a W or Z boson (called 'real' below) and the second is a 'fake', corresponding both non-prompt leptons and misidentified π^{0} mesons or conversions.

The dominant fake-muon mechanism is the decay of heavy-flavoured hadrons, in which a muon survives the isolation requirements. In the case of electrons, the three mechanisms are heavy-flavour hadron decay, light-flavour jets with a leading π^{0} overlapping with a charged particle, and conversion of photons. Processes that contribute are top-quark pair production, production of W bosons in association with jets and multi-jet production.

JHEP03(2013)128

The 'matrix method' [48] is applied to estimate the fraction of events in the signal regions that contain at least one fake lepton. The method measures the number of fake leptons in background-dominated control regions and extrapolates to the ZZ selection region using factors measured in data. The shape of the background is provided by taking the background as uniformly distributed among the bins and treating each bin as statistically uncorrelated. The dominant systematic uncertainty is due to the uncertainty on the extrapolation factors and the limited numbers of events in the control samples, giving a total uncertainty of 63% and 44% in the ee and $\mu\mu$ channels, respectively.

6 Results

Three types of measurements are presented:

- integrated fiducial and total ZZ cross sections;
- differential cross sections normalized to the overall measured cross sections for the p_{T}^{Z} and $\Delta\phi(\ell^+,\ell^-)$ of the leading Z boson, and the mass (transverse mass[7]) of the ZZ system for the $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ ($ZZ \to \ell^+\ell^-\nu\bar{\nu}$) selection; and
- limits on the anomalous nTGCs.

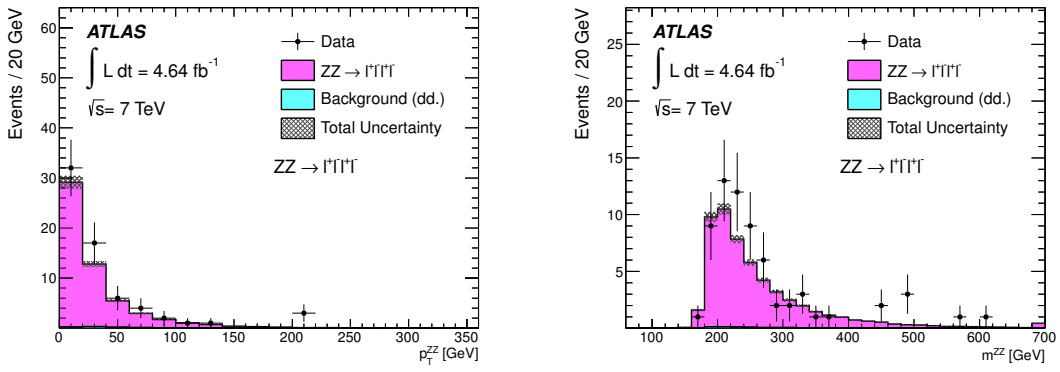
6.1 Cross section measurements

The expected and observed event yields after applying all selection criteria are shown in table 7 for both channels. Figure 4 shows the jet multiplicity in selected $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ and $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ events before the jet veto is applied. Figures 5 and 6 show the transverse momentum and mass of the ZZ system in selected $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ and $ZZ^* \to \ell^+\ell^-\ell'^+\ell'^-$ events respectively. Figure 7 shows the transverse momentum and mass of the two-charged-lepton system in selected $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ events. The shapes of the distributions are consistent with the predictions from the simulation.

The $ZZ^{(*)} \to \ell^+\ell^-\ell'^+\ell'^-$ and $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ fiducial cross sections are determined using a maximum likelihood fitting method, taking into account the integrated luminosity and the C_{ZZ} correction factors discussed in section 4. A Poisson probability function is used to model the number of expected events, multiplied by Gaussian distribution functions which model the nuisance parameters representing systematic uncertainties. The measured fiducial cross sections are:

$$\begin{aligned}
\sigma^{\mathrm{fid}}_{ZZ \to \ell^+\ell^-\ell'^+\ell'^-} &= 25.4^{+3.3}_{-3.0}\ (\mathrm{stat.})\ ^{+1.2}_{-1.0}\ (\mathrm{syst.})\ \pm 1.0\ (\mathrm{lumi.})\ \mathrm{fb},\\
\sigma^{\mathrm{fid}}_{ZZ^* \to \ell^+\ell^-\ell'^+\ell'^-} &= 29.8^{+3.8}_{-3.5}\ (\mathrm{stat.})\ ^{+1.7}_{-1.5}\ (\mathrm{syst.})\ \pm 1.2\ (\mathrm{lumi.})\ \mathrm{fb},\\
\sigma^{\mathrm{fid}}_{ZZ \to \ell^+\ell^-\nu\bar{\nu}} &= 12.7^{+3.1}_{-2.9}\ (\mathrm{stat.})\ ^{+1.7}_{-1.7}\ (\mathrm{syst.})\ \pm 0.5\ (\mathrm{lumi.})\ \mathrm{fb}.
\end{aligned}$$

where $\ell^+\ell^-\ell'^+\ell'^-$ refers to the sum of the $e^+e^-e^+e^-$, $e^+e^-\mu^+\mu^-$ and $\mu^+\mu^-\mu^+\mu^-$ final states and $\ell^+\ell^-\nu\bar{\nu}$ refers to the sum of the $e^+e^-E_{\mathrm{T}}^{\mathrm{miss}}$ and $\mu^+\mu^-E_{\mathrm{T}}^{\mathrm{miss}}$ final states.[8] The



[7] $m_{\mathrm{T}}^2 = \left(\sqrt{(m^Z)^2 + (p_{\mathrm{T}}^Z)^2} + \sqrt{(m^Z)^2 + (E_{\mathrm{T}}^{\mathrm{miss}})^2}\right)^2 - \left(\vec{p}_{\mathrm{T}}^{\,Z} + \vec{E}_{\mathrm{T}}^{\mathrm{miss}}\right)^2$.

[8] The $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ fiducial region is more restricted compared to the $ZZ^{(*)} \to \ell^+\ell^-\ell'^+\ell'^-$ channel.

Table 7. Summary of observed $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$, $ZZ^* \to \ell^+\ell^-\ell'^+\ell'^-$ and $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ candidates in the data, total background estimates and expected signal for the individual decay modes (columns 2 to 4) and for their combination (last column). The quoted uncertainties and limits represent 68% confidence intervals; the first uncertainty is statistical while the second is systematic. The uncertainty on the integrated luminosity (3.9%) is not included.

(a) (b)

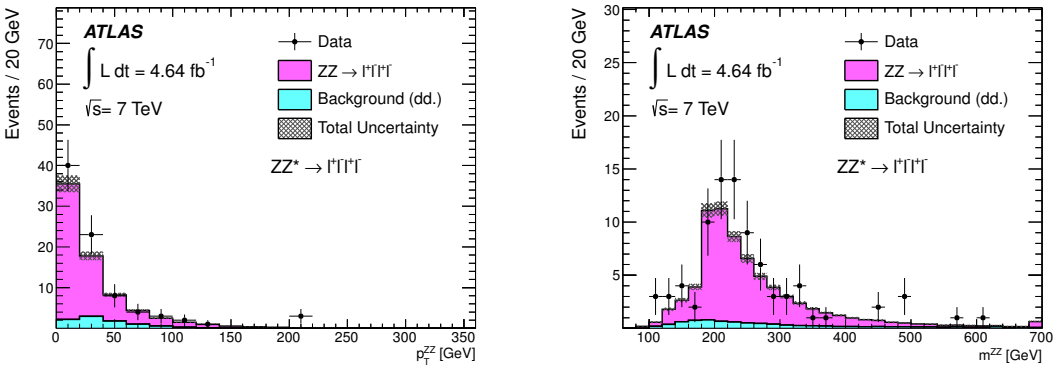

Figure 5. (a) Transverse momentum p_{T}^{ZZ} and (b) invariant mass m^{ZZ} of the four-lepton system for the ZZ selection. The points represent the observed data and the histograms show the prediction from simulation, where the background is normalized to the data-driven (dd) estimate as described in section 5.1. The shaded band shows the combined statistical and systematic uncertainty on the prediction.

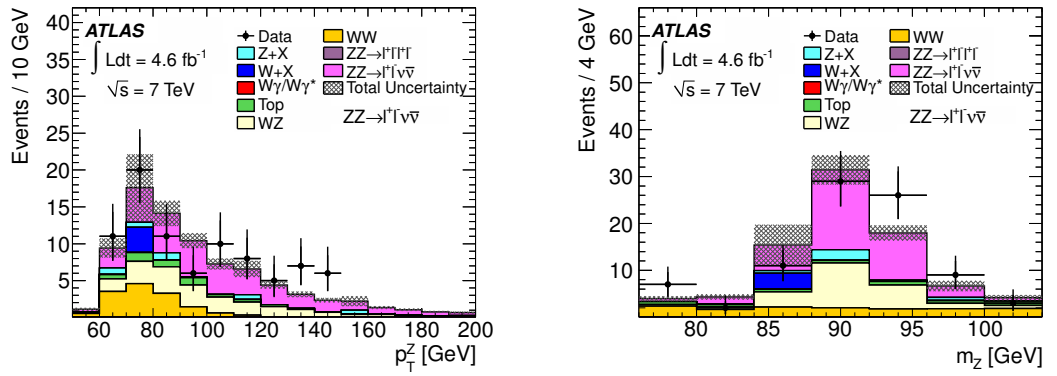
expected SM fiducial cross sections, derived from PowhegBox and gg2zz, are:

$$\begin{aligned}
\sigma^{\mathrm{fid,SM}}_{ZZ \to \ell^+\ell^-\ell'^+\ell'^-} &= 20.9 \pm 0.1\ (\mathrm{stat.})\ ^{+1.1}_{-0.9}\ (\mathrm{theory})\ \mathrm{fb}, \\
\sigma^{\mathrm{fid,SM}}_{ZZ^* \to \ell^+\ell^-\ell'^+\ell'^-} &= 25.6 \pm 0.1\ (\mathrm{stat.})\ ^{+1.3}_{-1.1}\ (\mathrm{theory})\ \mathrm{fb}, \\
\sigma^{\mathrm{fid,SM}}_{ZZ \to \ell^+\ell^-\nu\bar{\nu}} &= 12.5 \pm 0.1\ (\mathrm{stat.})\ ^{+1.0}_{-1.1}\ (\mathrm{theory})\ \mathrm{fb}.
\end{aligned}$$



The measured cross sections are compatible with these theoretical values.

Figure 6. (a) Transverse momentum p_{T}^{ZZ} and (b) invariant mass m^{ZZ} of the four-lepton system for the ZZ^* selection. The points represent the observed data and the histograms show the prediction from simulation, where the background is normalized to the data-driven (dd) estimate. The shaded band shows the combined statistical and systematic uncertainty on the prediction.

(a) (b)

Figure 7. (a) Transverse momentum p_{T}^{Z} and (b) mass m_Z of the two-charged-lepton system for the $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ selection. The points represent the observed data and the histograms show the prediction from simulation. The shaded band shows the combined statistical and systematic uncertainty on the prediction.

The total ZZ cross section is calculated by extrapolating to the full phase space while each Z boson is required to have a mass within the Z mass window. Both $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ and $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ events are combined in the maximum likelihood fit, taking into account the known Z branching fractions [46] and the A_{ZZ} kinematic and geometrical acceptances (section 4). Correlated systematic uncertainties between the $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ and $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ channels are taken into account in the fit using a single Gaussian for the nuisance parameter for each source of correlated uncertainty. The measured value of the total ZZ cross section is:

$$\sigma_{ZZ}^{\mathrm{tot}} = 6.7 \pm 0.7\ (\mathrm{stat.})\ {}^{+0.4}_{-0.3}\ (\mathrm{syst.}) \pm 0.3\ (\mathrm{lumi.})\ \mathrm{pb}.$$

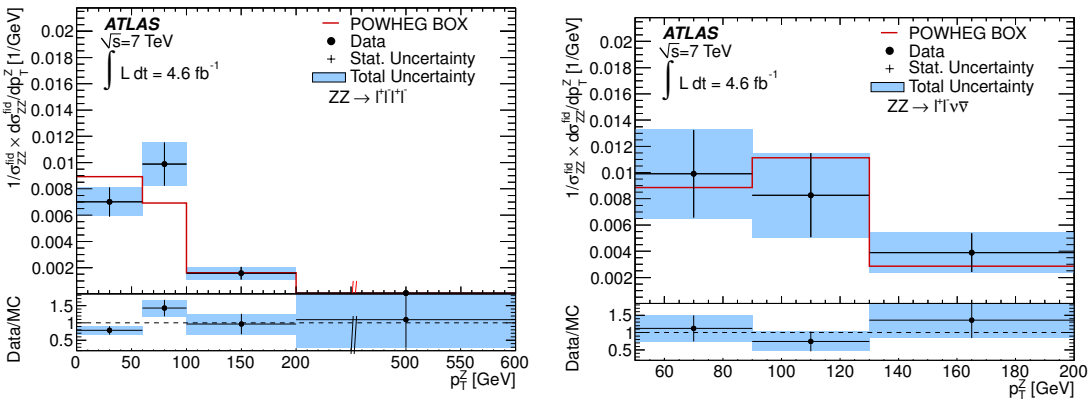
The result is consistent within errors with the NLO Standard Model total cross section for

JHEP03(2013)128

this process of $5.89^{+0.22}_{-0.18}$ pb, where the quoted theoretical uncertainties result from varying the factorization and renormalization scales simultaneously by a factor of two and from using the full CT10 PDF error set.

6.2 Differential cross sections

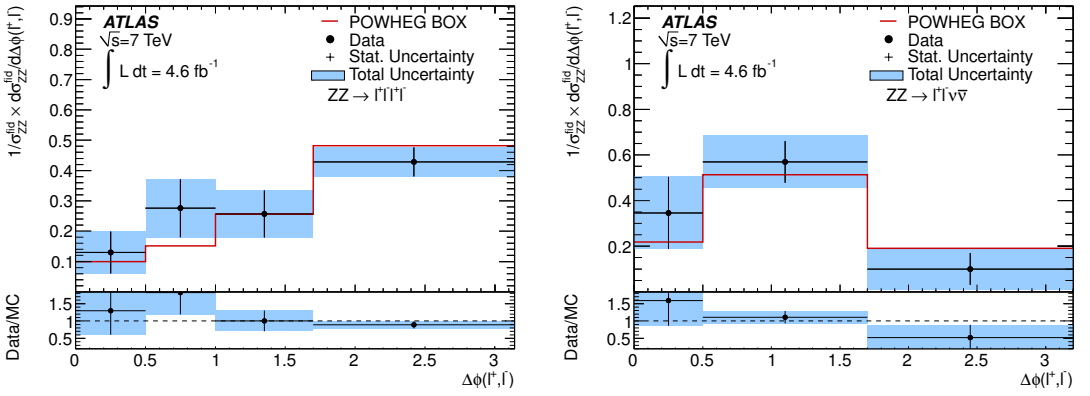
The differential cross sections present a more detailed comparison of theory to measurement, allowing a generic comparison of the kinematic distributions to new theories. Variables which are sensitive to new phenomena, such as p_{T}^{Z}, m^{ZZ} and $\Delta\phi(\ell^+,\ell^-)$, are used with bin boundaries chosen to maximize sensitivity to nTGCs. At the same time, the bin widths were chosen to be commensurate with the resolution.



The measured distributions are unfolded back to the underlying distributions, accounting for the effect of detector resolution, efficiency and acceptance, within the fiducial region of each measurement. The unfolding procedure is based on a Bayesian iterative algorithm [49]. The algorithm takes as input a prior for the kinematic distribution and iterates using the posterior distribution as prior for the next iteration. The initial prior is taken from the signal Monte Carlo expectation calculated using the PowhegBox generator and three iterations are performed. The uncertainty on the unfolded distributions is dominated by the statistical uncertainty, which is about 30% in most bins. The systematic uncertainty is no more than 5% in any bin. The dependence of the unfolded cross sections on the choice of the initial prior is tested by unfolding the measured distributions using a different generator (Sherpa). The difference between the two is taken as a systematic uncertainty to account for differences in generator modelling (e.g. QCD radiation). The difference in unfolded distributions between three iterations and four iterations is much lower than the statistical uncertainty and it is taken as a further uncertainty on the unfolding procedure. Systematic uncertainties related to detector effects (e.g. lepton reconstruction efficiency) are evaluated using pseudo-experiments.

Figures 8 to 10 show the differential cross sections normalized to the fiducial cross sections for the p_{T}^{Z} and $\Delta\phi(\ell^+,\ell^-)$ of the leading Z boson, and for the mass (transverse mass) of the ZZ system for the $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ ($ZZ \to \ell^+\ell^-\nu\bar{\nu}$) selection. The Standard Model prediction is consistent with the measurement in each case.

6.3 Anomalous neutral triple gauge couplings

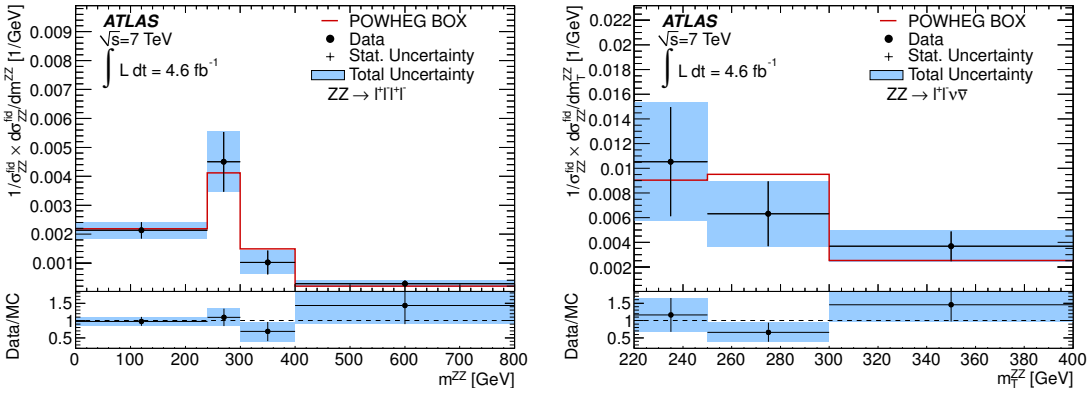


Anomalous nTGCs for on-shell ZZ production can be parameterized by two CP-violating (f_4^V) and two CP-conserving (f_5^V) complex parameters (where $V = Z, \gamma$) which are zero in the Standard Model [3]. A form-factor parameterization is introduced leading to couplings which vanish at high parton centre-of-mass energy $\sqrt{\hat{s}}$: $f_i^V = f_{i0}^V/(1+\hat{s}/\Lambda^2)^n$, ensuring partial-wave unitarity. Here, Λ is the energy scale at which physics beyond the Standard Model would be directly observable, f_{i0}^V are the low-energy approximations of the couplings, and n is the form-factor power. Values of $n = 3$ and $\Lambda = 3$ TeV are chosen, so that expected limits are within the values allowed by requiring that unitarity is not violated at LHC energies [3]. The results with an energy cutoff $\Lambda = \infty$ (i.e. without a form factor) are also presented as a comparison in the unitarity violating scheme.

JHEP03(2013)128

(a) (b)

Figure 8. Unfolded ZZ fiducial cross sections in bins of the p_{T} of the leading Z boson for (a) the $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ selection, where a discontinuity is indicated by the parallel pairs of lines, and (b) the $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ selection.



(a) (b)

Figure 9. Unfolded ZZ fiducial cross sections in bins of the $\Delta\phi(\ell^+, \ell^-)$ of the leading Z boson for (a) the $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ selection and (b) the $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ selection.

Limits on anomalous nTGCs are determined using the observed and expected numbers of $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ and $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ events binned[9] in p_{T}^Z, as seen in table 8. Figure 11 shows the observed p_{T}^Z distributions, together with the SM expectation and the predicted distributions for nTGC values close to the previous limits obtained by ATLAS [13]. Using an increased data sample compared with our previous measurement, including the $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ channel, and exploiting the differential event yields, the precision is expected to improve by about a factor of five. The dependency of the couplings on the expected number of events in each p_{T}^Z bin is parameterized using fully simulated events, generated with Sherpa [26], subsequently reweighted using the Baur-Rainwater [3, 50] and BHO [51] MC generators. The next-to-leading-order matrix elements with their nTGC dependence have been extracted from the BHO MC generator for $2 \to 5$ events and the Baur-Rainwater MC

[9]The raw (i.e. not unfolded) differential event yields are used, to avoid introducing theory dependence.

Table 8. Total background, expected signal and observed events as a function of the p_{T} of the leading Z for the $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ and $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ selections. For the expected signal and background events, the first uncertainty is statistical and the second is systematic.

generator for $2 \to 4$ events and introduced into a framework [52] that enables a calculation of the amplitude given the four vectors and the identity of the incoming and outgoing particles from the hard process.

Confidence intervals for the anomalous triple gauge couplings are determined using the maximum profile likelihood ratio. Limits are set on each coupling, assuming all of the other couplings are zero (as in the Standard Model), and on pairs of couplings assuming the remaining two couplings are zero. The profile likelihood ratio is calculated for the data, and also for 10000 pseudo-experiments generated using the expected number of events at each point in the one- or two-dimensional nTGC parameter space. A point is rejected if more than 95% of the pseudo-experiments have a larger profile likelihood ratio value than the one observed in data. The systematic errors are included as nuisance parameters.

(a) (b)

Figure 11. The leading Z boson transverse momentum distributions for (a) the $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ selection and (b) the $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ selection. The observed distributions are shown as filled circles, the SM expected signal and background are shown as filled histograms, and the predicted distributions for four different nTGC samples with form factor scales of $\Lambda = 3\,\text{TeV}$ and nTGC coupling values set near the edge of the exclusion set in the $1\,\text{fb}^{-1}$ analysis [13] are shown as dashed lines.

Λ	f_{40}^{γ}	f_{40}^{Z}	f_{50}^{γ}	f_{50}^{Z}
3 TeV	$[-0.022, 0.023]$	$[-0.019, 0.019]$	$[-0.023, 0.023]$	$[-0.020, 0.019]$
∞	$[-0.015, 0.015]$	$[-0.013, 0.013]$	$[-0.016, 0.015]$	$[-0.013, 0.013]$

Table 9. One-dimensional 95% confidence intervals for anomalous neutral gauge boson couplings, where the limit for each coupling assumes the other couplings are fixed at zero, their SM value. Limits are presented for form factor scales of $\Lambda = 3$ TeV and $\Lambda = \infty$ and include both statistical and systematic uncertainties; the statistical uncertainties are dominant.

The resulting limits for each coupling are listed in table 9. Two-dimensional 95% confidence intervals[10] are shown in figure 12. The one-dimensional limits are more stringent than those derived from measurements at LEP [8] and the Tevatron [9] and previously by ATLAS [13]; it should be noted that the limits from LEP do not use a form factor, and those from the Tevatron use $\Lambda = 1.2$ TeV. A comparison of the LHC limits with those derived from LEP and Tevatron is shown in figure 13.

7 Conclusions

A measurement of the $ZZ^{(*)}$ production cross section in LHC proton-proton collisions at $\sqrt{s} = 7\,\text{TeV}$ is presented with data collected by the ATLAS detector, using the $ZZ^{(*)} \to \ell^+\ell^-\ell'^+\ell'^-$ and $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ decay channels. Fiducial cross sections are measured for three production and decay selections, and the results are compatible with the SM expected cross sections. Using the $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ and $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ selections, the total ZZ

[10]Since most of the sensitivity of the measurement is contained in a single bin, the likelihood ratio used to obtain the two-dimensional limits has one effective degree of freedom.

JHEP03(2013)128

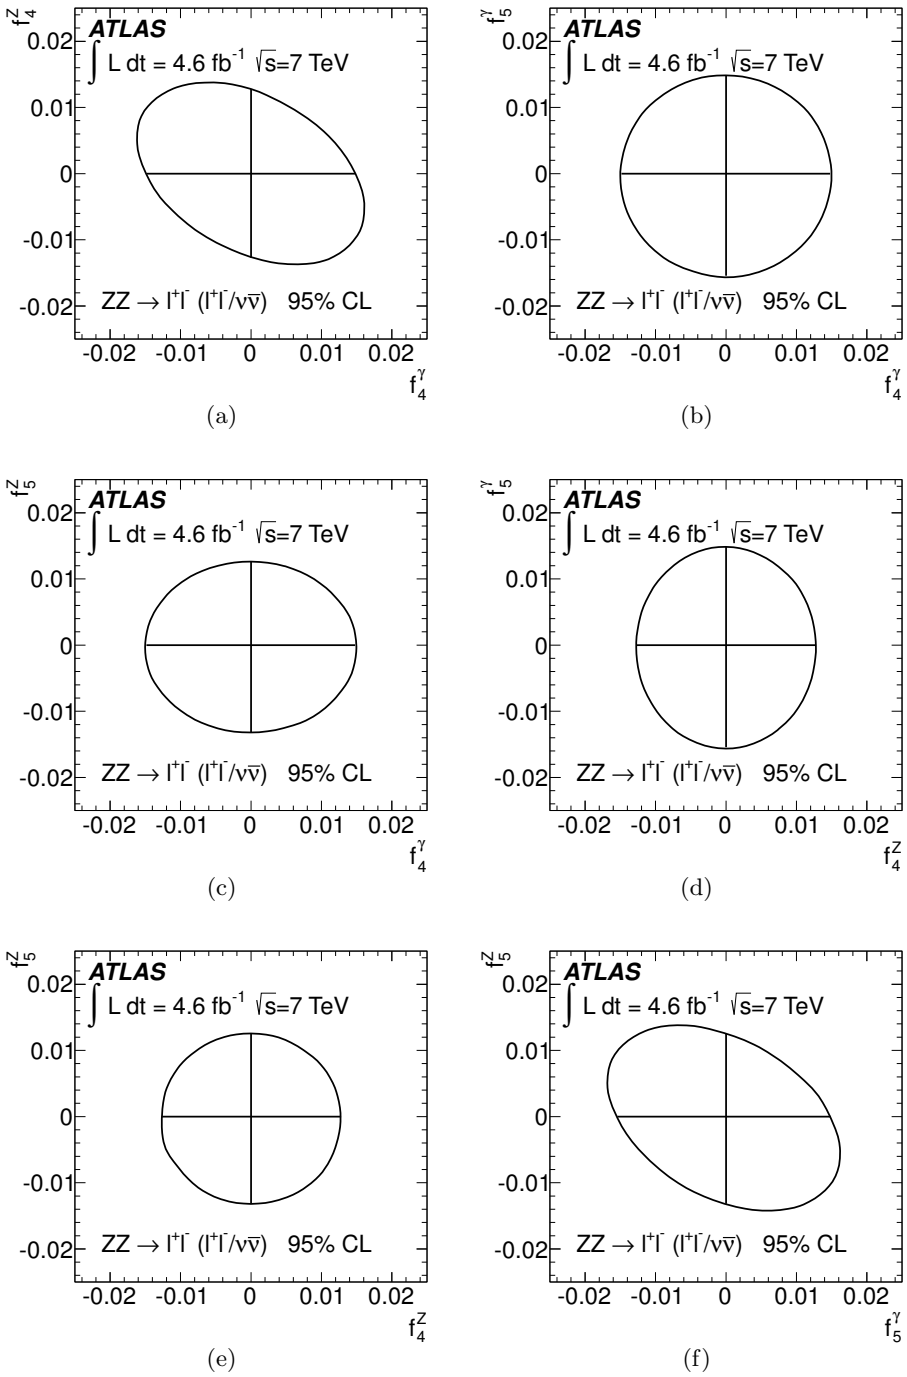

Figure 12. Two-dimensional triple gauge coupling limits for form factor scale $\Lambda = \infty$. The one-dimensional triple gauge coupling limits are shown as vertical and horizontal lines inside the two-dimensional ellipses, whose shape is determined by the theoretical correlations. For each two-dimensional limit the other TGC parameters are assumed to be zero. Since most of the sensitivity of the measurement is contained in a single bin, the likelihood ratio used to obtain the two-dimensional limits has one effective degree of freedom.

JHEP03(2013)128

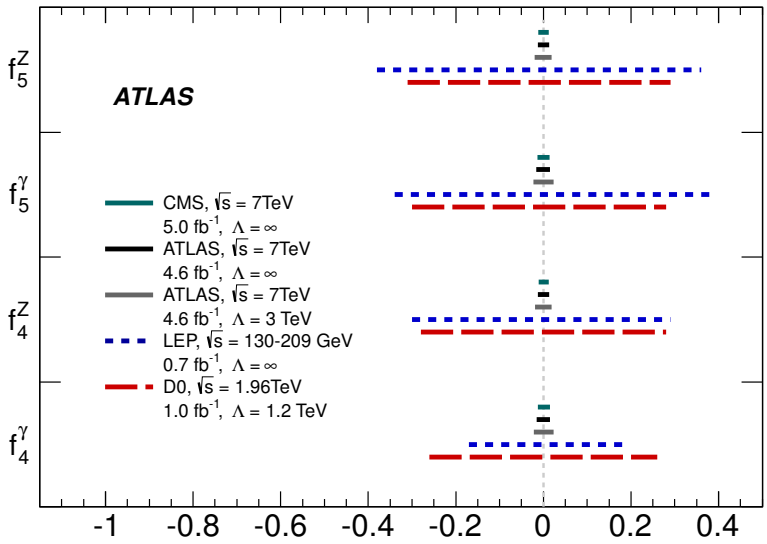

Figure 13. Anomalous nTGC 95% confidence intervals from ATLAS, LEP [8] and Tevatron [9] experiments. Luminosities, centre-of-mass energies and cut-offs Λ for each experiment are shown.

production cross section is determined to be:

$$\sigma_{ZZ}^{\text{tot}} = 6.7 \pm 0.7\ (\text{stat.})\ ^{+0.4}_{-0.3}\ (\text{syst.}) \pm 0.3\ (\text{lumi.})\ \text{pb}.$$

The result is statistically consistent with the NLO Standard Model prediction of $5.89^{+0.22}_{-0.18}$ pb, calculated with Z bosons with a mass between 66 and 116 GeV, and supersedes the previous measurements made with part of the same dataset [13]. Unfolded distributions of the fiducial cross sections are derived for the p_{T}^{Z} and $\Delta\phi(\ell^+,\ell^-)$ of the leading Z boson and for m^{ZZ} in the $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ selection and the m_{T} in the $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ selection.

The event yields as a function of the p_{T} of the leading Z boson for the $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ and $ZZ \to \ell^+\ell^-\nu\bar{\nu}$ selections are used to derive 95% confidence intervals for anomalous neutral triple gauge boson couplings. These limits are more stringent than those derived from measurements at LEP [8] and the Tevatron [9]. They improve the previous published results from ATLAS [13] by approximately a factor of five and supersede them.

Acknowledgments

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently.

計画研究 A04 班

課題名「トップクォークを用いた新しい素粒子現象の探索」

研究組織

(1)研究代表者
戸本 誠（TOMOTO, Makoto）
名古屋大学・大学院理学研究科・准教授
研究者番号：80432235

(2)研究分担者
寄田浩平（YORITA, Kohei）
早稲田大学・理工学術院・准教授
研究者番号： 60530590

長野邦浩（NAGANO, Kunihiro）
高エネルギー加速器研究機構・
素粒子原子核研究所・准教授
研究者番号： 90391705

(3)連携研究者
長坂康史（NAGASAKA, Yasushi）
広島工業大学・情報学部・教授
研究者番号： 20299655

下島真（SHIMOJIMA, Makoto）
長崎総合科学大学・情報学部・教授
研究者番号： 80302347

交付決定額

計画研究 A04 班に配分された交付額を表 1 に示す。

表 1. 交付決定額（配分額）　（金額単位：円）

年度	直接経費	間接経費	合計
平成 23 年度	22,600,000	6,780,000	29,380,000
平成 24 年度	20,100,000	6,030,000	26,130,000
平成 25 年度	19,600,000	5,880,000	25,480,000
平成 26 年度	18,500,000	5,550,000	24,050,000
平成 27 年度	18,500,000	5,550,000	24,050,000
総計	99,300,000	29,790,000	129,090,000

研究成果

1．研究開始当初の背景

（1）欧州 CERN の LHC 実験における研究は、ヒッグス粒子やテラスケール領域の新たな素粒子の直接発見を目指すと同時に、多量に生成される既知の素粒子の崩壊様式の中に現れる新粒子現象の探索にも挑戦する。LHC は年間 40 万(平成 23 年度)～8000 万(平成 27 年度)の t クォーク対事象生成能力（図 1）を誇る。世界最大の t クォーク工場実験で作られる t クォークの生成・崩壊によって、「直接的」に新しい素粒子を探索するとともに、生成断面積や崩壊分岐比、質量やスピンに代表される t クォークの固有な物理量の精密測定から「間接的」に新しい素粒子現象を発見することができるようになった。

（2）高エネルギー化、高輝度化が進む高エネルギー加速器実験において、更なる t クォーク研究へと展開させるため、膨大な背景事象の中から t クォーク事象を効率良く選択するトリガー系の開発が急務となる。最新の CMOS-VLSI 技術を駆使した高速プロセッサーや大容量メモリを搭載した高速飛跡再構成トリガー(FTK)回路は、数 10μ秒内に陽子・陽子衝突による全荷電粒子の飛跡再構成をハードウェア的に実現する。FTK 回路から共有される飛跡の生成点情報によって、t クォーク事象の特徴的な信号である b トリガー、つまり、t クォーク事象選別が可能となる。

2．研究の目的

（1）t クォーク対生成事象を緻密に研究し、高エネルギー領域における摂動 QCD モデルの有効性を探るとともに、標準模型からのズレの可能性を検証する。素粒子の「質量起源」や「世代構造」の解明に挑み、「真空構造」の理解へと繋げる。

① t クォーク対生成断面積を世界最高精度で測定する。

② t クォークの生成・崩壊の際に現れる粒子の運動量、方位角度、不変質量、電荷分布などの力学的物理量を詳細に測定し、t クォークの相互作用、結合などの観点から新粒子を探索する。新粒子が t クォーク生成・崩壊関与しているのであれば、その固有性をも明らかにする。

③ ttH 過程から t クォークとヒッグス粒子の湯川結合定数を測定する。

（2）FTK 回路の R&D 研究を推進する。本研究では、光ファイバを通して 40MHz の転送速度で送信されるシリコン検出器からのヒット情報を受信し、そのヒット情報をクラスタ化する Input Mezzanine（IM）ボードと呼ばれる回路の開発を行う。FTK トリガーのシミュレーションの構築や FTK トリガーの導入に伴う ATLAS トリガーシステムの改良研究を行い、b トリガー、つまり、t クォーク事象選別の可能性を模索する。

3．研究の方法

（1）LHC-ATLAS 実験は、2010 年から 2015 年までに重心系エネルギー7TeV（2010 年、2011 年）、8TeV（2012 年）、13TeV（2015 年）の陽子陽子衝突実験を行い、合計で約 30fb-1 の積分ルミノシティーのデータを蓄積した。本研究は、これらのデータを用いる。

t クォークの終状態は、t→Wb の W 粒子の崩壊様式（μ 粒子か電子とニュートリノ、τ 粒子と τ ニュートリノ、または、クォーク対）で特徴付けられ、2 荷電レプトン（両方の t クォークが電子または μ 粒子に崩壊する）、荷電レプトン＋ジェット（片方の t クォークは μ 粒子または電子に崩壊し、もう一方の t クォークはハドロンに崩壊する）、全ジェット（両方の t クォークがハドロンに崩壊する）、τ 粒子崩壊（どちらか片方の t クォークがタウ粒子に崩壊する）の 4 種類に分類される。t クォークに関する物理解析では、様々な終状態を用いて測定を行い、新物理の間接的な兆候をさぐる。

（2）FTK 回路の R&D 開発は、早稲田大学を中心に推進する。そのためのテストスタンドを早稲田大学に構築し、イタリアなどとの国際共同のもと FTK 回路の開発を行なう。

4．研究成果

（1）t クォークの精密測定では、研究目的に記した①から③に対応して、以下の研究成果を出し

た。

① t クォーク対生成断面積の精密測定では、7TeV の陽子陽子衝突データを用いて、t クォーク対事象の終状態のうち、2 レプトン事象、τ_{had}–レプトン事象、全ハドロン事象に対する世界最高精度の測定を主導した（図 1）。どの終状態を用いた断面積測定においても一致した結果を得た。荷電ヒッグス粒子に感度がある τ_{had}–レプトン事象でも新物理の兆候は得られなかった。8TeV と 13TeV の陽子陽子衝突実験では、最も測定精度のよい 2 レプトン事象に集中して、t クォーク対生成断面積を測定した。その結果、Tevatron 実験で測定した 2TeV の陽子反陽子衝突による t クォーク対生成から、本研究から出された 7TeV、8TeV 、13TeV の陽子陽子衝突による t クォーク対生成に至るまで、摂動 QCD が有効理論として正しく働いていることを示した（図 2）。

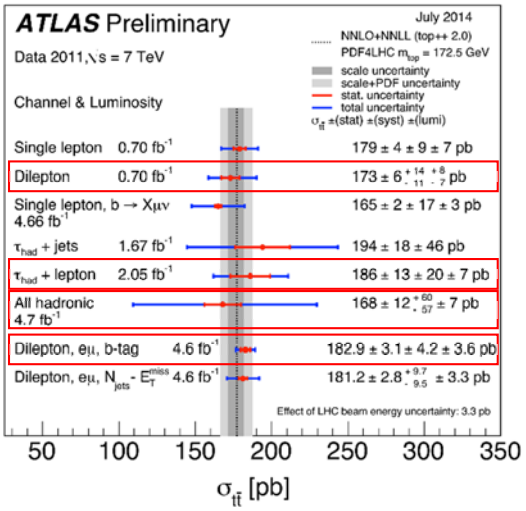

図 2：様々な終状態を用いて測定した重心系エネルギー7TeV の時の t クォーク対生成断面積の測定結果のまとめ。赤枠で示される結果は、特に本研究が主導して導出した結果である。

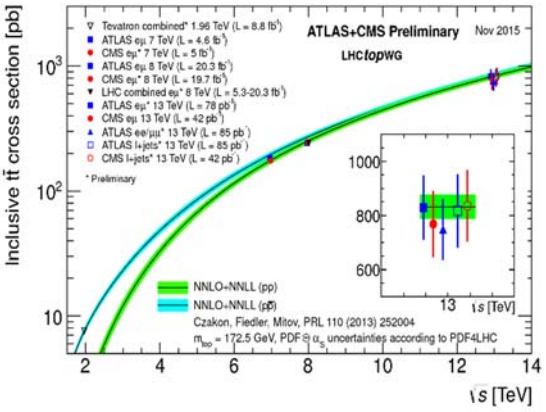

図 2：重心系エネルギーの関数とする t クォーク対生成断面積の測定結果。

② t→Wb 崩壊の W 粒子の偏極度測定では、t クォークから崩壊した荷電レプトンと b クォークの角度差を通じて、W 粒子の 3 種類の偏極度（F_L, F_0, F_R）を測定した。この結果から、V-A 型の弱い相互作用によって t クォークが崩壊する時の偏極度である $F_0 = 0.687 \pm 0.005$, $F_R =$

0.0017±0.0001（$F_L = 1 - F_0 - F_R$）と無矛盾であることを示した（図 3）。

③　LHC 実験による多量の t クォーク対生成事象数のおかげで、包含的 t クォーク対生成断面積

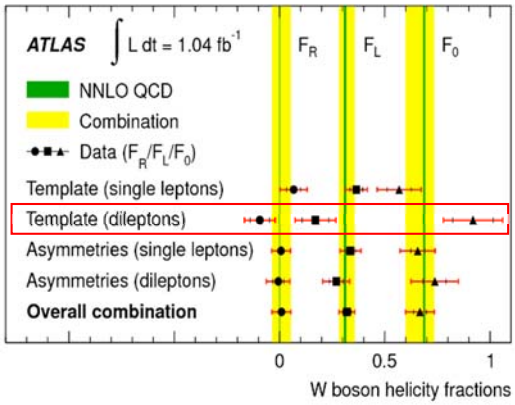

図 3：W 粒子偏極度測定のまとめ。本研究は、赤枠で示される 2 レプトン事象による測定を主導した。

測定の実験的精度は理論の予言能力を上回り始めた。そこで、t クォーク対の普遍質量や運動量、ラピディティーを関数とする t クォーク対生成微分断面積の測定や、t クォーク対に随伴して生成される粒子の種別ごとに終状態を分類する tt+X（X は、光子、W 粒子、Z 粒子、ジェットなど）断面積の測定などのより詳細な測定へと t クォーク物理を発展させている。

また、他の計画研究との連携を強化して④から⑥に示される研究成果を得た。

④　ヒッグス粒子の発見がされ、計画研究 A01 と連携して、ヒッグス粒子の t クォークとの随伴生成過程（ttH 過程）の生成断面積の測定を開始した。これにより、将来の LHC 実験において最重要課題の一つとなるヒッグス粒子と t クォークとの間の湯川結合の直接測定をこれから日本グループが主導することができる。

⑤　トップクォーク対生成事象の再構成は、W 粒子と b クォークの再構成が不可欠である。計画研究 A03 との共同研究によって、良質のトップクォーク対生成事象を取得した。

⑥　トップクォーク対生成事象は、ヒッグス粒子の測定や新物理探索における主なバックグラウンドとなる。例えば、ヒッグス粒子の発見の中で重要な終状態の一つであった pp→H+2 jets→WW+2 jets→$\ell\nu\ell\nu$+2 jets 過程（ℓ は電子または μ 粒子）の主な背景事象数の導出を本計画研究が行い、計画研究 A01 のヒッグス粒子発見に貢献した。同様に、計画研究 A02 の超対称性粒子や余剰次元粒子の探索においても、t クォークによる背景事象数の導出に本計画研究が大きく貢献した。

（2）FTK トリガーでは、IM 回路（図 4）の設計、プロトタイプ回路の製作、ATCA 規格で実装

されるマザーボードとの接続テストを早稲田大学が行った。さらに、FTK の回路要素を開発する世界中の大学・研究機関が CERN に集結して全回路要素を繋ぎ合わせる FTK 回路の統合テストを実施し、早稲田大学が開発する回路が量産要請を満たしていることを確認した。これらの成果によって、80 台の IM ボードの量産を開始し、本計画研究によって構築したテストスタンドを用いて、量産中に起きた諸問題のフィードバックを行い、量産を完遂することができた。一方で、シミュレーションの構築や FTK 導入による ATLAS トリガーシステムの改良研究など、ハードウェア・ソフトウェア双方で実質的な成果を上げることができた。

また、KEK の長野は、μ粒子、電子・光子、ジェットを主とする LHC-ATLAS 実験の全トリガーを統括し、興味ある物理事象の検出効率を高く保ったまま、トリガーレートを低く維持するアルゴリズムの開発を行った。その結果、t クォーク対生成事象の取得に用いるμ粒子トリガーや電子トリガーの運動量閾値を 25GeV 程度の低い値に保ち続けることに成功している。長野は LHC-ATLAS 実験の全トリガーの統括者として活躍している。

図 4：本研究で製作した最終版の IM ボード。

将来のハドロンコライダーにおいてトリガーは特に重要な開発要素であり、本計画研究によって FTK 回路を構築し、現在の LHC 実験のルミノシティーにて耐えられるトリガーを構築した。計画研究 A01、A03、A06 などの研究と合わせて、将来の実験の主要な実験開発要素をカバーすることができた。

最後に、本研究が進める世界最前線の研究を通じて、若手研究者の育成に貢献した。本研究で貢献した若手研究者の多くが国内外の大学・研究機関で別の職を得て異動している。また、名古屋大学、大阪大学、早稲田大学、総研大などから、t クォークの解析や FTK を主題として博士(理学)を取得し、国内外の大学・研究機関で研究者として活躍している。

Performance of the ATLAS muon trigger in pp collisions at $\sqrt{s} = 8$ TeV

ATLAS Collaboration[*]

CERN, 1211 Geneva 23, Switzerland

Received: 14 August 2014 / Accepted: 19 February 2015 / Published online: 13 March 2015
© CERN for the benefit of the ATLAS collaboration 2015. This article is published with open access at Springerlink.com

Abstract The performance of the ATLAS muon trigger system is evaluated with proton–proton collision data collected in 2012 at the Large Hadron Collider at a centre-of-mass energy of 8 TeV. It is primarily evaluated using events containing a pair of muons from the decay of Z bosons. The efficiency of the single-muon trigger is measured for muons with transverse momentum $25 < p_{\mathrm{T}} < 100$ GeV, with a statistical uncertainty of less than 0.01 % and a systematic uncertainty of 0.6 %. The p_{T} range for efficiency determination is extended by using muons from decays of J/ψ mesons, W bosons, and top quarks. The muon trigger shows highly uniform and stable performance. The performance is compared to the prediction of a detailed simulation.

1 Introduction

The presence of prompt muons in the final state is a distinctive signature for many physics processes studied in collisions of high energy protons at the LHC. These studies, which led to the discovery of the Higgs boson [1,2], include measurements of its properties, searches for new phenomena, as well as measurements of Standard Model processes, such as the production of electroweak bosons and top quarks. Therefore, a high-performance muon trigger is essential. In parallel, a good simulation of trigger performance is necessary.

There are many challenges in designing and implementing triggers which select pp interactions with muons in the final state with high efficiency and low transverse momentum, p_{T}, thresholds in the presence of high background conditions. The ATLAS design deploys a three-level, multi-pronged strategy with,

1. custom trigger electronics at Level-1,
2. dedicated fast algorithms to reconstruct muons and estimate their parameters at Level-2,
3. novel techniques to retain high efficiency at the event-filter while utilising offline tracking algorithms.

The Level-2 and event-filter together are called the High Level Trigger. In order to address a wide variety of physics topics, ATLAS has developed a suite of triggers designed to select muons. The single-muon trigger with p_{T} threshold of 24 GeV is used in many physics analyses. In addition, muon triggers in combination with electrons, jets and missing transverse momentum, as well as moderate-p_{T} multi-muon triggers, increase sensitivity for various physics topics which benefit from a lower p_{T} threshold. For the B-physics program, various low-p_{T} multi-muon triggers are used with a special configuration that allows a high efficiency also for non-prompt muons.[1]

The ATLAS experiment collected pp collision data in 2012 at a centre-of-mass energy of 8 TeV with a maximum instantaneous luminosity of 7.7×10^{33} cm^{-2} s^{-1}. The number of interactions occurring in the same bunch crossing (called pile-up interactions) was about 25 on average. In this paper, the performance of the ATLAS muon trigger is evaluated, primarily using samples containing muon pairs from Z-boson decays. The performance of the low-p_{T} muon trigger is evaluated with samples containing a pair of muons from the decay of J/ψ mesons. The performance for high-p_{T} muons is evaluated using events containing top-quarks[2] or W bosons, where a W boson decays into a muon and neutrino.

2 Muon trigger

2.1 ATLAS detector

The ATLAS detector is a multi-purpose particle physics apparatus with a forward–backward symmetric cylindrical

[*] e-mail: atlas.publications@cern.ch

[1] Non-prompt muons are muons which originate from the decay of a secondary particle rather than coming directly from the primary pp interaction.

[2] Unless otherwise stated CP conjugate states are always implied.

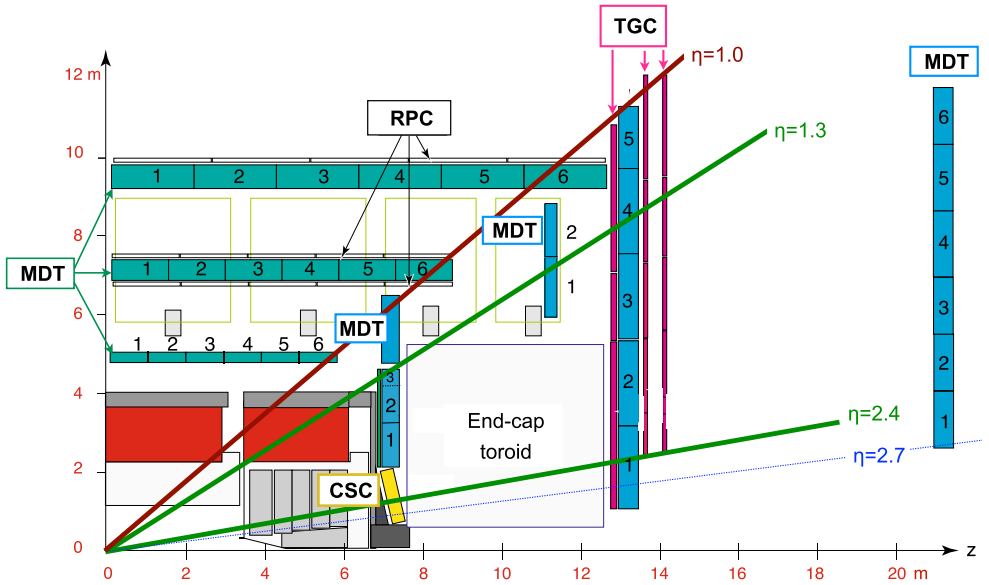

Fig. 1 A schematic picture showing a quarter-section of the muon system in a plane containing the beam axis, with monitored drift tube (MDT) and cathode strip (CSC) chambers for momentum determination and resistive plate (RPC) and thin gap (TGC) chambers for triggering

geometry and near 4π coverage in solid angle.[3] The detector consists of four major sub-systems: the inner detector, electromagnetic calorimeter, hadronic calorimeter and muon spectrometer. A detailed description of the ATLAS detector can be found in Ref. [3]. The inner detector measures tracks up to $|\eta| = 2.5$ in an axial magnetic field of 2 T using three types of sub-detectors: a silicon pixel detector closest to the interaction point, a semiconductor tracker surrounding the pixel detector, and a transition radiation straw tube tracker covering $|\eta| < 2.0$ as the outermost part of the inner detector. The calorimeter system covers the pseudorapidity range $|\eta| < 4.9$ and encloses the inner detector. The high-granularity liquid-argon electromagnetic sampling calorimeter is divided into one barrel ($|\eta| < 1.475$) and two endcap components ($1.375 < |\eta| < 3.2$). The hadronic calorimeter is placed directly outside the electromagnetic calorimeter. A steel/scintillator-tile calorimeter provides hadronic coverage in the range $|\eta| < 1.7$. The endcap and forward regions, spanning $1.5 < |\eta| < 4.9$, are instrumented with liquid-argon calorimeters. The calorimeters are then surrounded by the muon spectrometer.

2.2 Muon spectrometer

The muon spectrometer is based on three large air-core superconducting toroidal magnet systems (two endcaps and one barrel) providing an average magnetic field of approximately 0.5 T. Figure 1 shows a quarter-section of the muon system in a plane containing the beam axis.

In the central region, the detectors comprise a barrel that is arranged in three concentric cylindrical shells around the beam axis. In the endcap region, muon chambers form large wheels, perpendicular to the z-axis. Several detector technologies are utilised to provide both precision tracking and triggering.

The deflection of the muon trajectory in the magnetic field is detected using hits in three layers of precision monitored drift tube (MDT) chambers for $|\eta| < 2$. In the region $2.0 < |\eta| < 2.7$, two layers of MDT chambers in combination with one layer of cathode strip chambers (CSCs) are used. Muons are independently measured in the inner detector and in the muon spectrometer. Three layers of resistive plate chambers (RPCs) in the barrel region ($|\eta| < 1.05$), and three layers of thin gap chambers (TGCs) in the endcap regions ($1.05 < |\eta| < 2.4$) provide the Level-1 muon trigger.

2.3 Level-1 muon trigger

Muons are identified at Level-1 by the spatial and temporal coincidence of hits either in the RPCs or TGCs pointing to the beam interaction region [3,4]. The Level-1 triggers generated by hits in the RPC require a coincidence of hits in the three layers for the highest three p_T thresholds, and a coincidence

[3] ATLAS uses a right-handed coordinate system with its origin at the nominal interaction point (IP) in the centre of the detector and the z-axis along the beam pipe. The x-axis points from the IP to the centre of the LHC ring, and the y-axis points upward. Cylindrical coordinates (r, ϕ) are used in the transverse plane, ϕ being the azimuthal angle around the beam pipe. The pseudorapidity is defined in terms of the polar angle θ as $\eta = -\ln\tan(\theta/2)$.

of hits in two of the three layers for the rest of thresholds. The Level-1 triggers generated by hits in the TGC require a coincidence of hits in the three layers, except for limited areas in the lowest threshold.

The degree of deviation from the hit pattern expected for a muon with infinite momentum is used to estimate the p_{T} of the muon with six possible thresholds. The number of muon candidates passing each threshold is used in the conditions for the global Level-1 trigger. Following a global trigger, the p_{T} thresholds and the corresponding detector regions, region of interest (RoIs), are then sent to the Level-2 and event-filter for further consideration [3,4]. The typical dimensions of the RoIs are 0.1×0.1 (0.03×0.03) in $\Delta\eta \times \Delta\phi$ in the RPCs (TGCs) [3]. The geometric coverage of the Level-1 trigger is about 99 % in the endcap regions and about 80 % in the barrel region. The limited geometric coverage in the barrel region is due to gaps at around $\eta = 0$ (to provide space for services of the inner detector and calorimeters), the feet and rib support structures of the ATLAS detector and two small elevator shafts in the bottom part of the spectrometer.

2.4 Level-2 muon trigger

The RoI provided by Level-1 enables Level-2 to select the region of the muon detector in which the interesting features reside, therefore reducing the amount of data to be transferred and processed [4]. At Level-2, a track is constructed by adding the data from the MDT chambers to get a more precise estimate of the track parameters, leading to the Level-2 stand-alone-muon [5]. To achieve the needed resolution in sufficiently short time, the p_{T} of the Level-2 stand-alone-muon is reconstructed with simple parameterised functions. Then, the Level-2 stand-alone-muon is combined with a track found in the inner detector [5]. The closest inner detector track in the η and ϕ planes is selected as the best matching track. The p_{T} value is refined by taking the weighted average between that of the Level-2 stand-alone-muon and of the inner detector track, leading to the so called Level-2 combined-muon.

2.5 Event-filter muon trigger

Muons in the event-filter are found by two different procedures. The first focuses on RoIs defined by the Level-1 and Level-2 steps described above and is referred to as the RoI-based method. The second procedure searches the full detector without using the information from the previous levels and is referred to as the full-scan method.

In the RoI-based method, muon candidates are first formed by using the muon detectors (called event-filter stand-alone-muons), and are subsequently combined with inner detector tracks leading to event-filter combined-muons. If no combined-muon is formed, muon candidates are searched for by extrapolating inner detector tracks to the muon detectors. If there are corresponding track segments, combined-muons are formed. Additionally, the degree of isolation for the combined-muon is quantified by summing the p_{T} of inner detector tracks with $p_{\mathrm{T}}^{\mathrm{trk}} > 1\,\mathrm{GeV}$ found in a cone of $\Delta R = \sqrt{(\Delta\phi)^2 + (\Delta\eta)^2} < \Delta R_{\mathrm{cut}}$, centred around the muon candidate after subtracting the p_{T} of the muon itself ($\Sigma_{\Delta R < \Delta R_{\mathrm{cut}}} p_{\mathrm{T}}^{\mathrm{trk}}$).

The full-scan procedure is used in the event-filter to find additional muons that are not found by the RoI-based method. In the full-scan, muon candidates are first sought in the whole of the muon detectors, and then inner detector tracks are reconstructed in the whole of the inner detectors. Combined pairs of these inner detector and muon detector tracks form muon candidates called event-filter full-scan-muons.

2.6 Trigger selection criteria

The trigger system is configured to use a large set of selection criteria for each event. Each criterion consists of sequential selections at Level-1, Level-2 and the event-filter, and is referred to as trigger in this paper for simplicity. An event has to satisfy at least one of the triggers in order to be recorded.

Table 1 shows the Level-1 thresholds and the muon triggers discussed in this paper. For all trigger levels, the naming scheme typically follows a convention whereby the number that follows "mu" denotes the transverse momentum threshold and the letters, or combination of letters, characterize the muon type [isolated (i), stand alone (SA), found by full scan (FS)] and/or its origin.

The Level-1 thresholds were optimised to give an efficiency at the designated threshold that is typically 95 % of the maximum efficiency achieved well above the threshold.

The triggers described in Table 1 were designed to be as inclusive as possible.

The mu24i trigger is designed to collect isolated muons with $p_{\mathrm{T}} > 25\,\mathrm{GeV}$ with a loose isolation criterion of $\Sigma_{\Delta R<0.2} p_{\mathrm{T}}^{\mathrm{trk}} / p_{\mathrm{T}} < 0.12$. The isolation criterion was chosen to retain nearly 100 % efficiency for well isolated muons from the decays of Z-bosons while rejecting slightly over half of the muons from heavy flavor, pion and kaon decays.

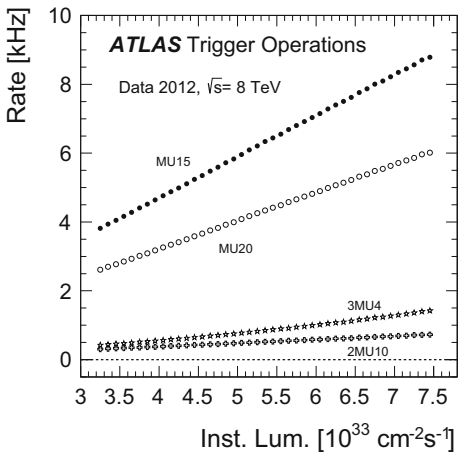
The mu36 trigger is designed to collect muons with large p_{T} without making an isolation requirement.

The mu40_SA_barrel trigger is designed to recover possible inefficiency due to muon spectrometer and inner detector combination at large p_{T}, and the decision is based only on muon spectrometer reconstruction. It was active only in the barrel region due to its high rate in the endcaps.

The mu24i, mu36 and mu40_SA_barrel triggers were used without prescale[4] for the 2012 data taking.

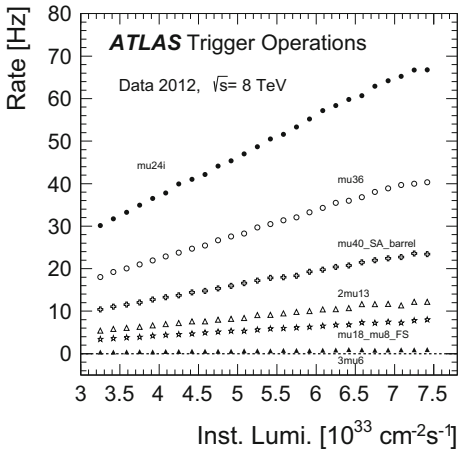
[4] The term prescale means that only one in N events passing the trigger is accepted at that trigger level, where N is an integer definite number

Table 1 Level-1 p_{T} thresholds and muon triggers. The sequence shows the requirements at Level-1, in the event-filter or at higher level trigger which then includes Level-2. The requirements at Level-2 are omitted for the single- and multi-muon triggers, as they are looser than those in the event-filter. The applied p_{T} and isolation requirements are also shown



Level-1	p_{T} threshold (GeV)	Number of layers in coincidence	
MU4	4	2 (3 in limited areas in the endcap region)	
MU6	6	2 (3 in the endcap region)	
MU10	10	2 (3 in the endcap region)	
MU11	10	3	
MU15	15	3	
MU20	20	3	
Single muon trigger	**Level-1**	**Event-filter**	
mu6	MU6	One or more combined-muon with $p_{\mathrm{T}} > 6$ GeV	
mu13	MU10	One or more combined-muon with $p_{\mathrm{T}} > 13$ GeV	
mu18	MU15	One or more combined-muon with $p_{\mathrm{T}} > 18$ GeV	
mu24i	MU15	One or more combined-muon with $p_{\mathrm{T}} > 24$ GeV and $\Sigma_{\Delta R<0.2} p_{\mathrm{T}}^{\mathrm{trk}}/p_{\mathrm{T}} < 0.12$	
mu36	MU15	One or more combined-muon with $p_{\mathrm{T}} > 36$ GeV	
mu40_SA_barrel	MU15	One or more stand-alone-muon with $p_{\mathrm{T}} > 40$ GeV in $\lvert\eta\rvert < 1.05$	
Multi muon trigger	**Level-1**	**Event-filter**	
2mu13	Two MU10	Two or more combined-muons with $p_{\mathrm{T}} > 13$ GeV (two or more mu13 triggers)	
mu18_mu8_FS	MU15	One or more combined-muon with $p_{\mathrm{T}} > 18$ GeV (mu18 trigger), and two or more full-scan muons with $p_{\mathrm{T}} > 18$ and > 8 GeV	
3mu6	Three MU6	Three or more muons with $p_{\mathrm{T}} > 6$ GeV (three or more mu6 triggers)	
J/ψ tag-and-probe trigger	Level-1	High level trigger	
mu18_J/ψ_FS	MU15	(Level-2)	One or more combined-muon with $p_{\mathrm{T}} > 18$ GeV
		(Event-filter)	One or more combined-muon with $p_{\mathrm{T}} > 18$ GeV, and at least one pair of combined-muons with a mass consistent with that of J/ψ
mu18_J/ψ_L2	MU15, MU4	(Level-2)	Two or more combined-muons with $p_{\mathrm{T}} > 18, 4$ GeV, and at least one pair of combined-muons with a mass consistent with that of J/ψ
		(Event-filter)	One or more combined-muon with $p_{\mathrm{T}} > 18$ GeV

The 2mu13 trigger requires two or more muon candidates, each of which passes the single-muon trigger mu13. The mu18_mu8_FS trigger requires at least one muon candidate which passes the single-muon trigger mu18, and subsequently employs the full-scan algorithm at the event-filter to find two or more muon candidates with $p_{\mathrm{T}} > 18$ and $p_{\mathrm{T}} > 8$ GeV for leading and sub-leading muons, respectively. The full-scan trigger processes the entire detector and utilises more computing resources than the triggers which process only data in one RoI. Computing resources, not bandwidth, is the limiting factor for these triggers. The leading muon was required to have a p_{T} of at least 18 GeV in the full-scan dimuon triggers for this reason. The 3mu6 trigger requires three or more muon candidates, each of which passes the single-muon trigger mu6. The 2mu13, mu18_mu8_FS and 3mu6 triggers were used without prescale for the 2012 data taking. The dimuon triggers used to select J/ψ decays will be discussed in more detail in Sect. 7.



2.7 Operation in the 2012 data taking

The typical maximum Level-1 rate was 70 kHz. The event acceptance was reduced at the event-filter which had an output rate of 700 Hz on average (with peaks of about 1 kHz). Of these rates, the single isolated muon trigger mu24i was fired at about 8.5 kHz at Level-1 and at about 65 Hz at the event-filter for an instantaneous luminosity of $7 \times 10^{33}\,\mathrm{cm}^{-2}\,\mathrm{s}^{-1}$. Figure 2 shows the rates of the single- and multi-muon triggers as a function of the instantaneous luminosity, separately for the Level-1 and for the event-filter.

Footnote4 continued
called the prescale factor. At Level-1 every Nth event is accepted. At the high level trigger a random number generator is utilised such that one out of every N events is accepted.

(a)

(b)

Fig. 2 Trigger rates as a function of instantaneous luminosity **a** for selected muon triggers at Level-1 and **b** for selected single- and multi-muon triggers at the event-filter as denoted in the legend (see Table 1 for details)

They are well described by a linear fit with an approximately zero intercept. This indicates a negligible contribution from effects not related to pp collisions. Typically the trigger rates were reduced by one to two orders of magnitude at Level-2 and by a factor of a few at the event-filter for the single and dimuon triggers. For example the rates were reduced by a factor of 28 at Level-2 (with respect to Level-1) and by a factor of 4.6 at the event-filter (with respect to Level-2) for the mu24i trigger. For the 2mu13 trigger, the rates were reduced by a factor of 71 at Level-2 and by a factor of 1.2 at the event-filter.

During data taking, the performance of the muon trigger was monitored in two stages. For quick online checks during data taking, the coverage in η–ϕ space and the distributions of some kinematic variables were produced by the high level trigger algorithms. A more detailed analysis was performed by calculating efficiencies of triggers during the reconstruction stage of the data processing.

3 Data samples and event selection

Several methods are used to measure the muon trigger performance. This section describes the selection requirements used to define the samples needed for the various methods.

3.1 Methods to measure trigger performance

The tag-and-probe method relies on a pair of muons. If one muon has caused the trigger to record the event (called the tag-muon), the other muon serves as a probe (called the probe-muon) to measure the trigger performance without any bias. This method was applied to dimuon decays of Z-boson and J/ψ meson candidates. Alternatively, muons contained in events that were recorded by triggers other than the muon trigger can be used as an unbiased sample to evaluate the efficiency of triggering on muons. This method was applied to events with muons from W-boson decays, either from top-quark or $W+$jets production. A trigger based on the missing transverse momentum, as measured with the calorimeter, was used to collect such samples.

Among these four samples, the tag-and-probe method using Z decays provides the most precise determination of the efficiency over a wide range of muon p_{T} ($10 \lesssim p_{\mathrm{T}} \lesssim 100\,\mathrm{GeV}$). The tag-and-probe method using J/ψ decays provides a coverage for lower p_{T} of the muon ($p_{\mathrm{T}} \lesssim 10\,\mathrm{GeV}$). Muons from Z decays are not frequently found to have $p_{\mathrm{T}} \gtrsim 100\,\mathrm{GeV}$. Events with muons from top-quark and $W+$jets production provide supplemental coverage at very high p_{T} ($p_{\mathrm{T}} \gtrsim 100\,\mathrm{GeV}$). The muons from top-quark decays tend to have a slightly larger p_{T} than those from the Z decays due to the larger mass of the top-quark. In the $W+$jet events, the W may recoil off of one or more high p_{T} jets. These higher p_{T} W-bosons can then decay into muons with very high p_{T}. In addition, top-quark events and $W+$jet events offer important cross-checks in the overlapping p_{T} region that is also covered by the tag-and-probe method using Z decays.

3.2 Data and Monte Carlo samples

Data were considered if recorded under stable beam conditions and with all relevant sub-detector systems fully operational.

The trigger performance observed in the data is compared with the ATLAS Monte Carlo (MC) simulation, which is the same as used for physics analysis. The generated samples were then processed through a simulation of the ATLAS detector based on GEANT4 [6,7]. The environmental backgrounds due to radiation were not simulated. The simulated events are overlaid with additional minimum-bias events generated with PYTHIA 8 [8] to account for the effect of pile-up interactions.

A sample of Z-boson production was generated using POWHEG- BOX [9] interfaced to PYTHIA 8 [10]. A sample of the production of J/ψ mesons decaying to muon pairs was generated using PYTHIA 8, requiring at least two muons in the final state having $p_{\mathrm{T}} > 15$ and 2.5 GeV. Similarly to the Z-boson production sample, a sample of top and antitop quark pair ($t\bar{t}$) events was generated using POWHEG- BOX interfaced to PYTHIA 8. Samples of single top-quark events were generated using ACERMC [11] interfaced to PYTHIA 8 for the t-channel production, and using POWHEG- BOX interfaced to PYTHIA 8 for the s- and Wt-channel production. Samples of W boson production were generated using ALPGEN [12] interfaced to PYTHIA 8. Samples of dijet events are used for background estimation, and were generated using PYTHIA 8.

3.3 Offline reconstruction

The offline reconstructed muons are obtained by matching tracks found in the muon spectrometer with those in the inner detector [13]. Muons are required to pass various cuts to ensure a high quality inner detector track and to be in a fiducial region of $|\eta| < 2.5$. The muon momentum is calibrated by comparing the dimuon mass of Z boson candidates measured in data and MC [13].

The identification and reconstruction of the electrons, jets, jets containing B-hadrons (called b-jets), and missing transverse momentum ($E_{\mathrm{T}}^{\mathrm{miss}}$) are necessary for the efficiency measurement with top-quark and W-boson candidates.

Electron candidates [14,15] are required to satisfy $E_{\mathrm{T}}^{\mathrm{el}} > 25$ GeV and $|\eta^{\mathrm{el}}| < 2.47$ excluding $1.37 < |\eta^{\mathrm{el}}| < 1.52$, where $E_{\mathrm{T}}^{\mathrm{el}}$ is the transverse energy, and η^{el} is the pseudorapidity of the electromagnetic cluster of energy deposits in the calorimeter. Candidates are required to be isolated by means of calorimeter- and track-based isolation parameters [16].

Jets are reconstructed using the anti-k_t jet clustering [17] algorithm with a radius parameter $R = 0.4$, running on three-dimensional clusters of cells with significant calorimeter response [18]. Their energies have object-based corrections applied as well as corrections for upstream material, non-instrumented material, and sampling fraction. Jets are required to satisfy $p_{\mathrm{T}}^{\mathrm{jet}} > 25$ GeV and $|\eta^{\mathrm{jet}}| < 2.5$, where $p_{\mathrm{T}}^{\mathrm{jet}}$ is the transverse momentum, and η^{jet} is the pseudo-rapidity of the jet. Duplication between electron and jet objects is avoided by removing the jet closest to an electron if their separation is $\Delta R < 0.2$.

The b-jets are identified among the reconstructed jets with an artificial neural network using variables that exploit the impact parameter, the secondary vertex and the topology of b- and c-hadron weak decays [19]. An identification criterion with 70 % efficiency is chosen, as evaluated on jets in a simulated $t\bar{t}$ sample with $p_{\mathrm{T}} > 20 GeV$ and $|\eta| < 2.5$.

Hadronically decaying taus are reconstructed using clusters in the electromagnetic and hadronic calorimeter [3]. A Boosted Decision Tree tau identification method is used to select candiates with a 55–60 % efficiency. Tau candidates are required to have a charge ± 1 and only one or three tracks in a cone of radius $\Delta R < 0.2$.

Photons are identified by electromagnetic cluster of energy deposits in the calorimeter similar to electron identification [20]. In the case of photons, isolated electromagnetic clusters without matching tracks are classified as unconverted photon candidates. Clusters matched to a pair of tracks that are consistent with the hypothesis of a $\gamma \to e^+e^-$ conversion process are classified as converted photon candidates.

The $E_{\mathrm{T}}^{\mathrm{miss}}$ is calculated using the reconstructed jets, electrons, muons, τ leptons, photons, as well as calorimeter energy clusters not associated with these physics objects [21].

In this paper, reconstructed objects (using algorithms applied after the event is recorded) are distinguished from trigger objects (formed either at Level-1, Level-2, or the event-filter during the fast online reconstruction of the event).

3.4 Event selection for the Z-boson sample

For the selection of the Z-boson sample, events are required to pass either the isolated single-muon trigger mu24i or the single-muon trigger mu36.

A pair of oppositely charged muons with invariant mass, $m_{\mu\mu}$, consistent with the mass of the Z boson, $|m_Z - m_{\mu\mu}| < 10$ GeV, is required. The two muons are required to originate from the same interaction vertex. If one of the two muons has $p_{\mathrm{T}} > 25$ GeV and is isolated, $\Sigma_{\Delta R<0.2} p_{\mathrm{T}}^{\mathrm{trk}}/p_{\mathrm{T}} < 0.1$, it is a candidate for the tag-muon, and the other muon is a candidate for the corresponding probe-muon. From a pair of muons, two candidate tag- and probe-muons are allowed. Furthermore, the tag-muon candidate must have an angular distance of $\Delta R < 0.1$ to an event-filter combined-muon that passes either the mu24i or mu36 trigger. In addition, the probe-muon candidate has to be isolated, $\Sigma_{\Delta R<0.2} p_{\mathrm{T}}^{\mathrm{trk}}/p_{\mathrm{T}} < 0.1$.

The probe-muon is matched to a trigger object if it lies within a distance $\Delta R < 0.1$ from an event-filter combined-muon and $\Delta R < 0.5$ from a Level-1 trigger object. The trigger efficiency is defined as the fraction of probe-muons that are associated with at least one trigger muon-object after applying the above criteria.

3.5 Event selection for the J/ψ meson sample

Due to rate restrictions, samples of J/ψ candidates were selected using the two dedicated triggers as in Table 1. One trigger requires a pair of muons found by the event-filter full-scan with a mass consistent with that of the J/ψ, with at least one muon with $p_{\mathrm{T}} > 18$ GeV. It is used to determine the

efficiency at Level-1 and Level-2. The other trigger requires a pair of muons found by Level-1 and Level-2 with the same requirements as above. It is used to determine the efficiency at the event level with respect to the Level-1 and Level-2. Then the total efficiency can be obtained by multiplying these two partial efficiencies.

All combinations of oppositely charged offline muons are considered as J/ψ candidates if each of the muon tracks satisfies $|d_0| < 0.2\,\text{mm}$, where d_0 is the distance of closest approach between the inner detector track and the proton–proton interaction in the plane transverse to the beam. The two inner detector tracks that are associated with the two muon tracks are refitted under the assumption that they originate from the same vertex. The invariant mass constructed from the refitted tracks, $m_{\mu\mu}$, is required to be consistent with the J/ψ mass, $|m_{J/\psi} - m_{\mu\mu}| < 0.3\,\text{GeV}$. To enhance the fraction of muons originating from a J/ψ decay a further requirement is made on L_{xy} , the signed two-dimensional decay length of the J/ψ. The variable L_{xy} is defined as $L_{xy} \equiv \mathbf{L} \cdot \mathbf{p_T^{J/\psi}}/p_T^{J/\psi}$ with $\mathbf{L}$ being the vector originating from the proton–proton interaction vertex. A requirement of $L_{xy} < 1$ mm is made on the muons. The requirements on d_0 and L_{xy} are used to suppress non-prompt muons, such as those from the decays of B-hadrons [22].

The fact that these two dedicated triggers were used to select J/ψ candidates implies that the J/ψ mesons are boosted and therefore the spacial distance between the two muons from the decays is small. To ensure correct one-to-one matching between trigger and offline muons, the distance between them is gauged by the separation of the impact points of the tracks at the locations of the RPC and TGC detectors after extrapolation based on the refitted inner detector track parameters. If one of the two muons has $p_T > 18\,\text{GeV}$ and its distance from an event-filter combined-muon that passes the mu18 trigger is within $\Delta R < 0.08$, as evaluated by using the extrapolated positions, it is considered as a tag-muon. If the other muon is beyond the distance of $\Delta R > 0.2$ from the tag-muon, at the extrapolated positions, it is regarded as a probe-muon. The ΔR cut value is sufficiently large compared to the typical dimensions of the Level-1 trigger segmentation, as described in Sect. 2.3. A probe-muon is matched to trigger objects, if it is within $\Delta R < 0.12$ from a Level-1 muon object and an event-filter combined-muon.

3.6 Selection of top quark and W + jets candidate events

The top quark and W + jets candidate events have to pass a trigger that requires $E_T^{\text{miss}}(\text{calo}) > 80\,\text{GeV}$, where $E_T^{\text{miss}}(\text{calo})$ is the magnitude of the missing transverse momentum as measured using only the calorimeter information. Several additional cuts are then imposed to remove events with noise bursts in the calorimeters and those with cosmic-ray showers.

The muon candidate is required to have $p_T > 40\,\text{GeV}$ and $|z_0| < 2\,\text{mm}$, where z_0 is the track impact parameter in the z-direction with respect to the proton–proton interaction vertex. The probe-muon is required to be isolated from neighbouring jets and energy depositions in the calorimeter. Probe-muons are required to satisfy $\Sigma_{\Delta R<0.3} p_T^{\text{trk}}/p_T < 0.05$ and $\Delta R_{\text{min}}(\text{jet, muon}) > 0.4$, where $\Delta R_{\text{min}}(\text{jet, muon})$ is the minimum distance between the muon and any jet. In addition, no other muon with $p_T > 25\,\text{GeV}$ is allowed.

Events are further required to have $E_T^{\text{miss}} > 20\,\text{GeV}$ and $m_T^W + E_T^{\text{miss}} > 60\,\text{GeV}$, where m_T^W is the transverse mass[5] of the W candidate. The W is reconstructed with four-vectors of the E_T^{miss} and the muon.

For the top quark sample, there must be at least three jets with at least one b-jet. For the W sample, there must be one or two jets with no b-jets. Events with an electron are rejected.

4 Trigger purity

The trigger purity is defined as the fraction of muon triggers that can be associated to an offline muon. The ΔR distance between the trigger object and the offline muon was used to define this matching.

The η distribution of the Level-1 MU15 object that seeds the mu24i event-filter is shown in Fig. 3a for all triggers and for those associated with a reconstructed offline muon. No explicit cut on offline muon p_T was applied in the association between trigger and offline objects. Figure 3 shows that the Level-1 rate is dominated by triggers without associated offline muons (called fake triggers). The overall trigger purity (fraction of Level-1 rate from true muons) is 40 %. Most of the Level-1 fakes originates in the end-cap. The cause of these fakes in the endcap region was extensively investigated [23], and is understood as mainly due to charged particles, for instance protons, produced in large amounts of dense material such as the toroid coils and shields. Figure 3b shows the MU15 trigger rate as a function of the instantaneous luminosity. Also shown is the rate due to fake triggers. The error bars show statistical uncertainties only. Both the total rate and the fake rate at Level-1 scale linearly with the instantaneous luminosity.

Figure 4a shows the η distribution of the trigger objects recorded with the isolated single-muon trigger at the event-filter. The fake triggers, not associated to an offline reconstructed muon, are rejected by the subsequent High-Level-

[5] Transverse mass is defined as $m_T^2 = m^2 + p_x^2 + p_y^2$ and has the useful propriety that it is invariant under Lorentz boosts along the beam direction.

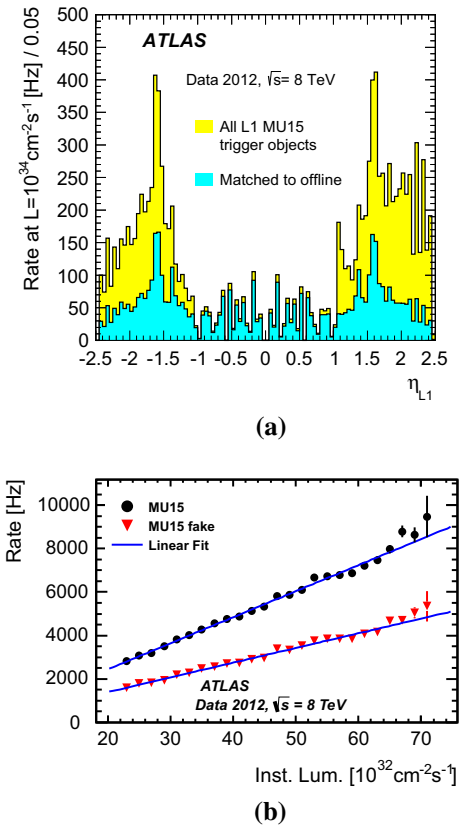


Fig. 3 Trigger rate of the Level-1 MU15 as a function of **a** pseudo-rapidity η_{L_1} of all the trigger objects (*light histogram*) and of the ones associated with offline reconstructed muons (*dark histogram*) and **b** instantaneous luminosity, for all triggers (*dots*) and for the fake ones not-associated with offline-reconstructed muons (*triangles*) with the *lines* representing the results of the corresponding linear fits

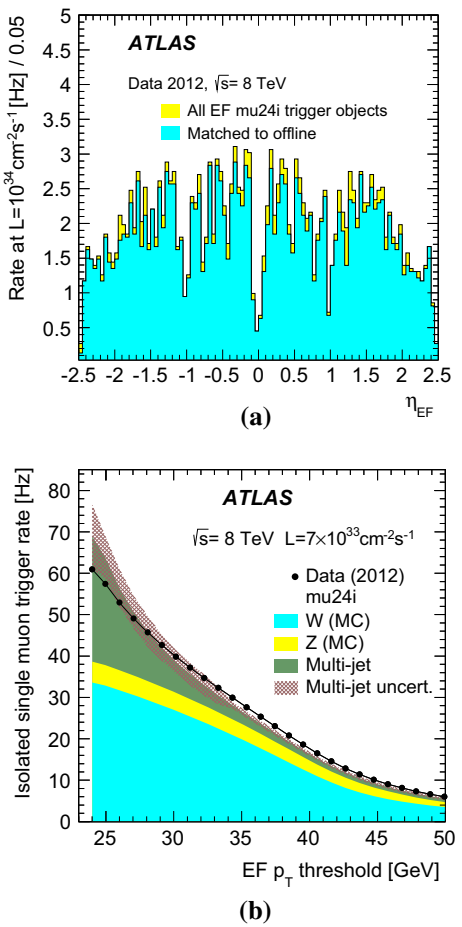

Fig. 4 Rate of the isolated single-muon trigger, mu24i, at the event-filter **a** as a function of pseudorapidity η_{EF} for all combined-muons (*light histogram*) and for the ones associated with offline reconstructed muons (*dark histogram*), **b** as a function of the transverse momentum p_T threshold at the event-filter (EF) at an instantaneous luminosity of $7 \times 10^{33}\,\mathrm{cm}^{-2}\,\mathrm{s}^{-1}$, for combined-muons in the data (*dots*) compared to the expectations from W- and Z-bosons production and from the data-driven estimate for multi-jet production, as described in the legend

Trigger decisions, and a purity of about 90 % is achieved. The physics origin of muons at the event-filter is illustrated in Fig. 4b, which shows the expected composition of the trigger rate of the isolated single-muon as a function of the lower threshold value on the muon p_T. The vertical scale gives the trigger rate as a function of p_T at an instantaneous luminosity of $7 \times 10^{33}\,\mathrm{cm}^{-2}\,\mathrm{s}^{-1}$. The expectations for W and Z production were evaluated by using MC simulations with their predicted cross sections. Multi-jet production, where one or more jets produce a muon from the decay of a heavy quark or from a pion or kaon decay in flight, also contribute to this rate. The multi-jet contribution was evaluated in a data-driven approach as described below.

A multi-jet enriched control-region is obtained by using events that are triggered by a single-muon trigger with the same p_T threshold but without isolation requirement.[6] The control-region is defined by inverting the trigger isolation criteria, by requiring at least one jet in an event, and by requiring matching to an offline muon to remove the fake contribution. The multi-jet contribution in the signal region is estimated by the following procedure. The fraction of multi-jet events in the signal region is taken from dijet MC simulation. The total normalization for the multi-jet contribution is then evaluated in the control-region. The contribution to the signal region is then taken as the total estimated multi-jet contribution weighed by the signal fraction from simulation. The uncertainty of this estimation is dominated by the statistical uncertainty in the control-region/signal-region transfer factors from MC simulation, and is shown in Fig. 4b. The rate was evaluated as a function of the p_T threshold on the event-filter combined-muon. As shown in Fig. 4b, at $p_T = 24\,\mathrm{GeV}$ about 60 % of the events triggered by mu24i are due to muons from W and Z production.

[6] This trigger was active but with a prescale factor of 10.

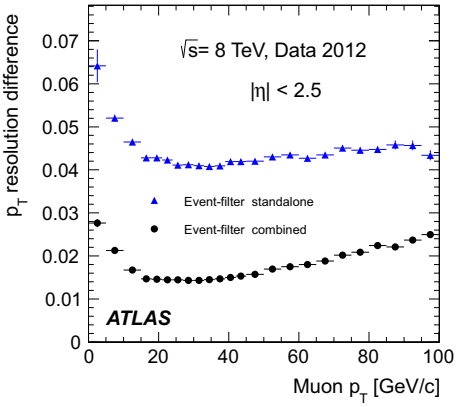

Fig. 5 Resolution difference in transverse momentum p_{T} determination in the offline and in the event-filter reconstruction, as a function of p_{T} of the offline muon

5 Resolution

The tag-and-probe method applied to Z-boson candidates was used to evaluate the quality of the p_{T}, η and ϕ determination at the event-filter, compared to the offline reconstruction. The online algorithms are nearly identical to the offline versions but have some simplifications in the pattern recognition because of timing constraints. Additionally, the offline reconstruction uses updated calibration and alignment corrections not available at the time the data was recorded. Therefore, finite difference can be expected even when the event-filter combined muon is compared with the offline muon that is also reconstructed by combining the inner detector and muon detectors.

The offline momentum resolution is < 3.5 % up to transverse momenta p_T of 200 GeV and < 10 % up to 1 TeV [24]. The residual of the trigger-reconstructed p_{T} with respect to the offline value is defined as $\delta_{p_{\mathrm{T}}} = \frac{1/p_T^{\mathrm{trigger}} - 1/p_{\mathrm{T}}}{1/p_{\mathrm{T}}}$, where p_T^{trigger} is the transverse momentum reconstructed by the trigger, and the p_{T} is that of the offline muon. The resolution difference between the trigger and offline reconstruction was defined as the standard deviation of a Gaussian function fitted to the $\delta_{p_{\mathrm{T}}}$ distribution. Figure 5 shows the p_{T} resolution differences, as a function of the offline muon p_{T}, of the event-filter stand-alone and event-filter combined muons in the barrel and endcap regions. The p_{T} resolution difference is about 2 and 5 % for event-filter combined and event-filter stand-alone muon, respectively.

The resolution differences of the η and ϕ determination were examined similarly by defining the residual as the absolute value of the difference between the trigger and offline reconstructed values. Figure 6 shows the η and ϕ resolution differences of the event-filter muons. It shows that the trigger–offline matching criterion used in the efficiency measurements, for instance $\Delta R < 0.1$ for the tag-and-probe method using Z bosons (see Sect. 3.4), is sufficiently loose.

6 Efficiency measurements with Z boson candidates

In the next several sections, measurements of the efficiency of the muon trigger in different kinematic regions are presented, preceded by a discussion of systematic uncertainties. The efficiency is primarily measured as a function of muon p_{T}. In addition, the efficiency is measured in two-dimensions, for instance in η and ϕ bins, and compared to the simulated one. To more accurately model data, all ATLAS physics analysis which use events selected with the muon trigger are provided with the ratios of measured to simulated efficiencies to make small corrections to the simulated samples.

6.1 Systematic uncertainty

In the following, sources of systematic uncertainty are discussed and the quoted uncertainty values are presented for the efficiency measured in the region of $25 < p_{\mathrm{T}} < 100$ GeV.

– Dependence on pile-up interactions:
the efficiency was measured as a function of the number of reconstructed vertices, Nvtx, separately for data

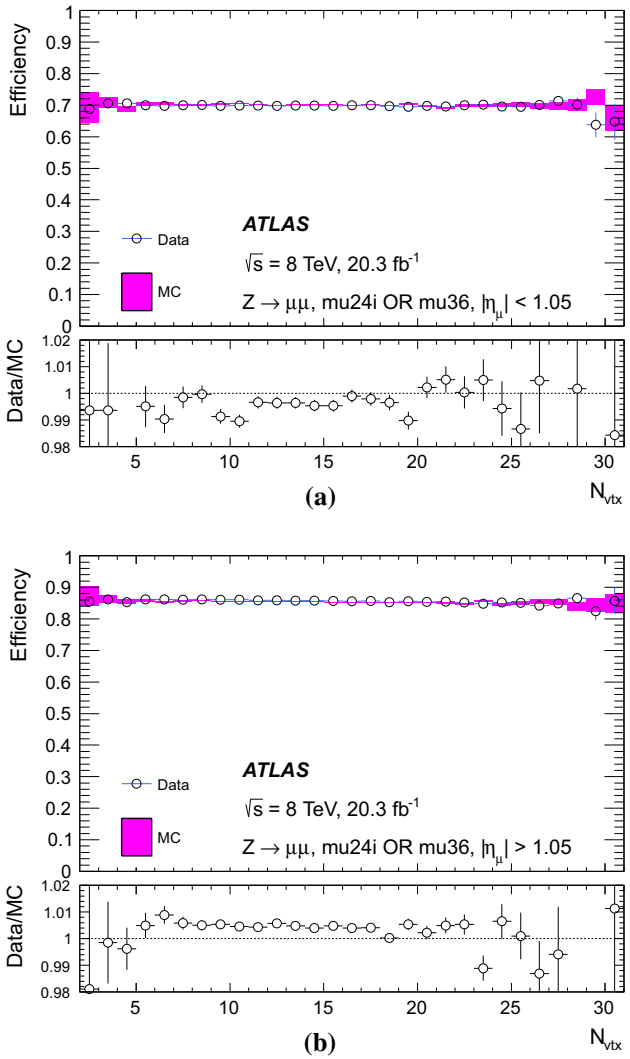

Fig. 7 Efficiency to pass either mu24i or mu36 triggers, as a function of the number of reconstructed vertices in an event, N_{vtx} in **a** the barrel region, and in **b** the endcap region, for data (*dots*) and MC simulation (*bands*). The *lower panels* show the ratio of the efficiencies in data and in MC simulation. The *error bars* reflect statistical uncertainties only

and MC simulation, as shown in Fig. 7. The efficiency is largely independent of the number of pile-up interactions. Separate linear fits to the data and MC simulation were performed in the range from Nvtx = 5 to Nvtx = 30 and extrapolated out to Nvtx = 50. The dependence on the fit range was observed to be negligible. The largest difference observed between the fits in data and MC simulation were observed to be 0.1 (0.5) % in the barrel (endcap). This difference is taken as an estimate of the systematic uncertainty due to the presence of pile-up interactions.

– Correlation between tag- and probe-muons from Z decays:
for medium p_{T}, tag- and probe-muons tend to be back-to-back in ϕ. Since the barrel and endcap have 16-fold and 12-fold symmetries, respectively, this can potentially lead to some bias; a tag-muon from a Z-boson decay inside a highly efficient region of the detector tends to be accompanied by a probe-muon in a region of high efficiency. This effect is evaluated by adding a requirement to the tag and probe pairs to prevent them from being back-to-back, $\Delta\phi(\text{tag, probe}) < \pi - 0.1$, where $\Delta\phi(\text{tag, probe})$ denotes the azimuthal angle between the tag- and probe-muons. The resulting uncertainty in the efficiency determination is 0.3 % (0.2 %) in the barrel (endcap) region.
– Matching between probe-muon and trigger muon:
this effect was estimated by changing the ΔR thresholds of the matching criteria. The change in the efficiency determination was found to be negligible.
– Probe-muon momentum scale and resolution:
this effect was estimated by changing the momentum scale and momentum resolution for the probe-muon by their respective uncertainties, as determined from the calibration using Z-bosons. The resulting change in efficiency was negligible.
– Probe-muon selection criteria:
this effect was estimated by changing, typically by 10 %, the cuts in various selection criteria, leading to negligible changes in the efficiency determination.
– Background contribution:
the amount of background was estimated by using the dijet, $t\bar{t}$, and W MC simulations and the effect on the efficiency determination was found to be negligible [25]. Also, varying the Z mass window cut gave negligible effect.
– MC modelling:
the sensitivity of the efficiency determination to the MC modelling was tested by comparing samples generated with a different MC generator, namely by adding SHERPA [26]. Again, the change in efficiency was found to be negligible [25].
– Dependence on p_{T}:
after correcting the MC efficiency in η and ϕ so as to reproduce the one observed in the data , any residual deviations between data and MC in the p_{T} dependence are taken as systematic uncertainty. This resulted in a 0.4 % effect.
– Probe-muon charge dependence:
it was estimated by comparing the efficiencies measured with positively charged and negatively charged probe-muons. The estimated uncertainty is 0.2 % in the endcap region.

The individual systematic uncertainties are added in quadrature to obtain the total systematic uncertainty, resulting in 0.6 % for the efficiency measured in the region of $25 < p_{\mathrm{T}} < 100$ GeV.

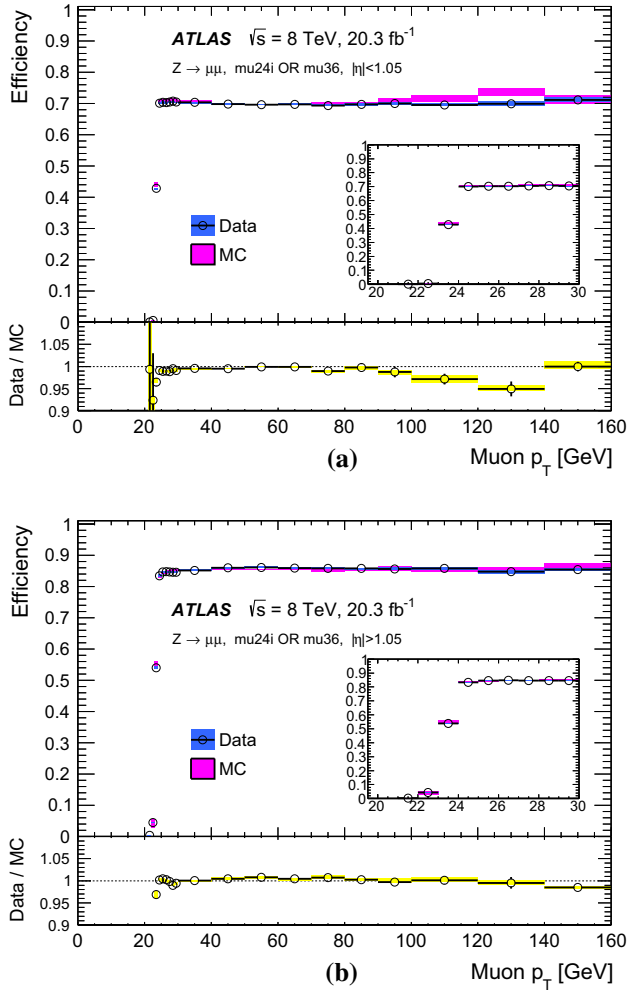

Fig. 8 Efficiency of passing either the mu24i or mu36 trigger as a function of the probe-muon transverse momentum p_{T}, for **a** the barrel region and **b** the endcap region, for data (*dots*) and MC simulation (*bands*). The *lower panels* show the ratio of the data and MC efficiencies. The *error bars* include both statistical and systematic uncertainties

6.2 Single-muon triggers: mu24i, mu36

Requiring events to pass either the mu24i or the mu36 trigger serves as a general-purpose single-muon triggers for many physics analyses. Figure 8 shows the efficiency to pass either the mu24i or the mu36 trigger as determined in the barrel and endcap regions. The efficiency was measured as a function of the p_{T} of the reconstructed probe-muon for both data and simulation. The efficiency in the simulation is seen to match that of the data over a wide p_{T} range. The slight excess in simulation in the p_{T} bin centred at 130 GeV was studied in detail. High p_{T} muons from Z-boson decays tend to be slightly more forward where there is the largest difference in trigger efficiency between data and simulation.

The efficiency curve turns on sharply around the threshold, reaching a plateau already around $p_{\mathrm{T}} \sim 25\,\mathrm{GeV}$. In order to quantitatively evaluate the turn-on behaviour and the agreement between data and MC simulation, a fit was made using a Fermi function $f(p_T)$.[7] From the fit, the low edge of the efficiency plateau region was defined as the value of p_{T} for which the efficiency decreases by 1 % from the plateau value. Table 2 shows these evaluated plateau values as well as the location of the low edges of the plateaus. The single-muon trigger that requires either the mu24i or mu36 trigger exhibits a plateau efficiency for physics analysis with muon $p_{\mathrm{T}} > 25\,\mathrm{GeV}$. The efficiency plateau is smooth at $p_{\mathrm{T}} = 36\,\mathrm{GeV}$ indicating that there is no inefficiency due to the isolation requirement in this sample.

Figure 9 shows the efficiency of requiring to pass either mu24i or mu36 triggers, as measured separately for the three trigger levels, Level-1, Level-2 and event-filter. The trigger selection becomes tighter and the efficiency turn-on becomes sharper as the trigger level increases. The plateau efficiency is mostly determined by Level-1. The high level trigger efficiency with respect to Level-1 is about 98–99 %.

Figure 10 shows the ratio of the data and MC efficiencies to pass either the mu24i or the mu36 trigger, as determined in bins of η and ϕ of the probe-muon, for the barrel and endcap regions. The measurement was performed for muons with $p_{\mathrm{T}} > 25\,\mathrm{GeV}$. The bins in η and ϕ are fine enough to reflect the hardware segmentation of the Level-1 detectors but coarse enough to have sufficient statistics in each bin. The typical size of the statistical uncertainty is less than 1 %, except for a few specific areas where the uncertainty is about 3 %.

6.3 Other single-muon triggers

Figure 11 shows the efficiencies of the mu36 trigger and of the mu40_SA_barrel trigger, together with that of mu24i trigger, as measured in data. The turn-on behaviour of mu24i and mu36 are sharp, while it is slower at threshold for mu40_SA_barrel. The latter relies only on the information from the muon detectors, and thus the p_{T} resolution is coarser (see Sect. 5). On the other hand, the requirement to pass either mu36 or mu40_SA_barrel results in about 2 % higher efficiency in the barrel region than achieved when requiring mu36 only, because mu40_SA_barrel does not require an inner detector track match. Therefore, requiring that either the mu36 or mu40_SA_barrel triggers are passed serves as a primary single-muon trigger for any processes that include muons with $p_{\mathrm{T}} \gtrsim 50\,\mathrm{GeV}$.

Figure 11 also shows the efficiencies of the medium-p_{T}, single-muon triggers, mu13 and mu18. The plateau efficiency of mu13 is about 6 % higher in the barrel region than that of mu18 and other higher-p_{T} triggers like mu24i. This is

[7] The functional form is $\frac{a}{1+\exp\{b(c-p_{\mathrm{T}})\}}$, where a indicates the plateau value, b the steepness of the turn-on slope, and c the threshold value.

Table 2 Result of fitting a Fermi function to the efficiency turn-on curve as a function of transverse momentum p_T for the single-muon trigger, for data and MC simulation. The location in p_T of the low edge of the plateau region is defined such that the efficiency decreases by 1 % from the plateau value

because mu13 is seeded from Level-1 MU10, which requires a two-station coincidence, while mu18 and the others are seeded from Level-1 MU15 which requires a three-station coincidence (see Sect. 2.3).

A fit using a Fermi function was performed to quantify the turn-on behaviour of these medium-p_T single-muon triggers. Table 3 shows the evaluated plateau and low edge p_T values for mu13 and mu18. It is seen that the offline cut of muon $p_T > 15(20)$ GeV is sufficient to ensure the mu13 (mu18) trigger efficiency is described by the plateau value. These middle-p_T triggers are used in various triggers, such as dimuon triggers 2mu13 and mu18_mu8_FS. The efficiencies of the single-muon triggers, mu13 and mu18, are necessary ingredients to calculate the dimuon trigger efficiencies.

6.4 Full-scan-muon trigger

As described in Sect. 2.6, the mu18_mu8_FS trigger is split into the RoI-based single-muon trigger, mu18, and the full-scan triggers of mu18_FS and mu8_FS. The full-scan trigger efficiencies were evaluated using the same method and sources of systematic uncertainties as for the single-muon trigger (see Sect. 6.1). Only two sources of systematic uncer-

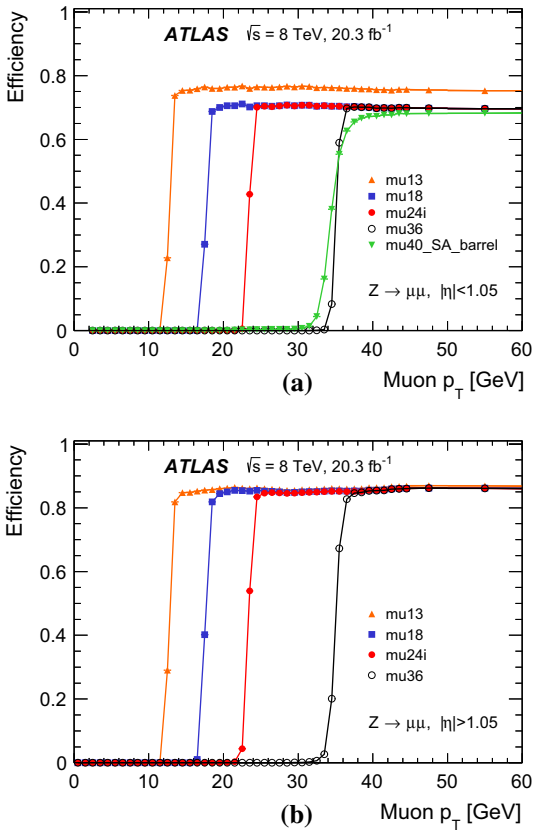

Fig. 11 Efficiency of single-muon triggers, mu13, mu18, mu24i, mu36 and mu40_SA_barrel, measured in data as a function of the probe-muon transverse momentum p_{T}, for **a** the barrel region and **b** the endcap region. The *error bars* indicate statistical uncertainties only

tainties resulted in visible changes in the efficiency, while all others lead to negligible changes.

– Dependence on p_{T}:
the uncertainty was estimated by comparing data and MC efficiencies as a function of p_{T} after correcting MC to reproduce data efficiency in η and ϕ. This resulted in a 0.2 % effect in the barrel and a 0.5 % effect in the endcap region.

– Dependence on pile-up interactions:
as shown in Fig. 12, the efficiency has a small dependence on the number of pileup events in the end cap region, with about 1.0 % efficiency loss per 20 vertices. The MC simulation reproduces the effect well. This is accounted for by changing the distribution of the average number of pile-up interactions, resulting in a 0.1 % uncertainty.

The resulting uncertainties were added in quadrature to form the total systematic uncertainty.

Figure 13 shows the data and MC efficiencies for the mu8_FS trigger for the barrel and endcap regions. The efficiency plateaus for the barrel and endcap regions are 98.7 and 97.6 %, respectively. This results in a higher efficiency for the dimuon trigger than achieved by requiring two RoI-based single-muon triggers.

The ratio of the efficiencies in data and MC is shown as a function of η and ϕ in Fig. 14 for the probe-muons with p_T 10 GeV. It is consistent with unity to within 2 % except in two bins where the difference is as large as 5 %.

7 Efficiency measurements at low p_{T}

7.1 Efficiency measurements with J/ψ

For the kinematic region of $p_{\mathrm{T}} \lesssim 10$ GeV, the efficiency was measured with the tag-and-probe method using J/ψ meson decays.

A MC study shows that the efficiency is slightly dependent on the measured d_0. Therefore, the efficiencies of prompt and non-prompt muons can be different due to different d_0 distribution. This effect is mostly removed by the cuts on d_0 and L_{xy} described in Sect. 3.5. The residual effect is then suppressed by reweighting the d_0 distribution to that of the prompt muons, which is obtained from the events with $L_{xy} < 0$.

Owing to a very high purity of the offline muon identification, the background also consists of muons, where the

latter do not originate from the decay of a J/ψ meson. The background fraction in the J/ψ mass window is about 16 %, ranging between 13 and 20 % depending on the muon p_{T}. The efficiency was measured by correcting the background effect using the side-bands of the invariant mass distribution.

7.2 Systematic uncertainty

The following sources of systematic uncertainty were evaluated. The uncertainty numbers quoted in the following are for the efficiency measured as a function of the probe-muon p_{T} in the region of $4 < p_{\mathrm{T}} < 10\,\mathrm{GeV}$.

- Matching between probe-muon and trigger muon:
  the effect was estimated by relaxing the ΔR criterion from 0.12 to 0.15, and also by relaxing the ΔR distance cut between the two muons from 0.2 to 0.25. The estimated uncertainty is up to 3 % (2 %) at $p_{\mathrm{T}} = 4\,\mathrm{GeV}$ in the barrel (endcap) region, decreasing to 1 % at $p_{\mathrm{T}} \gtrsim 6\,\mathrm{GeV}$.
- Reweighting of the d_0 distribution:
  the effect was estimated by comparing the efficiency with that obtained by not applying the d_0 reweighting. The estimated uncertainty is 1 % at $p_{\mathrm{T}} \sim 4\,\mathrm{GeV}$, decreasing to a negligible level at $p_{\mathrm{T}} \gtrsim 6\,\mathrm{GeV}$.
- Probe-muon charge dependence:
  the effect was estimated by comparing the efficiencies measured with positively charged and with negatively charged probe-muons. The estimated uncertainty is 1 % at low $p_{\mathrm{T}} \sim 4\,\mathrm{GeV}$, decreasing to 0.5 % at $p_{\mathrm{T}} \gtrsim 6\,\mathrm{GeV}$.
- Background contribution:
  the effect was estimated by not doing the background correction, resulting in a uncertainty of 0.1 %.
- Probe-muon selection criteria:

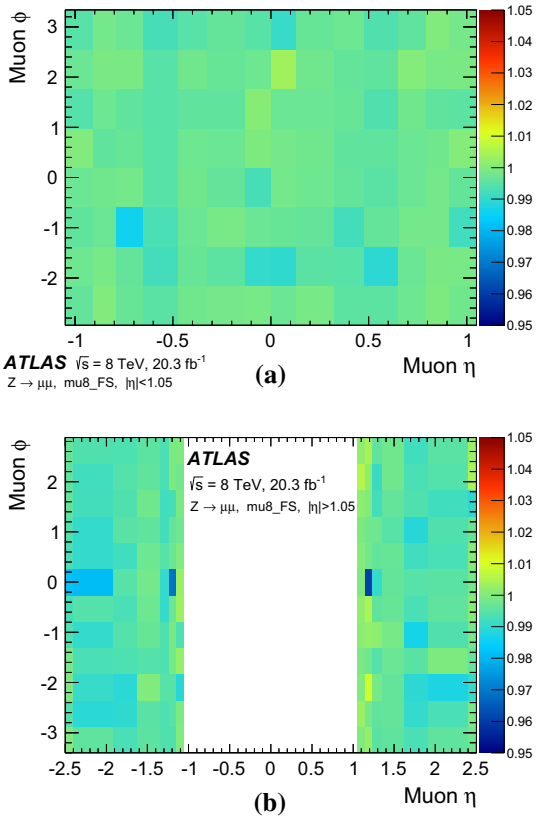

Fig. 14 Ratio of the data and MC efficiencies for the mu8_FS trigger in bins of the probe-muon pseudorapidity η and azimuthal angle ϕ, in **a** the barrel region and **b** the endcap region

the effect was estimated by changing typically by 10 % the thresholds of various selection criteria, leading to negligible effects.

– Dependence on pile-up interactions:
Separate linear fits to the efficiency dependence on Nvtx in the data and MC simulation were performed in the range from Nvtx = 5 to Nvtx = 30 and extrapolated out to Nvtx = 50. The dependence on the fit range was observed to be negligible. The largest difference between the fit results in data and MC simulation were observed to be 0.2 (0.4) % in the barrel (endcap). This difference is taken as the estimate of the resulting systematic uncertainty.

The total systematic uncertainties are obtained by adding the individual ones in quadrature.

7.3 Low-p_{T} single-muon triggers

Figure 15 shows the efficiency of the lowest-p_{T} single-muon triggers, mu4, mu6 and mu8 as a function of the p_{T} of the probe-muon.The efficiency of mu4 is about 40 % at the nominal threshold of 4 GeV. The mu4 turn-on curve rises slowly until $p_{\mathrm{T}} \sim 8$ GeV. The plateau efficiency of mu4 is higher by

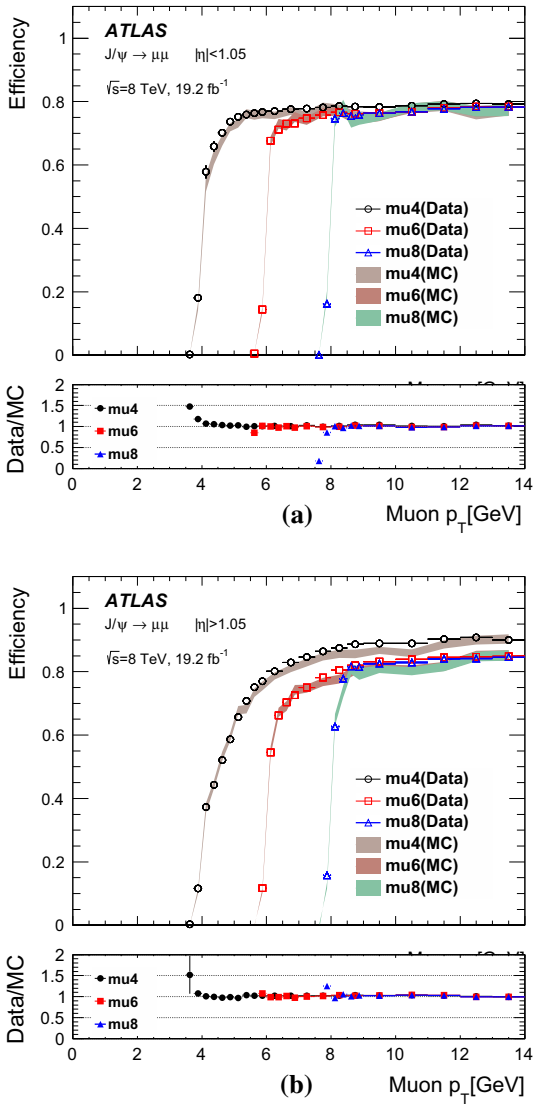

Fig. 15 Efficiency of low transverse momentum p_{T} single-muon triggers, mu4, mu6 and mu8, as a function of the probe-muon transverse momentum p_{T} in **a** the barrel region and **b** the endcap region, in the data (*symbols*) and in the MC (*bands*). The *error bars* for MC indicate the statistical uncertainties only, while those for data indicate both the statistical and systematic uncertainties

about 3 % in the endcap region, compared to those of mu6 and mu8.

The ratio of data and MC efficiencies of the mu4 trigger determined in bins of p_{T} and $Q\eta$, where Q stands for the charge of the probe-muon is shown in Fig. 16.

The ratio is significantly lower than unity at $Q\eta \sim -1.1$ for p_{T} values up to $\sim$ 12 GeV. In the muon spectrometer toroid magnetic field, the muons with $Q\eta > 0$ (< 0) bend toward the large (small) $|\eta|$ direction in the r–z plane. The muons with $Q\eta \sim -1.1$ are thus likely to pass through only one layer of the RPC (see Fig. 1) and hence are not triggered. Figure 16 shows that this is not well modelled in the MC simulation.

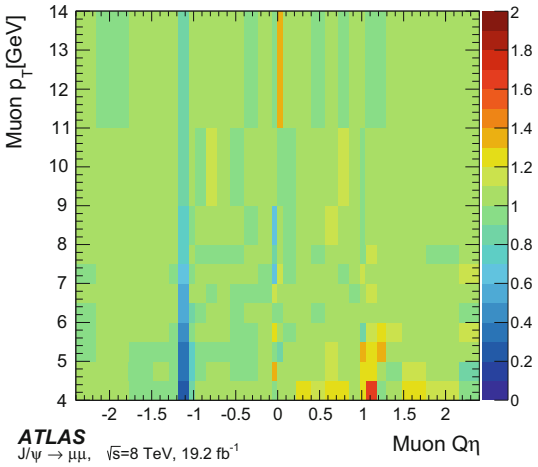

Fig. 16 Ratio of the data and MC efficiencies of the mu4 trigger in bins of the probe-muon pseudorapidity η multiplied by its charge, $Q\eta$, and the transverse momentum p_{T}

8 Efficiency measurements at very high p_{T}

8.1 Efficiency measurements with top quarks and W associated with jets

For the kinematic region of $p_{\mathrm{T}} \gtrsim 100\,\mathrm{GeV}$, the efficiency was measured using muons from top quark and W + jet candidate events. Because they are statistically independent of each other and also correspond to background-enriched samples of each other, the efficiencies using muons in top quark and W + jet events can be obtained by solving the following two equations

$$\epsilon^{t,\mathrm{data}} = f_t^{t,\mathrm{data}}\epsilon_t + (1 - f_t^{t,\mathrm{data}})\epsilon_W,$$
$$\epsilon^{W,data} = f_W^{W,\mathrm{data}}\epsilon_W + (1 - f_W^{W,\mathrm{data}})\epsilon_t,$$

where $\epsilon_{t(W)}$ is the efficiency in pure top quark (W + jets) events, and $\epsilon^{t(W),\mathrm{data}}$ is the measured efficiency in the top quark (W + jets) sample. The factors $f_t^{t,data}$ and $f_W^{W,\mathrm{data}}$ denote the fraction of true top quark (W + jets) events in the top quark (W with jets) sample, as determined by using MC simulation.

8.2 Systematic uncertainty

In the following, sources of systematic uncertainty are discussed and the quoted uncertainty values are presented for the efficiency measured using the W + jets sample as a function of p_{T}, in the region of $100 < p_{\mathrm{T}} < 400\,\mathrm{GeV}$.

- Muon isolation:
  to estimate this effect, the efficiency was measured by varying the isolation cut, both by loosening and by tightening the criteria, as well as by changing the ΔR cone size. The estimated uncertainty is typically 0.2 %;
- Muon–jet separation:
  the requirement on muon–jet separation serves also as an isolation cut. This effect was estimated by changing the ΔR criterion in the matching from 0.4 to 0.3 and 0.5. The estimated uncertainty is typically 0.1 and 0.3 % at maximum,
- $E_{\mathrm{T}}^{\mathrm{miss}}$ reconstruction:
  the effect was estimated by changing the threshold from 20 to 50 GeV, and also by introducing another tight cut of $E_{\mathrm{T}}^{\mathrm{miss}}(\mathrm{calo}) > 120\,\mathrm{GeV}$. The estimated uncertainty is 0.5 % at maximum.
- Identification of b-jets:
  the effect was estimated by repeating the measurements with a different b-jet identification criterion, namely with 60 % efficiency and 80 % efficiency. The estimated uncertainty is typically less than 0.1 %.
- Cut on $p_{\mathrm{T}}^{\mathrm{jet}}$:
  the effect was estimated by raising the $p_{\mathrm{T}}^{\mathrm{jet}}$ threshold to 35 GeV. The estimated uncertainty is typically less than 0.1 %.
- Background contribution:
  the number of background events was estimated by using the dijet and Z MC simulations and was found to be negligible at $p_{\mathrm{T}} > 100\,\mathrm{GeV}$.

All the contributions were added in quadrature to obtain the total systematic uncertainties.

8.3 Single-muon trigger efficiency at $p_{\mathrm{T}} \gtrsim 100\,\mathrm{GeV}$

Figure 17 shows the efficiencies measured using top quark and W with jets events for the single isolated-muon trigger, mu24i, in the barrel and endcap regions as a function of the p_{T} of the probe-muon, up to $p_{\mathrm{T}} \sim 400\,\mathrm{GeV}$. The data and MC simulation agree well up to the very high p_{T} values.

Also shown in Fig. 17 are the ratios of the efficiencies in the data and MC simulation for the three samples used for the efficiency determination. The three measurements are in good agreement with each other throughout a large p_{T} range, providing a consistency check of the efficiency measurement in different physics processes with different experimental techniques and in the presence of different backgrounds.

The efficiency in the end cap is seen to drop off slightly at the highest p_{T} which is not observed in the barrel. This was further investigated and it was found that for the highest energy muons (≈1000 GeV) there is a slight loss of efficiency at the event-filter when combining the muon spectrometer and inner detector track. While the offline algorithm looks for large energy deposits in the calorimeter which arise from bremsstrahlung, the event-filter algorithm always uses

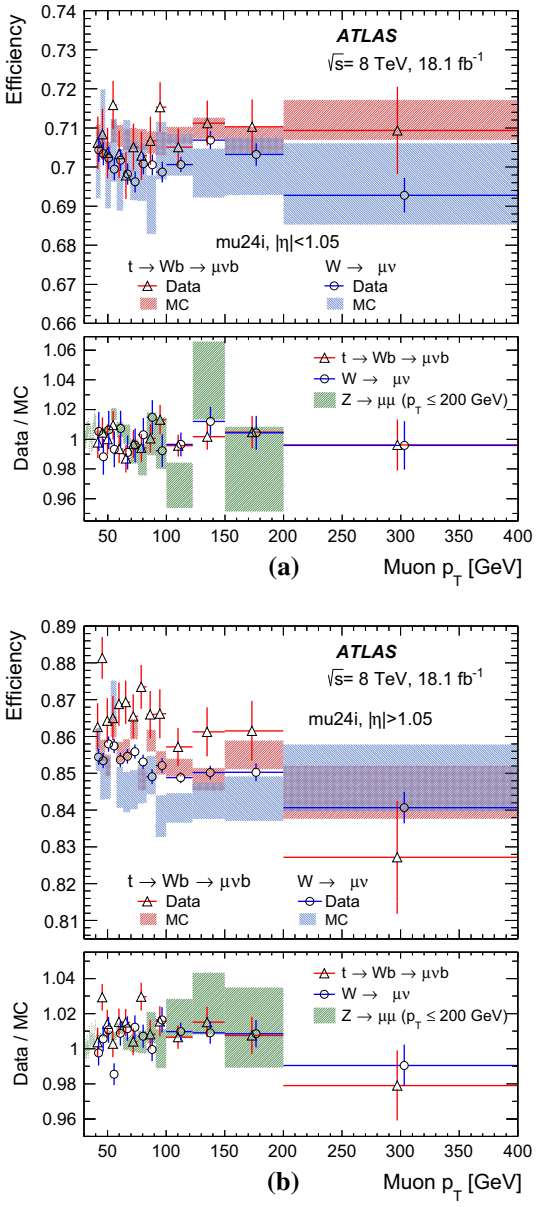

Fig. 17 Efficiency of the mu24i trigger as a function of the probe-muon transverse momentum p_{T}, as measured with the top quark and W + jet candidate events in the **a** barrel and **b** endcap regions. The *lower panels* show the ratio of the efficiencies in the data and MC simulation. Also shown is the efficiency as measured with the Z decays using the tag-and-probe method. The *error bars* for MC simulation indicate the statistical uncertainties only while the *error bars* for data include both statistical and systematic uncertainties

a parameterised energy loss for a minimum ionising particle. Without correction, this can cause a mismatch in the momentum estimate in the inner detector and muon spectrometer causing the combination to fail. This occurs in the end cap where kinematically, for fixed p_{T}, the energy of muons is much higher and thus high energy bremsstrahlung is more likely to occur. However, the effect is small, only occurs in the highest few p_{T} bins and accounts for a 4 % efficiency loss with a 2 % uncertainty.

9 Conclusions

The ATLAS muon trigger has been successfully adapted to the challenging environment at the LHC such that stable and highly efficient data taking was achieved in the year 2012. The transverse momentum threshold for the single-muon trigger was kept at 24 GeV, with a well-controlled trigger rate of typically about 8.5 kHz at the Level-1 and 65 Hz at the event-filter. The processing times of the Level-2 and event-filter muon trigger algorithms were sufficiently short to fit within the computing resource limitations. The purity of the trigger is about 90 % at the event-filter, and more than half of the triggers originate from electroweak bosons production. The efficiencies are measured extensively with the proton–proton collision data at a centre-of-mass energy of 8 TeV. The systematic uncertainty in the measured efficiency for the single-muon trigger is evaluated to be about 0.6 % in a kinematic region of $25 < p_{\mathrm{T}} < 100$ GeV. The efficiency was measured over a wide p_{T} range (few GeV to several hundred GeV) by using muons from J/ψ mesons, Z- and W-bosons, and top quark decays showing highly uniform and stable performance.

Acknowledgments We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently. We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWFW and FWF, Austria; ANAS, Azerbaijan; SSTC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR and VSC CR, Czech Republic; DNRF, DNSRC and Lundbeck Foundation, Denmark; EPLANET, ERC and NSRF, European Union; IN2P3-CNRS, CEA-DSM/IRFU, France; GNSF, Georgia; BMBF, DFG, HGF, MPG and AvH Foundation, Germany; GSRT and NSRF, Greece; ISF, MINERVA, GIF, I-CORE and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; BRF and RCN, Norway; MNiSW and NCN, Poland; GRICES and FCT, Portugal; MNE/IFA, Romania; MES of Russia and ROSATOM, Russian Federation; JINR; MSTD, Serbia; MSSR, Slovakia; ARRS and MIZŠ, Slovenia; DST/NRF, South Africa; MINECO, Spain; SRC and Wallenberg Foundation, Sweden; SER, SNSF and Cantons of Bern and Geneva, Switzerland; NSC, Taiwan; TAEK, Turkey; STFC, the Royal Society and Leverhulme Trust, United Kingdom; DOE and NSF, United States of America. The crucial computing support from all WLCG partners is acknowledged gratefully, in particular from CERN and the ATLAS Tier-1 facilities at TRIUMF (Canada), NDGF (Denmark, Norway, Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy), NL-T1 (Netherlands), PIC (Spain), ASGC (Taiwan), RAL (UK) and BNL (USA) and in the Tier-2 facilities worldwide.

ABSTRACT

The Fast Tracker (FTK) processor is an approved ATLAS upgrade that will reconstruct tracks using the full silicon tracker at Level-1 rate (up to 100 KHz). FTK uses a completely parallel approach to read the silicon tracker information, execute the pattern matching and reconstruct the tracks. This approach, according to detailed simulation results, allows full tracking with nearly offline resolution within an execution time of 100 μs. A central component of the system is the associative memories (AM); these special devices reduce the pattern matching combinatoric problem, providing identification of coarse resolution track candidates. The system consists of a pipeline of several components with the goal to organize and filter the data for the AM, then to reconstruct and filter the final tracks. This document presents an overview of the system and reports the status of the different elements of the system.

challenge. The current three-level trigger, designed to allow a rate reduction from 40 MHz to about 400 Hz [1], has to evolve to fit in these constraints. The Fast Tracker (FTK) is an upgrade to the current ATLAS trigger system that will operate at full Level-1 output rates, providing high-quality tracks reconstructed in the entire inner detector by the start of processing in the Level-2 trigger. This frees execution time in the Level-2 farm for more complex selection algorithms, allowing interesting events to be selected with higher efficiency while rejecting uninteresting events. FTK solves the combinatorial challenge inherent to tracking by exploiting the massive parallelism of associative memories that can compare inner detector hits to billions of precalculated patterns simultaneously.

The tracking problem within the matched patterns, referred as roads, is further simplified by transforming the helix parameters and the quality estimator calculations into a set of scalar products in the form

$$p_i = \sum_j C_{ij} x_j + q_i$$

where x_j are the hit coordinates in each detector layer, C_{ij} and q_i are precalculated terms, p_i can be either helix parameters or χ^2 components. Using this transformation fast DSPs in modern commercial FPGAs can perform the calculation in a very efficient and parallel way.

2. FTK architecture

The FTK system will receive a copy of the data from Read-Out Drivers (ROD) of the ATLAS pixel and strip detectors. This functionality was not present in the original HOLA card, responsible for the ROD output; a specific dual-output HOLA card was developed for FTK: it has two independent streams, one for the standard DAQ stream and the second for FTK. All the 270 HOLA cards required to install FTK have been produced and tested. The testing procedure was particularly detailed and important because these cards are used by the general DAQ; indeed a failure will prevent normal ATLAS operations. During the 2012 winter shutdown 32 HOLA cards were installed and included in the normal operations.

The data collected by the HOLAs will be collected by the Data Formatter (DF). The DF organizes the data to be used by the FTK system. It maps the silicon Inner Detector (ID) modules to 64 $\eta-\phi$ independent towers. The DF also organizes the data for use by the remaining boards in the system. In particular, the DF sends to the AM chip the data from 8 out of the 11 layers that a track can cross. The data from the other three layers are sent to the Second Stage Boards (SSB). Technically, the DF boards will be installed in ATCA crates, using a full-mesh backplane. This architecture was chosen because of the data sharing flexibility in ATCA. For the inter-shelf communication an optical fiber will be used.

A special role is played by the input mezzanine card installed in the DF boards: the FTK input mezzanine (FTK_IM). This mezzanine card receives as input the S-link fibers connected to the HOLA cards and runs a clustering algorithm. The clustering algorithm is crucial in the pixel layer to identify the clusters and calculate the centroids; the execution speed is crucial and the selection of the final FPGA is in progress. The SCT data are already clustered by the front-end chip, however for instrumental reasons clusters can be split at chip boundaries; a refinement of SCT clusters will improve system performance.

The data collected by the DF will be sent to the real processing units, composed by the AM board and an auxiliary card (AUX) installed on the VME backplane. Technically the AUX card receives the clusters and converts each to coarse resolution hit for pattern recognition (superstrip or SS). The SS information is routed within the AM board to 128 AMChip04 chips [2] and matched to patterns, about 10 millions per board. The found roads will then be sent back to the AUX where all the full resolution clusters will be retrieved and combined to build candidate tracks with 1 hit per layer. For each candidate a χ^2 is calculated and the bad tracks are rejected. This task is performed in an FPGA with an average fit rate of 1 track per ns.

The good tracks in the AUX cards are sent to SSB and extrapolated. If hits are found around the extrapolated coordinates these are added to the track; if the there are not hits, the track is discarded. This procedure rejects fakes and increases the quality of the tracks. The final tracks are sent to the FLIC (FTK to Level 2 Interface Crate), collected and prepared for the ATLAS HLT processing farm.

3. Expected performance

Using a detailed emulation of the system it has been possible to evaluate the expected performance of the system up to 3×10^{34} cm^{-2} s^{-1}, verifying that FTK is able to compute the helix parameters for all tracks in an event, apply quality cuts in less than 100 μs, with nearly offline quality. This quality allows us to implement selection algorithms based on tracks, like high-p_T lepton identification, b- or τ-tagging of jets. However the integration with the ATLAS HLT will allow other, more sophisticated algorithms [3].

4. Conclusion

The FTK system design was defined and the performance presented. The design of individual boards is in progress. In particular some of the dual output HOLA cards are already installed. Other parts, like the AM board, the AUX card or the FTK_IM are already at prototype level. Prototypes for the rest of the boards are expected soon. The final TDR of the system, where the first test of the prototypes will be included, is expected for the spring 2013. The installation is expected to start in 2014.

Measurement of the W boson polarization in top quark decays with the ATLAS detector

The ATLAS collaboration

E-mail: atlas.publications@cern.ch

Abstract: This paper presents measurements of the polarization of W bosons in top quark decays, derived from $t\bar{t}$ events with missing transverse momentum, one charged lepton and at least four jets, or two charged leptons and at least two jets. Data from pp collisions at a centre-of-mass energy of 7 TeV were collected with the ATLAS experiment at the LHC and correspond to an integrated luminosity of $1.04\,\text{fb}^{-1}$. The measured fractions of longitudinally, left- and right-handed polarization are $F_0 = 0.67 \pm 0.07$, $F_\text{L} = 0.32 \pm 0.04$ and $F_\text{R} = 0.01 \pm 0.05$, in agreement with the Standard Model predictions. As the polarization of the W bosons in top quark decays is sensitive to the Wtb vertex Lorentz structure and couplings, the measurements were used to set limits on anomalous contributions to the Wtb couplings.

1 Introduction

Discovered in 1995 by the CDF and DØ experiments [1, 2], the top quark is the heaviest known fundamental particle, with a mass of 173.2±0.9 GeV [3]. Measurements of top quark properties play an important role in testing the Standard Model and its possible extensions. One particular test is the study of the Wtb vertex Lorentz structure and couplings, which can be probed by measuring the polarization of W bosons produced in top quark decays.

At the LHC, top quarks are produced mainly in pairs via the strong interaction and are predicted to decay via the electroweak interaction into a W boson and a bottom quark with a nearly 100% branching fraction. Events with $t\bar{t}$ pairs can thus be classified according to the decay of the two produced W bosons. Each boson can decay either into

a quark-antiquark pair or into a charged lepton and a neutrino. The single-lepton and dilepton topologies, both considered in the analyses presented in this paper, have one and two isolated charged leptons in the final state. Only electrons and muons, including those from τ decays, are considered here.

The Wtb vertex is defined by the electroweak interaction and has a $(V-A)$ structure where V and A are the vector and axial-vector contributions to the vertex. Since the W bosons are produced as real particles in top quark decays, their polarization can be longitudinal, left-handed or right-handed. The fractions of events with a particular polarization, F_0, F_{L} and F_{R}, are referred to as helicity fractions. They are predicted in next-to-next-to-leading-order (NNLO) QCD calculations to be $F_0 = 0.687 \pm 0.005$, $F_{\mathrm{L}} = 0.311 \pm 0.005$, $F_{\mathrm{R}} = 0.0017 \pm 0.0001$ [4]. These fractions can be extracted from measurements of the angular distribution of the decay products of the top quark. The angle θ^* is defined as the angle between the momentum direction of the charged lepton from the decay of the W boson and the reversed momentum direction of the b-quark from the decay of the top quark, both boosted into the W boson rest frame [5]. The angular distribution is:

$$\frac{1}{\sigma}\frac{\mathrm{d}\sigma}{\mathrm{d}\cos\theta^*} = \frac{3}{4}\left(1-\cos^2\theta^*\right)\,F_0 + \frac{3}{8}\left(1-\cos\theta^*\right)^2\,F_{\mathrm{L}} + \frac{3}{8}\left(1+\cos\theta^*\right)^2\,F_{\mathrm{R}}\,. \tag{1.1}$$

All previous measurements of the helicity fractions, performed by the CDF and DØ Collaborations [6–8] at the Tevatron, are in agreement with Standard Model predictions.

Information about the polarization of the W bosons can also be obtained through complementary observables, such as the angular asymmetries, A_+ and A_-, defined as:

$$A_\pm = \frac{N(\cos\theta^* > z) - N(\cos\theta^* < z)}{N(\cos\theta^* > z) + N(\cos\theta^* < z)}\,, \tag{1.2}$$

with $z = \pm(1-2^{2/3})$ for $A_\pm$, allowing the dependence on F_{L} and F_{R} to cancel, respectively. The asymmetries can be related to the helicity fractions by a simple system of equations [9, 10]. In the Standard Model, the NNLO values for these asymmetries are $A_+ = 0.537 \pm 0.004$ and $A_- = -0.841 \pm 0.006$ [4].

In the presence of anomalous Wtb couplings the helicity fractions and angular asymmetries depart from their Standard Model values [5, 10]. In effective field theories, dimension-six operators can be introduced which modify the Wtb vertex [11–13]. Coefficients controlling the strength of these operators can be constrained by measurements of the helicity fractions or the angular asymmetries.

This paper describes measurements of the W boson polarization in top quark decays and the constraints on the Wtb vertex structure based on a data set recorded with the ATLAS detector between March and June 2011 and corresponding to an integrated luminosity of $1.04\,\mathrm{fb}^{-1}$. The helicity fractions were measured using two different methods. The first compares the observed $\cos\theta^*$ distribution with templates for different W boson helicity states obtained from simulation. The second method extracts angular asymmetries from an unfolded $\cos\theta^*$ spectrum corrected for background contributions. Limits on anomalous couplings, generated by the aforementioned dimension-six operators, were set using the combined result from the two measurements.

JHEP06(2012)088

This paper is structured as follows. Data samples and simulated samples modelling signal and background processes are described in section 2, followed by a summary of the event selection in section 3. The analysis strategies can be found in section 4. Sources of systematic uncertainty are discussed in section 5, the results are summarized in section 6 and section 7 concludes the paper.

2 Data and simulation samples

The ATLAS detector [14] at the LHC covers nearly the entire solid angle around the collision point. It consists of an inner tracking detector surrounded by a thin superconducting solenoid, electromagnetic and hadronic calorimeters, and an external muon spectrometer incorporating three large superconducting toroid magnet assemblies. A three-level trigger system, designed to reduce the event rate from 40 MHz to about 200 Hz, is used to select events of interest.

2.1 Data sample

Data from pp collisions at a centre-of-mass energy of 7 TeV were collected using single-lepton triggers with transverse momentum thresholds of 20 GeV for electrons and 18 GeV for muons. The size of the data sample corresponds to an integrated luminosity of $1.04 \pm 0.04\,\text{fb}^{-1}$ [15, 16].

2.2 Signal and background modelling

Signal and most background processes were modelled by Monte Carlo (MC) simulation. The signal process was simulated using two different generators. The leading order (LO) Monte Carlo generator Protos [10, 17] was used with the CTEQ6L1 sets of parton distribution functions (PDFs) [18] to generate three samples assuming $F_0 = 1$, $F_\text{L} = 1$ and $F_\text{R} = 1$. This was achieved by choosing appropriate values for anomalous Wtb couplings, as described in refs. [9, 10]. The output was interfaced to Pythia [19] to simulate parton showers and hadronization. In addition, the next-to-leading-order (NLO) generator MC@NLO [20–22] was used with the CTEQ6.6 PDF set [23] for studies of systematic differences in the top quark production and decay modelling.

The W and Z boson production in association with multiple jets was simulated using the Alpgen generator [24] and the CTEQ6L1 PDF set. Tree-level matrix elements with up to five final-state partons were included. The standard Alpgen matching scheme was used to remove overlaps between the n and $n+1$ parton samples. Heavy flavour samples containing $Wb\bar{b}$, $Wc\bar{c}$, Wc and $Zb\bar{b}$ events were simulated separately. The Z+jets samples were generated with dileptons in the invariant mass range $10 < m_{\ell\ell} < 2000$ GeV. Diboson processes were simulated using Herwig [25]. Single top quark production was simulated using MC@NLO, invoking the 'diagram removal scheme' [26] to remove overlaps between the single top quark and $t\bar{t}$ final states. An additional sample of W+jets events was generated with Sherpa [27] and used to study systematic uncertainties. Details are described in section 5. Apart from the Protos $t\bar{t}$ samples, all events were hadronized with

JHEP06(2012)088

HERWIG using JIMMY [28] for the underlying event model. Different underlying event tunes were used, depending on the hadronization program used (i.e. PYTHIA or HERWIG) [29].

Additional MC samples were used for the evaluation of systematic uncertainties. These were generated with the ACERMC [30] and POWHEG [31, 32] generators interfaced to PYTHIA for hadronization. They are described in section 5. A top quark mass of 172.5 GeV was assumed for all signal samples if not stated otherwise. Additional MC@NLO samples were generated assuming different top quark masses.

All simulated events contain multiple pp-interactions and contain pileup contributions corresponding to a bunch spacing of 50 ns. These simulated events were re-weighted such that the average number of interactions per proton-proton bunch crossing was the same in data and MC simulation. The average number of interactions per event was roughly six. All samples were processed by the detector and trigger simulation after event generation [33, 34], and subjected to the same reconstruction algorithms as the data.

The cross-section of simulated $t\bar{t}$ samples was normalized to 164.6 pb, the value obtained from approximate NNLO calculations [35–37], and consistent with recent measurements [38]. While the Z+jets normalization was obtained from the NNLO QCD cross-section calculations in the single-lepton channels, a data-driven estimate for the normalization was used for the dilepton channels [38]. The diboson with jets production was rescaled to match NLO calculations of the inclusive cross-sections.

For the single-lepton analysis, the multijet production background, where an electron or muon originates from hadron decay or instrumental background, was estimated from data as described in refs. [39, 40]. The W+jets background was obtained from simulation, except that its normalization was derived from data, from a study of the asymmetry in the production of W^+ and W^- bosons [40]. For the dilepton analysis, background contributions from W+jets, single-lepton $t\bar{t}$ and single top quark production were estimated using the method described in ref. [38]. In the single-lepton and dilepton analyses this source of background is labelled as "misidentified leptons".

3 Event selection

3.1 Physics object definition

The reconstruction and identification of electrons, muons, jets and the magnitude of the missing transverse momentum ($E_{\mathrm{T}}^{\mathrm{miss}}$) used in the analyses presented here followed the criteria employed for the measurement of the $t\bar{t}$ production cross-section [39]. More details, including a description of the trigger and the vertex requirements, can be found in ref. [40].

The $t\bar{t}$ events with at least one isolated charged lepton (electron or muon) in the final state were considered as signal. Events with τ leptons decaying into muons or electrons in the final state were also considered to be part of the signal.

All the considered events were required to fulfil general event quality criteria and to have a well-defined primary vertex with at least five associated tracks. Reconstructed electrons were required to have $E_{\mathrm{T}} > 25$ GeV and $|\eta| < 2.47$ excluding $1.37 < |\eta| < 1.52$,

JHEP06(2012)088

while muons were required to have $p_{\mathrm{T}} > 20$ GeV and $|\eta| < 2.5$.[1] Jets were reconstructed with the anti-k_t algorithm [41] with a radius parameter equal to 0.4. They were required to have $p_{\mathrm{T}} > 25$ GeV and $|\eta| < 2.5$. For electrons, the energy not associated to the electron cluster but contained in a cone of $\Delta R = \sqrt{(\Delta\phi)^2 + (\Delta\eta)^2} = 0.2$ around it was required not to exceed 3.5 GeV. For muons, the sum of track transverse momenta and the total energy deposited in a cone of $\Delta R = 0.3$ around the muon were both required to be less than 4 GeV. Muons reconstructed within a $\Delta R = 0.4$ cone of a jet satisfying $p_{\mathrm{T}} > 20$ GeV were removed to reduce the contamination caused by muons from hadron decays within jets. Subsequently, jets within $\Delta R = 0.2$ of an electron candidate were removed to avoid double counting, which can occur because electron clusters are also reconstructed as jets.

A combination of two algorithms was used for b-jet identification (b-tagging). They are based on reconstructed secondary vertices and the impact parameter significances of tracks within jets. The chosen working point resulted in a b-tagging efficiency of 70% for jets originating from b-quarks in a sample of simulated $t\bar{t}$ events and a light-quark jet rejection factor of about 100 [42].

3.2 Single-lepton channels

The single-lepton $t\bar{t}$ signal is characterized by a high-p_{T} isolated charged lepton and missing transverse momentum from the neutrino, from the leptonically decaying W boson, two light-quark jets from the hadronically decaying W boson and two b-quark jets. The two channels with either an electron or a muon in the final state are referred to as single-electron and single-muon channels. The following event selection requirements were applied:

- the appropriate single-electron or single-muon trigger had fired;
- events were required to contain exactly one isolated electron or muon;
- in the single-electron channel, $E_{\mathrm{T}}^{\mathrm{miss}} > 35$ GeV and $m_{\mathrm{T}}(W) > 25$ GeV were required[2] while in the single-muon channel the criteria were $E_{\mathrm{T}}^{\mathrm{miss}} > 20$ GeV and $E_{\mathrm{T}}^{\mathrm{miss}} + m_{\mathrm{T}}(W) > 60$ GeV;
- events were required to have at least four jets, with at least one of them being tagged as a b-jet.

The numbers of events expected after all selection requirements are shown in table 1 for the single-electron and single-muon channels, together with the observed numbers of events in the data sample. The single-electron channel contains significantly fewer events than the single-muon channel due to the more stringent requirements on the lepton E_{T} (p_{T}), $E_{\mathrm{T}}^{\mathrm{miss}}$ and $m_{\mathrm{T}}(W)$. The observed numbers of events are in agreement with those

[1] ATLAS uses a right-handed coordinate system with its origin at the nominal interaction point (IP) in the centre of the detector and the z-axis along the beam pipe. The x-axis points from the IP to the centre of the LHC ring, and the y-axis points upward. Cylindrical coordinates (r, ϕ) are used in the transverse plane, ϕ being the azimuthal angle around the beam pipe. The pseudorapidity is defined in terms of the polar angle θ as $\eta = -\ln\tan(\theta/2)$.

[2] Here $m_{\mathrm{T}}(W)$ is the W boson transverse mass, reconstructed as $\sqrt{2p_{\mathrm{T}}^{\ell}p_{\mathrm{T}}^{\nu}\left[1-\cos(\phi^{\ell}-\phi^{\nu})\right]}$ where the measured missing transverse momentum provides the neutrino information.

expected, with purities of 75% and 72% for the single electron and single muon channels. The systematic uncertainty discussed in section 5 dominates the error on the event yields, with jet energy scale, signal and background modelling, and b-tagging being the dominant sources of uncertainty. Example distributions in data are compared with the Standard Model predictions in figure 1. The data are described well by the expected distributions.

3.3 Dilepton channels

The dilepton $t\bar{t}$ signal is characterized by two high-p_{T} isolated charged leptons, missing transverse momentum corresponding to the undetected neutrinos from the two leptonically decaying W bosons, and two b-quark jets. The three channels are referred to as ee, $\mu\mu$ and $e\mu$ channels. The following event selection requirements were applied:

- the single-electron trigger had fired for the ee channel, the single-muon trigger had fired for the $\mu\mu$ channel and either of these triggers had fired for the $e\mu$ channel;
- events were required to contain exactly two oppositely charged and isolated leptons (ee, $\mu\mu$ or $e\mu$);
- at least two jets, with at least one of them being b-tagged, were required;
- in order to avoid the low-mass Drell-Yan background region, events were required to have $m_{\ell\ell} > 15$ GeV;
- in the ee and $\mu\mu$ channels, the missing transverse momentum had to satisfy $E_{\mathrm{T}}^{\mathrm{miss}} > 40$ GeV, and the invariant mass of the two leptons had to differ by at least 10 GeV from the Z boson mass, i.e. $|m_{\ell\ell} - m_Z| > 10$ GeV, with $m_Z = 91$ GeV, in order to suppress backgrounds from Z+jets events and events containing misidentified leptons;

JHEP06(2012)088

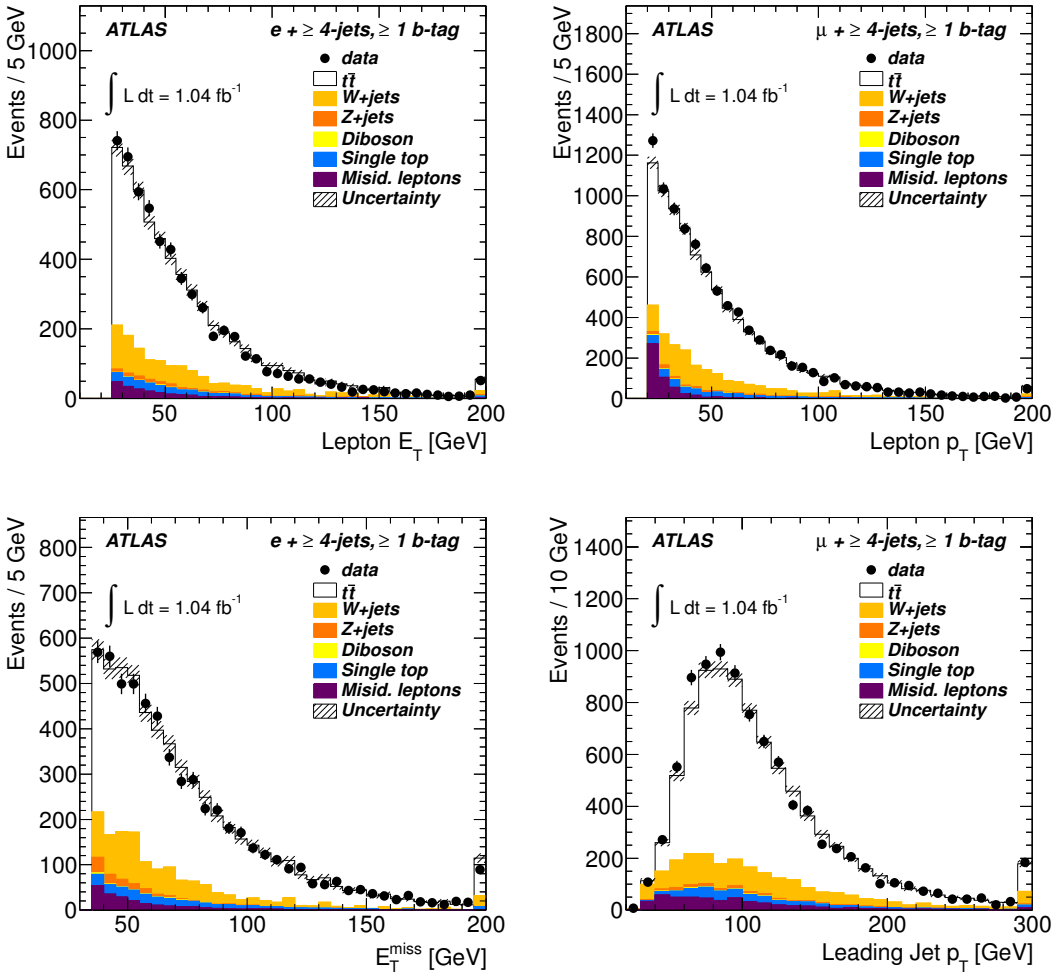

Figure 1. The top row shows (left) the E_{T} spectrum of the electron in the single-electron channel and (right) the p_{T} spectrum of the muon in the single-muon channel. The bottom row shows (left) the missing transverse momentum in the single-electron channel and (right) the p_{T} spectrum of the leading jet in the single-muon channel. The error band shows the statistical uncertainty from the Monte Carlo simulation. The last bin in each distribution includes the overflow.

- in the $e\mu$ channel, no $E_{\mathrm{T}}^{\mathrm{miss}}$ or Z boson mass veto cuts were applied; however, the event H_{T}, defined as the scalar sum of the transverse energies of the two charged leptons and all selected jets, had to satisfy $H_{\mathrm{T}} > 130$ GeV to suppress backgrounds from Z+jets production;

- events were required to pass the $t\bar{t}$ reconstruction criteria, as described in section 4.1.

The numbers of events expected after all selection requirements are shown in table 2 for the three dilepton channels, together with the observed numbers of events in the data sample. The observed numbers of events is in agreement with those expected, with a purity of 94% for all three channels. The systematic uncertainty discussed in section 5

dominates the error on the event yields, with jet energy scale, jet energy resolution, signal and background modelling, and b-tagging being the dominant sources of uncertainty. Example distributions in data are compared with the Standard Model predictions in figure 2. The data are described well by the expected distributions.

4 Measurement strategies

The two methods to extract the helicity fractions are described below. The analysis was carried out for the single-electron, single-muon, ee, $e\mu$ and $\mu\mu$ channels separately. The reconstruction of $t\bar{t}$ events in the single-lepton channels differs for the two methods: the template method relies more strongly on the structure of the $\cos\theta^*$ distribution than the calculation of the angular asymmetries. It thus relies on an improved estimate of the particle energies. A common reconstruction method was used in the dilepton channels. The results of the analyses and their combination are described in section 6.

4.1 Measurement using the template method

Templates for different signal and background processes were fitted to the observed $\cos\theta^*$ distributions based on events reconstructed with a kinematic fit in the single-lepton channels [40, 43]. The fit was based on a likelihood which took into account the Breit-Wigner forms of the lineshapes of the top quark and the W boson as well as the energy resolution of the measurements of the jets and the charged leptons. The missing transverse momentum was identified with the x- and y-components of the neutrino momentum. The top quark mass was fixed to 172.5 GeV, and the mass of the W boson was fixed to 80.4 GeV. The likelihood was maximized with respect to the energies of the final state quarks for each association of jets to quarks. The permutations were weighted according to the b-tagging information and the weights were derived from the efficiency and mis-tag rate of the b-tagger. The permutation with the largest value of the likelihood was used in the

JHEP06(2012)088

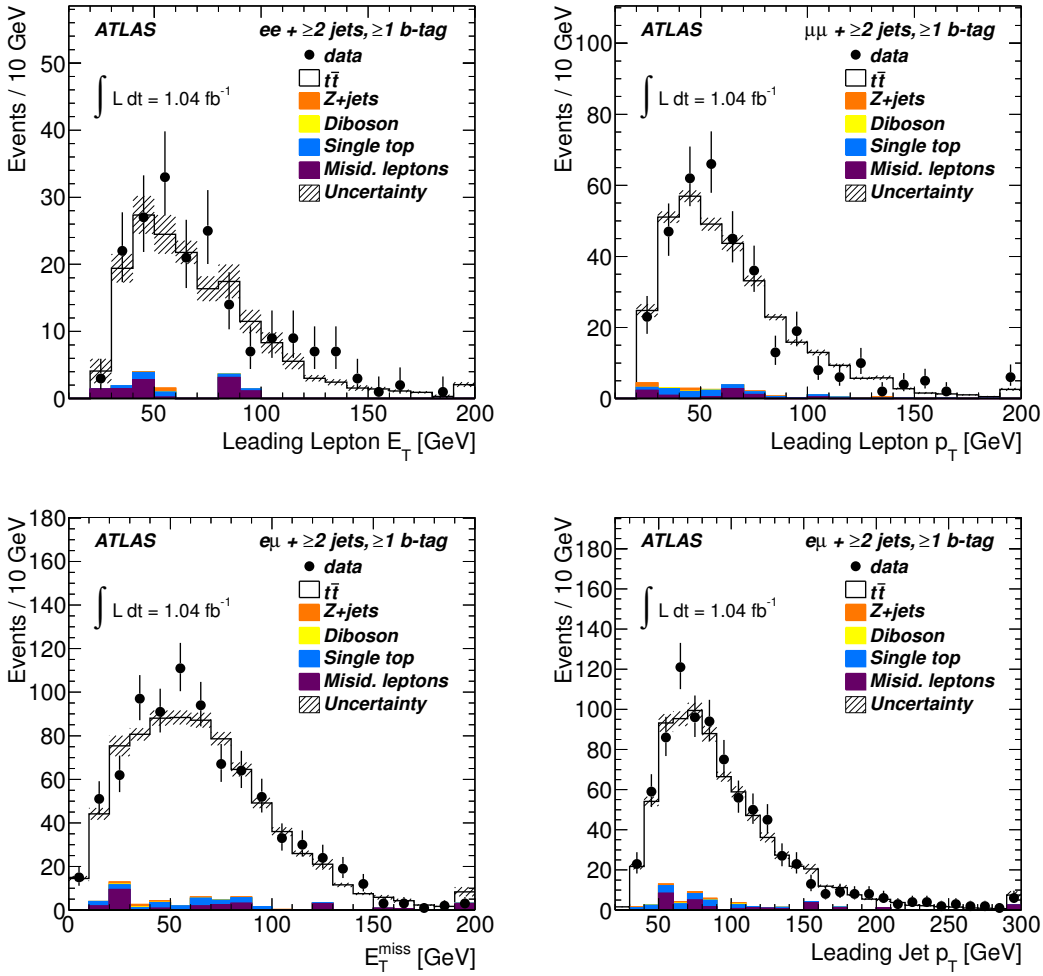

Figure 2. The top row shows (left) the E_{T} spectrum of the leading electron in the ee channel and (right) the p_{T} spectrum of the leading muon in the $\mu\mu$ channel. The bottom row shows (left) the missing transverse momentum in the $e\mu$ channel and (right) the p_{T} spectrum of the leading jet in the $e\mu$ channel. The error band shows the statistical uncertainty from the Monte Carlo simulation. The last bin in each distribution includes the overflow.

following steps of the analysis. The overall efficiency for the reconstruction of the correct event topology was found to be 74% in simulated $t\bar{t}$ events. Only those events where four jets and a lepton are matched to partonic particles, corresponding to roughly 30% of the events, were considered for the efficiency computation.

For the dilepton channels, the $t\bar{t}$ system was reconstructed by solving a set of six independent equations:

$$\begin{aligned} p_x^{\nu_1} + p_x^{\nu_2} &= E_x^{\mathrm{miss}}; & p_y^{\nu_1} + p_y^{\nu_2} &= E_y^{\mathrm{miss}}; & (p_{\ell_1} + p_{\nu_1})^2 &= m_W^2; \\ (p_{\ell_2} + p_{\nu_2})^2 &= m_W^2; & (p_{W_1} + p_{j_1})^2 &= m_t^2; & (p_{W_2} + p_{j_2})^2 &= m_t^2. \end{aligned} \tag{4.1}$$

E_x^{miss} and E_y^{miss} represent the x- and y-components of the missing transverse momentum,

JHEP06(2012)088

p_{ℓ_1} and p_{ℓ_2} (p_{j_1} and p_{j_2}, p_{ν_1} and p_{ν_2}) correspond to the four-momenta of the two charged leptons (jets, neutrinos). Here, m_W and m_t are the W boson and top quark masses, respectively. For events with only one b-tagged jet, this jet and the non-tagged one with the highest p_{T} were taken as b-jets from the top quark decays. If at least two b-tagged jets are present, the two b-tagged jets with the largest p_{T} in the event were used. The pairing of the jets with the charged leptons was based on the minimization of the sum of the invariant masses $m_{\ell_1 j_1}$ and $m_{\ell_2 j_2}$. Simulations show that this criterion gives the correct pairing in 68% of the events. Up to four solutions can be found to the Equations 4.1. The solution with the minimum product of neutrino transverse momenta was chosen and is motivated by the low p_{T}-spectrum of the neutrinos. In case no solution was found, the top quark mass parameter was varied in the 157.5–187.5 GeV range, to try to find one or more solutions. In case a range of top masses provided a solution, that with the top quark mass parameter closest to 172.5 GeV was taken. Again, multiple ambiguities were resolved by taking the solution with the minimum product of neutrino transverse momenta. If still no solution was found, the second pairing of jets and charged leptons was used. If no solution was found after this procedure the event was discarded. This happened in about 25% of the events in data and in simulated $t\bar{t}$ events.

In the single-lepton channels, the following six processes were used as templates: three different helicity state signal processes, the background from events with misidentified leptons, the W+jets contribution and the sum of all other sources of background. The three signal templates were derived from simulation and include single-lepton and dilepton events which pass the event selection. These distributions are shown in figure 3. The W+jets template was obtained from simulation. The template for events with misidentified leptons was obtained from data. Other processes contributing to the observed spectrum include single top quark, diboson and Z+jets production and were summed in a single template obtained from simulation.

In the dilepton channels, templates for the three different helicity state signal processes were used as well as a single template representing the different background contributions, namely single top quark production, processes with misidentified leptons, production of Z bosons with additional jets and diboson production. All templates were obtained from simulation, except the misidentified leptons template, which was obtained from data.

A binned likelihood fit was used to estimate the expected number of events contributing to the distribution, assuming independent Poisson-distributed fluctuations in each bin. The number of events expected in the ith bin, λ_i, is given as:

$$\lambda_i = \sum_{h=-1,0,+1} \lambda_i^h \cdot \epsilon^h + \sum_{j=1}^{N_{\mathrm{bkg}}} \lambda_i^j \,, \tag{4.2}$$

where the first term describes the expected number of signal events at particle level with defined helicity h. These are reduced by reconstruction efficiencies and acceptances summarized by the factors ϵ^h estimated from simulation. The second term describes the expected number of events from background processes and N_{bkg} is the number of background templates. The contributions of the various background templates were constrained according

JHEP06(2012)088

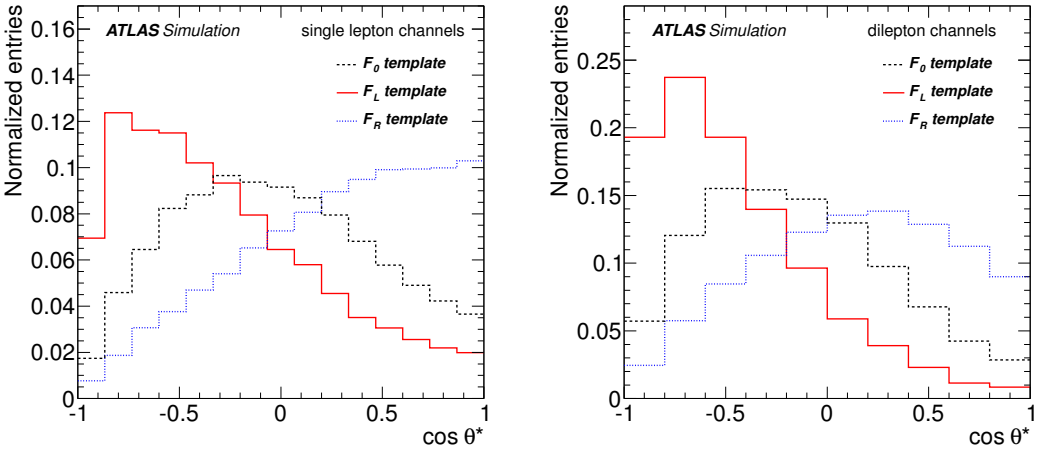

Figure 3. Distributions of $\cos\theta^*$ for each of the three simulated signal templates. The templates for the combined (left) single-lepton and (right) dilepton channels are shown.

to the central values and uncertainties given in table 1 and table 2. The uncertainties were assumed to be uncorrelated.

4.2 Measurement using the angular asymmetries

The angular asymmetries were measured using the $\cos\theta^*$ distribution obtained by reconstructing the events with a χ^2 minimization technique in the single-lepton channels [44]. The χ^2 was defined according to:

$$\chi^2 = \frac{(m_{\ell\nu j_a} - m_t)^2}{\sigma_t^2} + \frac{(m_{j_b j_c j_d} - m_t)^2}{\sigma_t^2} + \frac{(m_{\ell\nu} - m_W)^2}{\sigma_W^2} + \frac{(m_{j_c j_d} - m_W)^2}{\sigma_W^2} \,, \qquad (4.3)$$

where $m_t = 172.5\,\text{GeV}$, $m_W = 80.4\,\text{GeV}$, $\sigma_t = 14\,\text{GeV}$ and $\sigma_W = 10\,\text{GeV}$ are the expected top quark and W boson mass resolutions, ℓ represents the selected electron or muon, $m_{\ell\nu}$ is the invariant mass of the electron (muon) and the neutrino, and $j_{a,b,c,d}$ corresponds to all possible combinations of four jets among all selected jets in the event (with $m_{\ell\nu j_a}$, $m_{j_b j_c j_d}$ and $m_{\ell\nu j_a}$ being the corresponding invariant masses). The neutrino was reconstructed using the missing transverse energy, with the longitudinal component of the neutrino momentum (p_z^ν) allowed to vary. The solution corresponding to the minimum χ^2 value is chosen. No b-tagging information was used in resolving the ambiguities in assigning jets.

The method described in the previous subsection was used to reconstruct dilepton $t\bar{t}$ events.

For the measurement of the angular asymmetries, A_+ and A_-, the $\cos\theta^*$ distribution was divided into four non-uniform bins, which were used to count the number of events above and below $z = \pm(1 - 2^{2/3})$, as defined in Equation 1.2. A background subtraction in the observed $\cos\theta^*$ distribution was performed. Subsequently, the following steps were applied iteratively: the number of reconstructed events above and below $\cos\theta^* = z$ were counted in data for each asymmetry and correction factors were evaluated by comparing

JHEP06(2012)088

the Standard Model expectation with the reconstructed number of simulated $t\bar{t}$ events. These factors allowed corrections to be made for event selection and reconstruction effects. The obtained angular asymmetries were then converted into W boson helicity fractions and these values were used to re-derive the $\cos\theta^*$ distribution and evaluate new correction factors. The procedure was repeated until the method converged, i.e. until the differences between the output observables and the input hypothesis at the previous iteration step were below 0.5%. Closure tests were performed using Monte Carlo samples with different helicity fractions and no bias was observed.

5 Systematic uncertainties

5.1 Sources of systematic uncertainty

Several sources of systematic uncertainty were taken into account in the analyses presented here. These were categorized into the modelling of the signal and background processes, and the detector modelling. The impact of the systematic uncertainties on the final results is summarized in table 3.

5.1.1 Signal and background modelling

The signal process was modelled with different Monte Carlo generators. Sources of systematic uncertainty considered here were the choice of generator and parton shower model, the choice of parton distribution functions, the assumed top quark mass and the choice of parameters which control the amount of initial and final state radiation. Predictions from the MC@NLO and POWHEG generators were compared. The parton showering was tested by comparing two POWHEG samples interfaced to HERWIG and PYTHIA, respectively. The amount of initial and final state radiation was varied by modifying parameters in ACERMC interfaced to PYTHIA. The parameters were varied in a range comparable with those used in the Perugia Soft/Hard tune variations [45]. The impact of the choice of parton distribution functions was studied using the reweighting procedure described in ref. [44]. MC@NLO samples were generated assuming different top quark masses and their predictions were compared. The observed differences in the results were scaled to variations of 0.9 GeV in the top quark mass according to the uncertainty on its Tevatron average value [3]. The impact of different models of colour reconnection was studied by comparing samples simulated with ACERMC using the Perugia 2010 tune with and without colour reconnection [45] as well as the tune A-Pro and ACR-Pro [46, 47].

Background processes were either modelled by simulation or were estimated in auxiliary measurements. The number of events with misidentified leptons was estimated in data for each channel [40] and the uncertainty on the normalization was estimated to be 50% before and 100% after the b-tagging requirement. The normalization of W+jets processes was estimated from supplementary measurements using the asymmetric production of positively and negatively charged W bosons. The uncertainty was estimated using Berends-Giele-scaling [48] which yielded 48% for events with four jets and increased with the jet multiplicity by 24% per additional jet [39]. Systematic uncertainties on the shapes of the W+jets distributions were assigned based on samples with different simulation parameters such as

JHEP06(2012)088

the minimum transverse momentum of the parton and the functional form of the factorization scale in Alpgen. Scaling factors correcting the fraction of heavy flavour contributions in simulated W+jets samples were estimated in auxiliary measurements described in ref. [40]. The uncertainties were 76% for $Wb\bar{b}$+jets and $Wc\bar{c}$+jets contributions, and 35% for Wc+jets contributions. The uncertainty on the normalization of Z+jets events was estimated using Berends-Giele-scaling. The uncertainties in the normalization were 48% for events with four jets and increased with the jet multiplicity by 24% per additional jet. A systematic uncertainty in the shape was accounted for by comparing simulated samples generated with Alpgen and Sherpa. The uncertainty on the normalization of the small background contributions from single top quark and diboson production was estimated to be about 10% (depending on the channel) and 5%, respectively. The former estimate was based on the difference between the predictions from MC@NLO and MCFM [49], whereas the latter comes from scale and PDF uncertainties evaluated with MCFM.

For the template method, the bin content in each template was varied according to a Poisson distribution to estimate the impact of the finite Monte Carlo sample size used. For the measurement of the angular asymmetries, the $t\bar{t}$ reconstruction parameters were varied. In the single-lepton channels, the top quark and W boson mass resolutions used in the χ^2 definition were changed by 25%. For the dilepton channels, the assumed top quark mass window used in the kinematic equations was reduced by 50%, taking the difference in the observables with respect to the nominal procedure as the uncertainty estimate. The uncertainty due to the finite Monte Carlo sample size was found to be negligible since fewer bins were used in the unfolding than for the templates. These sources of uncertainty are labelled "method-specific uncertainties" in table 3.

5.1.2 Detector modelling

The mis-modelling of lepton trigger, reconstruction and selection efficiencies in simulation was corrected for by scale factors derived from auxiliary measurements of the processes $Z \to \mu\mu$ and $Z \to ee$ [50, 51]. The uncertainties were evaluated by changing the event selection of the supplementary measurement and by testing the stability of the results against changing LHC and ATLAS run conditions. The same processes were used to measure the lepton momentum scale and resolution. Scale factors and their uncertainties were derived to match the simulation to observed distributions. Details are given in ref. [39].

The jet energy scale was derived using information from test-beam data, LHC collision data and simulation. Its uncertainty varies between 2.5% and 7% in the central η region, depending on jet p_{T} and η [52]. This includes uncertainties in the flavour composition of the samples and mis-measurements from close-by jets. An additional p_{T}-dependent uncertainty of up to 2.5% was assigned to jets matched to b-quarks (using Monte Carlo generator-level information) due to differences between light-quark and gluon jets as opposed to jets containing b-hadrons. Additional uncertainties of up to 5% (8%) in the central (forward) region were added due to pileup. The energy resolution for jets in Monte Carlo simulation was adjusted to that observed in data. Uncertainties on the energy resolution of 4–45%, decreasing with jet p_{T}, were assigned. The reconstruction efficiency of jets was found to be in good agreement with the predictions from simulation and uncertainties of 1–2% were assigned.

Table 3. Sources of systematic uncertainty and their impact on the measured W boson helicity fractions for the combined single-lepton and dilepton channels. The systematic uncertainties were symmetrized by using the larger uncertainty.

JHEP06(2012)088

The uncertainties on the momenta of electrons, muons and jets were propagated into the missing transverse momentum. A 10% uncertainty from pileup was added in addition.

The b-tagging efficiencies and mis-tag rates have been measured in data [42]. Jet p_T-dependent scale factors, applied to simulation to match the data, have uncertainties which range from 9% to 16% and 12% to 45%, respectively.

The uncertainty on the measured luminosity was estimated to be 3.7% [15].

Due to a hardware failure, a small, rectangular region of the ATLAS electromagnetic calorimeter could not be read out in a subset of the data ($0.87\,\text{fb}^{-1}$). Data and Monte Carlo events in which a jet or an electron were close to the affected calorimeter region were rejected. The systematic uncertainty labelled "calorimeter readout" in table 3 was evaluated by varying the criteria to reject these events.

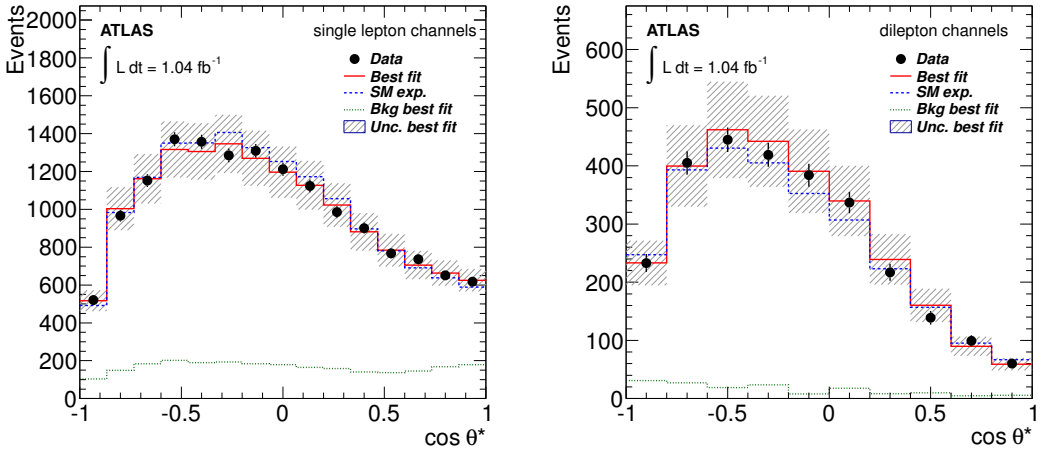

Figure 4. Distributions of the reconstructed $\cos\theta^*$ used in the template method for data (markers), fitted background (dotted line), the Standard Model prediction (dashed line) and the best fit value (solid line) for the (left) single-lepton and (right) dilepton channels. The total uncertainties on the helicity fractions for the best fit values are represented by the grey band. For the dilepton channels, each event contributed with two entries, corresponding to the two leptonic decays of the W bosons.

6 Results

The two methods discussed in section 4 were applied to the data set described in section 2. Figure 4 shows the observed distribution of $\cos\theta^*$ in the single-lepton and dilepton channels together with the sum of the templates scaled to the best fit parameters obtained from the template method as well as the Standard Model expectations. Figure 5 shows the distribution of $\cos\theta^*$ in the single-lepton and dilepton channels after the background subtraction and the correction for detector and reconstruction effects as used by the asymmetry method as well as the Standard Model expectations.

The combination of the individual measurements of the W boson helicity fractions (F_0 and F_L) and asymmetries (A_+ and A_-) in the single-lepton and dilepton channels was done using the best linear unbiased estimator (BLUE) method [53, 54]. The impact of the systematic uncertainties described in section 5 was studied and the results are summarized in table 4, which also gives the combination of all channels for each method. The results are compatible with each other and with the final combination. In addition, the template fit was repeated with F_R fixed to zero.[3] With the precision of the current measurements, this differs negligibly from the Standard Model value, and also follows the approach suggested in ref. [13]. The results can also be found in table 4.

The results for the angular asymmetries from the single-lepton channels are $A_+ = 0.52 \pm 0.02$ (stat.) ± 0.03 (syst.) and $A_- = -0.84 \pm 0.01$ (stat.) ± 0.02 (syst.) whereas

[3] In the evaluation of the angular asymmetries no assumption is made for the helicity fractions, so it is not possible to fix F_R to zero.

JHEP06(2012)088

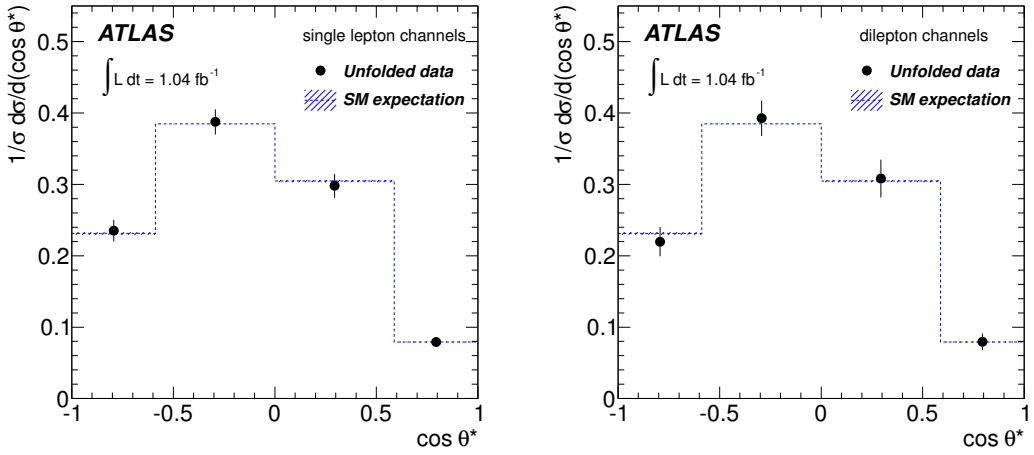

Figure 5. Unfolded distributions of $\cos\theta^*$ for the (left) single-lepton and (right) dilepton channels. The error bars on unfolded data (markers) include both the statistical and systematic contributions. For comparison, the Standard Model NNLO QCD prediction (dashed line) and its uncertainty [4] are also shown.

the results for the dilepton channels are $A_+ = 0.56 \pm 0.02$ (stat.) ± 0.04 (syst.) and $A_- = -0.84 \pm 0.02$ (stat.) ± 0.04 (syst.).

Most of the measurements and the combined result are limited by systematic uncertainties. The largest sources of uncertainty are the signal and background modelling, as well as the jet energy scale and jet reconstruction. The template fits are more sensitive to shape-related uncertainties, such as ISR/FSR and jet reconstruction, while the angular asymmetries are more sensitive to background normalization uncertainties, due to the background subtraction which needs to be performed.

6.1 Combination

The results presented in the previous sections were combined using the BLUE method. Both the statistical correlations between analyses, and the correlations of systematic uncertainties, were taken into account. The statistical correlations were estimated to be between 40% and 49% for the single-lepton channels and between 83% and 89% for the dilepton channels using pseudo-experiments obtained from simulated samples. The background-related systematic uncertainties were assumed to be fully correlated within single-lepton channels and within dilepton channels, but uncorrelated between single-lepton and dilepton measurements. The only exception is the uncertainty due to misidentified lepton background which depends on the lepton flavour and thus belongs to the group of lepton-related uncertainties, which were assumed to be fully correlated between the channels with same flavour leptons. The method systematic uncertainties were assumed to be uncorrelated between channels and the remaining sources of systematic uncertainty were assumed to be fully correlated between channels. Various tests were performed in which the correlations among the sources of systematic uncertainty were varied. It was found that the values

JHEP06(2012)088

Channel	F_0	F_L	F_R
W boson helicity fractions from the template fit			
Single leptons	$0.57 \pm 0.06 \pm 0.09$	$0.37 \pm 0.03 \pm 0.04$	$0.07 \pm 0.03 \pm 0.06$
Dileptons	$0.92 \pm 0.10 \pm 0.10$	$0.17 \pm 0.06 \pm 0.07$	$-0.09 \pm 0.05 \pm 0.06$
Combination	$0.66 \pm 0.06 \pm 0.07$	$0.33 \pm 0.03 \pm 0.03$	$0.01 \pm 0.03 \pm 0.06$
F_R fixed	$0.66 \pm 0.03 \pm 0.04$	$0.34 \pm 0.03 \pm 0.04$	0 (fixed)
W boson helicity fractions from the angular asymmetries			
Single leptons	$0.66 \pm 0.03 \pm 0.08$	$0.33 \pm 0.02 \pm 0.05$	$0.01 \pm 0.01 \pm 0.04$
Dileptons	$0.74 \pm 0.06 \pm 0.10$	$0.27 \pm 0.03 \pm 0.05$	$-0.01 \pm 0.03 \pm 0.05$
Combination	$0.67 \pm 0.04 \pm 0.07$	$0.32 \pm 0.02 \pm 0.04$	$0.01 \pm 0.02 \pm 0.04$
Overall combination	$0.67 \pm 0.03 \pm 0.06$	$0.32 \pm 0.02 \pm 0.03$	$0.01 \pm 0.01 \pm 0.04$

Table 4. Summary of the W boson helicity fractions measured using the two different techniques described and the combination. The quoted uncertainties are the statistical (first) and the systematic (second) uncertainties.

assumed for the correlations were conservative. The systematic uncertainties on the combined values are summarized in table 3. The four measurements of the helicity fractions and the combined values are shown in table 4 and figure 6.

The individual measurements agree reasonably well within their total uncertainties. The χ^2/dof for the global combination of the template fit and asymmetries measurements was 0.8 with a χ^2-probability of 75%, where dof is the number of degrees of freedom. The largest difference between two measurements is that between the single-lepton and dilepton channels obtained with the template method. Since the measurements were performed in five independent channels (single electron, single muon, ee, $e\mu$ and $\mu\mu$), the combination was performed based on the five individual measurements taking into account all correlations. The χ^2/dof calculated using the BLUE method for this combination was 1.3 with a χ^2-probability of 23%.

The combined W boson helicity fractions are:

$$\begin{aligned} F_0 &= 0.67 \pm 0.03\ (\text{stat.}) \pm 0.06\ (\text{syst.})\,, \\ F_L &= 0.32 \pm 0.02\ (\text{stat.}) \pm 0.03\ (\text{syst.})\,, \\ F_R &= 0.01 \pm 0.01\ (\text{stat.}) \pm 0.04\ (\text{syst.})\,. \end{aligned}$$

The correlation coefficient between F_0 and F_L was estimated to be -0.96. For completeness, these results can be translated into angular asymmetries, yielding $A_+ = 0.53 \pm 0.02$ and $A_- = -0.84 \pm 0.02$.

An alternative analysis, based on requiring two b-tagged jets to further suppress the W+jets background and events with misidentified leptons, was used to measure the helicity fractions in the single-lepton channels as a cross-check. The observed $\cos\theta^*$ distributions were corrected by subtracting the expected background contributions and were unfolded

JHEP06(2012)088

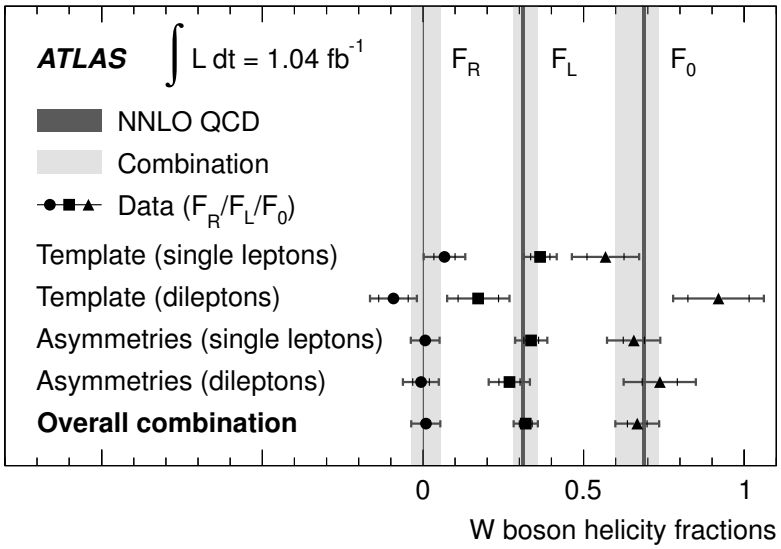

Figure 6. Overview of the four measurements of the W boson helicity fractions and the combined values. The error bars correspond to the statistical and total uncertainties.

using correction functions in an iterative method similar to the one used in the measurement of the angular asymmetries described in section 4.2. The results were found to be in agreement with the single-lepton measurements presented in this paper.

6.2 Constraints on the Wtb vertex structure

Any deviation of F_0, F_L, F_R (or A_+ and A_-) from the Standard Model prediction could be caused by new physics contributing to the Wtb vertex. Such new interactions associated with the top quark may exist at higher energies. New physics can be parameterized in terms of an effective Lagrangian [11] above the electroweak symmetry breaking scale of $v = 246$ GeV. After electroweak symmetry breaking, the Wtb Lagrangian [12, 55] is:

$$\mathcal{L}_{Wtb} = -\frac{g}{\sqrt{2}}\bar{b}\,\gamma^{\mu}\,(V_L P_L + V_R P_R)\,t\,W^-_{\mu} - \frac{g}{\sqrt{2}}\bar{b}\,\frac{i\sigma^{\mu\nu}q_{\nu}}{M_W}\,(g_L P_L + g_R P_R)\,t\,W^-_{\mu} + \text{h.c.}\,, \quad (6.1)$$

where P_L (P_R) is the left-handed (right-handed) chirality operator and

$$V_L = V_{tb} + C^{(3,3+3)}_{\phi q}\frac{v^2}{\Lambda^2}\,, \quad V_R = \frac{1}{2}C^{33*}_{\phi\phi}\frac{v^2}{\Lambda^2}\,, \quad g_L = \sqrt{2}C^{33*}_{dW}\frac{v^2}{\Lambda^2}\,, \quad g_R = \sqrt{2}C^{33}_{uW}\frac{v^2}{\Lambda^2}\,. \quad (6.2)$$

The parameter Λ is the new physics scale and $C^{(3,3+3)}_{\phi q}$, $C^{33*}_{\phi\phi}$, C^{33*}_{dW} and C^{33}_{uW} are the effective operator coefficients [13, 55]. The anomalous couplings V_R, g_L, g_R, generated by dimension-six operators, are absent in the Standard Model at tree level, while the coupling V_{tb} receives a correction from the operator $O^{(3,3+3)}_{\phi q}$.

Limits on anomalous couplings (V_R, g_L and g_R) were obtained from the combined measurement of the W boson helicity fractions by exploiting their dependence on these

JHEP06(2012)088

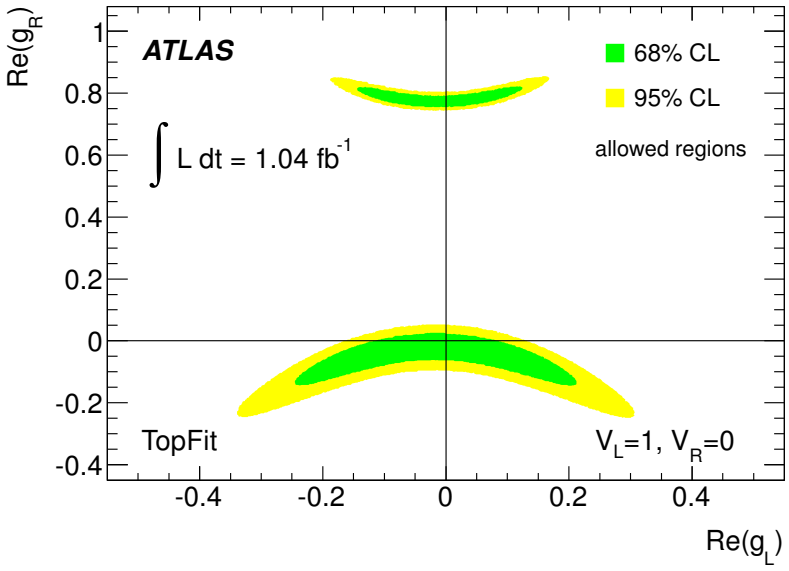

Figure 7. Allowed regions at 68% and 95% confidence level (CL) for the Wtb anomalous couplings g_{L} and g_{R}. In the Standard Model, the anomalous couplings vanish at tree level [59].

couplings, as implemented in the TopFit program [10, 56] and normalizing to $V_{\mathrm{L}} = 1$. The allowed regions of (g_{L}, g_{R}) are shown in figure 7, assuming $V_{\mathrm{R}} = 0$. The upper disconnected region in the plot shows a large-g_{R} second solution to the quadratic equation relating the observables to the anomalous couplings. However, this region is disfavored by the measured cross-section for single top production at the Tevatron [17, 57, 58].

In addition to this two-dimensional limit it is useful to set limits on single anomalous couplings, taking only one of them non-zero at a time. These are, at 95% confidence level,

$$\begin{aligned}
\mathrm{Re}\,(V_{\mathrm{R}}) \in [-0.20, 0.23] &\rightarrow \frac{\mathrm{Re}\,(C^{33}_{\phi\phi})}{\Lambda^2} \in [-6.7, 7.8] \ \ \mathrm{TeV}^{-2}\,, \\
\mathrm{Re}\,(g_{\mathrm{L}}) \in [-0.14, 0.11] &\rightarrow \frac{\mathrm{Re}\,(C^{33}_{dW})}{\Lambda^2} \in [-1.6, 1.2] \ \ \mathrm{TeV}^{-2}\,, \\
\mathrm{Re}\,(g_{\mathrm{R}}) \in [-0.08, 0.04] &\rightarrow \frac{\mathrm{Re}\,(C^{33}_{uW})}{\Lambda^2} \in [-1.0, 0.5] \ \ \mathrm{TeV}^{-2}\,.
\end{aligned}$$

The considered W boson helicity observables also allow a second region for g_{R} when the remaining anomalous couplings vanish: $\mathrm{Re}\,(g_{\mathrm{R}}) \in [0.75, 0.80]$ at 95% confidence level. It should be noticed, however, that such large coupling values would imply a single top production cross-section value disfavored by the Tevatron measurements [17, 57, 58]. Using a Bayesian approach [60], the measurement of the W boson helicity fractions with F_{R} fixed at zero, was translated into a 95% probability interval on $\mathrm{Re}\,(C^{33}_{uW})/\Lambda^2$, as proposed in ref. [13]. This interval was found to be $[-0.9, 2.3]$ TeV^{-2}.

It can be seen that the limits on C^{33}_{dW} (mediating the production of right-handed b-quarks in the top decay) are of the same order of magnitude as the limits on C^{33}_{uW} (involving

JHEP06(2012)088

left-handed quarks). This reflects a good sensitivity to the effective operator corresponding to C_{dW}^{33}, even if its contribution is suppressed by $1/\Lambda^2$ instead of $1/\Lambda$ [61].

These limits are more stringent than those obtained by the DØ Collaboration [58, 62].[4] Indirect, model-dependent limits on the anomalous couplings have been inferred from measurements of radiative B-meson decays, measurements of $B\bar{B}$-mixing and electroweak precision data [63–67], but these limits include assumptions on the absence of additional new physics effects that are not needed in this analysis.

7 Conclusions

A measurement of the polarization of the W bosons in top quark decays was presented, based on $1.04\,\text{fb}^{-1}$ of data collected with the ATLAS detector in 2011. The single-lepton and dilepton decay topologies of top quark pairs were considered in the analysis.

The helicity fractions obtained from a combination of template fits to the reconstructed $\cos\theta^*$ distributions and angular asymmetries calculated from the unfolded $\cos\theta^*$ distributions are $F_0 = 0.67 \pm 0.07$, $F_\text{L} = 0.32 \pm 0.04$ and $F_\text{R} = 0.01 \pm 0.05$. These results are in agreement with NNLO QCD predictions and are more precise than previous results obtained by the CDF and DØ Collaborations [6–8].

Limits on the Wtb vertex anomalous couplings were obtained from the combined results on the W boson helicity fractions. These results are consistent with the $(V-A)$ structure of the Wtb vertex and improve on the previously obtained limits [58].

Acknowledgments

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently.

We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWF, Austria; ANAS, Azerbaijan; SSTC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR and VSC CR, Czech Republic; DNRF, DNSRC and Lundbeck Foundation, Denmark; EPLANET and ERC, European Union; IN2P3-CNRS, CEA-DSM/IRFU, France; GNAS, Georgia; BMBF, DFG, HGF, MPG and AvH Foundation, Germany; GSRT, Greece; ISF, MINERVA, GIF, DIP and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; RCN, Norway; MNiSW, Poland; GRICES and FCT, Portugal; MERYS (MECTS), Romania; MES of Russia and ROSATOM, Russian Federation; JINR; MSTD, Serbia; MSSR, Slovakia; ARRS and MVZT, Slovenia; DST/NRF, South Africa; MICINN, Spain; SRC and Wallenberg Foundation, Sweden; SER, SNSF and Cantons of Bern and Geneva, Switzerland; NSC, Taiwan; TAEK, Turkey; STFC, the Royal Society and Leverhulme Trust, United Kingdom; DOE and NSF, United States of America.

The crucial computing support from all WLCG partners is acknowledged gratefully, in particular from CERN and the ATLAS Tier-1 facilities at TRIUMF (Canada), NDGF

[4]The limits from the DØ Collaboration were derived assuming a massless b-quark.

ABSTRACT

A measurement of the cross section of top quark pair production in proton–proton collisions recorded with the ATLAS detector at the Large Hadron Collider at a centre-of-mass energy of 7 TeV is reported. The data sample used corresponds to an integrated luminosity of 2.05 fb^{-1}. Events with an isolated electron or muon and a τ lepton decaying hadronically are used. In addition, a large missing transverse momentum and two or more energetic jets are required. At least one of the jets must be identified as originating from a b quark. The measured cross section, $\sigma_{t\bar{t}} = 186 \pm 13$ (stat.) ± 20 (syst.) ± 7 (lumi.) pb, is in good agreement with the Standard Model prediction.

1. Introduction

Measuring the top quark pair ($t\bar{t}$) production cross section ($\sigma_{t\bar{t}}$) in different decay channels is of interest because it can indicate physics beyond the Standard Model (SM). In the SM, the top quark decays with a branching ratio close to 100% into a W boson and a b quark, and $t\bar{t}$ pairs are identified by either the hadronic or leptonic decays of the W bosons and the presence of additional jets. The ATLAS Collaboration has previously used the single-lepton channel [1] from a 35 pb^{-1} data sample, and the dilepton channels including only electrons and muons [2] from a 0.7 fb^{-1} data sample, to perform cross-section measurements at 7 TeV proton–proton centre-of-mass energy. Similar measurements have been performed by the CMS Collaboration [3–5]. All these measurements are systematics limited.

The large data samples for $t\bar{t}$ production at the Large Hadron Collider (LHC) provide an opportunity to measure $\sigma_{t\bar{t}}$ using final states with an electron or a muon and a τ lepton with high precision. The $\sigma_{t\bar{t}}$ in this channel has been measured at the Tevatron in $p\bar{p}$ collisions at 1.96 TeV with 25% precision [6] and recently by the CMS Collaboration at the LHC with 18% precision [7]. A deviation from the value of $\sigma_{t\bar{t}}$ measured in other final states would be an indication of non-Standard Model decays of the top quark, such as a decay to a charged Higgs (H^+) and a b quark with H^+ decaying to a τ lepton and a τ neutrino, or of contributions from other non-Standard Model processes [8–10]. Upper limits on the branching ratio of top quark decays to H^+ bosons decaying to a τ lepton and a neutrino have been published by Tevatron and LHC experiments [11–13].

2. Analysis overview

This analysis uses 2.05 fb^{-1} of data collected by ATLAS from pp collisions in the LHC at a centre-of-mass energy of 7 TeV between March and August 2011. The $t\bar{t}$ events are selected with kinematic criteria that make use of the fact that they feature two W bosons and two b quarks. The selections favour events with one W decay to a charged ℓ (with ℓ denoting an electron or a muon; either prompt or from a τ lepton decay to ℓ) and a neutrino and the other W decays to a τ lepton and a neutrino with the τ lepton in turn decaying hadronically. In addition at least one jet is tagged (b-tag) as originating from a b quark (b-jet) by means of an algorithm that can identify b-jets with high efficiency while maintaining a high rejection of light-quark jets. Isolated electrons and muons are well identified, but because of the large cross section for multi-jet production the background from jets misidentified as isolated electrons or muons is not negligible. This background is reduced by requiring significant missing transverse momentum signalling the presence of energetic neutrinos. Hadronic τ lepton decays are more difficult to identify and require elaborate techniques to reject jets and electrons misidentified as a τ lepton.

Section 5 describes how the objects used in the event selection are defined. After all selections given in Section 5.2, the dominant background to the $t\bar{t} \to \ell + \tau + X$ channel is the $t\bar{t} \to \ell +$ jets channel in which the τ candidate is from jets misidentified as hadronic τ lepton decays. Therefore, τ lepton identification (τ ID) is critical

for separating signal and background. The τ ID methodology employed in this analysis exploits a multivariate technique to build a discriminant [14]. A boosted decision tree (BDT) algorithm is used [15,16]. The number of τ leptons in the selected samples is extracted by fitting the distributions of BDT outputs to background and signal templates. Section 6 describes how the background templates are constructed using control data samples. They exploit the fact that events with ℓ and τ candidates of opposite sign charge (OS) contain real τ leptons while those with same sign charge (SS) are pure background. Events with τ leptons are not all from $t\bar{t}$; the contribution from processes other than $t\bar{t} \to \ell + \tau + X$ is estimated from Monte Carlo simulation. Section 7 describes the fitting procedure and the results of the fit. The fit results are also checked using an alternative method, referred to as the "matrix method", based on a cut on the BDT output (Section 7.1). The measured cross section is given in Section 8 and the conclusions are in Section 9.

3. ATLAS detector

The ATLAS detector [17] at the LHC covers nearly the entire solid angle around the collision point.[1] It consists of an inner tracking detector surrounded by a thin superconducting solenoid, electromagnetic (EM) and hadronic calorimeters, and an external muon spectrometer incorporating three large superconducting toroid magnet assemblies. The inner tracking detector provides tracking information in a pseudorapidity range $|\eta| < 2.5$. The liquid-argon (LAr) EM sampling calorimeters cover a range of $|\eta| < 3.2$ with fine granularity. An iron-scintillator tile calorimeter provides hadronic energy measurements in the central rapidity range ($|\eta| < 1.7$). The endcap and forward regions are instrumented with LAr calorimeters for both EM and hadronic energy measurements covering $|\eta| < 4.9$. The muon spectrometer provides precise tracking information in a range of $|\eta| < 2.7$.

ATLAS uses a three-level trigger system to select events. The level-1 trigger is implemented in hardware using a subset of detector information to reduce the event rate to below 75 kHz. This is followed by two software-based trigger levels, level-2 and the event filter, which together reduce the event rate to about 300 Hz recorded for analysis.

4. Simulated event samples

Monte Carlo (MC) simulation samples are used to optimise selection procedures, to calculate the signal acceptance and to evaluate the background contributions from single top quark, WW, WZ and ZZ production and $Z \to \tau^+\tau^-$ decays. After event generation, all samples are processed with the GEANT4 [18] simulation of the ATLAS detector, the trigger simulation and are then subject to the same reconstruction algorithms as the data [19].

For the $t\bar{t}$ and single top quark final states, the next-to-leading-order (NLO) generator MC@NLO [20–22] is used with a top quark mass of 172.5 GeV and with the NLO parton distribution function (PDF) set CTEQ6.6 [23]. The MC@NLO program uses HERWIG [24] to simulate the parton shower and hadronise the partons. The "diagram removal scheme" is used to remove overlaps between the single top quark and the $t\bar{t}$ final states. The $t\bar{t}$ cross section is normalised to the prediction of HATHOR (164^{+11}_{-16} pb) [25], which employs an approximate next-to-next-to-leading-order (NNLO) perturbative Quantum Chromodynamics (QCD) calculation. The diboson samples are generated with HERWIG. W + jets events and Z/γ^* + jets events (with dilepton invariant mass $m_{\ell^+\ell^-} > 40$ GeV) are generated by the ALPGEN generator [26] with up to five outgoing partons from the hard scattering process, in addition to the lepton pairs.[2] The MLM matching scheme [27] of the ALPGEN generator is used to remove overlaps between matrix-element and parton-shower products. Parton evolution and hadronisation is handled by HERWIG, as is the generation of diboson events. The leading-order PDF set CTEQ6L is used for all backgrounds described above.

All samples that use HERWIG for parton shower evolution and hadronisation rely on JIMMY [28] for the underlying event model. The τ-lepton decays are handled by TAUOLA [29]. The effect of multiple pp interactions per bunch crossing ("pile-up") is modelled by overlaying simulated minimum bias events over the original hard-scattering event [30]. MC events are then reweighted so that the distribution of interactions per crossing in the MC simulation matches that observed in data. The average number of pile-up interactions in the sample is 6.3.

5. Object identification and event selection

The event selection uses nearly the same object definition as in the $t\bar{t}$ cross-section measurement in the dilepton channel [2] with the exception of a τ candidate instead of a second electron or muon candidate. The electrons must be isolated and have $E_{\mathrm{T}} > 25$ GeV and $|\eta_{\mathrm{cluster}}| < 2.47$, excluding the barrel-endcap transition region ($1.37 < |\eta_{\mathrm{cluster}}| < 1.52$), where E_{T} is the transverse energy and η_{cluster} is the pseudorapidity of the calorimeter energy cluster associated with the candidate. The electron is defined as isolated if the E_{T} deposited in the calorimeter and not associated with the electron in a cone in η–ϕ space of radius $\Delta R = 0.2$ is less than 4 GeV. The muons must also be isolated and have transverse momentum $p_{\mathrm{T}} > 20$ GeV and $|\eta| < 2.5$. For isolated muons, both the corresponding E_{T} and the analogous track isolation transverse momentum must be less than 4 GeV in a cone of $\Delta R = 0.3$. The track isolation p_{T} is calculated from the sum of the track transverse momenta for tracks with $p_{\mathrm{T}} > 1$ GeV around the muon. Jets are reconstructed with the anti-k_t algorithm [31] with a radius parameter $R = 0.4$, starting from energy deposits (clusters) in the calorimeter reconstructed using the scale established using $Z \to e^+e^-$ events for electromagnetic objects. These jets are then calibrated to the hadronic energy scale using p_{T}- and η-dependent correction factors obtained from simulation [32]. The jet candidates are required to have $p_{\mathrm{T}} > 25$ GeV and $|\eta| < 2.5$. A jet is tagged as a b-jet by a vertex tagging algorithm that constructs a likelihood ratio of b- and light-quark jet hypothesis using the following discriminating variables: the signed impact parameter significance of well measured tracks associated with a given jet, the decay length significance associated with a reconstructed secondary vertex, the invariant mass of all tracks associated to the secondary vertex, the ratio of the sum of the energies of the tracks associated with the secondary vertex to the sum of the energies of all tracks in the jet assuming a pion hypothesis, and the number of two-track vertices that can be formed at the secondary vertex. The cut on the combined likelihood ratio has been chosen to give an average efficiency of 70% for b-quark jets from $t\bar{t}$ events and a 1% efficiency for light-quark and gluon jets [33].

[1] Atlas uses a right-handed coordinate system with its origin at the nominal interaction point in the centre of the detector and the z-axis along the beam pipe. The x-axis points to the centre of the LHC ring, and the y-axis points upwards. The azimuthal angle ϕ is measured around the beam axis and the polar angle θ is the angle from the beam axis. The pseudorapidity is defined as $\eta = -\ln[\tan(\theta/2)]$. The distance ΔR in η–ϕ space is defined as $\Delta R = \sqrt{(\Delta\phi)^2 + (\Delta\eta)^2}$.

[2] The fraction of events with $m_{\ell^+\ell^-} < 40$ GeV is estimated to be less than 0.2% of the total after all selections. The estimate is based on ALPGEN samples for Drell–Yan simulation and confirmed by a good agreement with data.

The missing transverse momentum is constructed from the vector sum of all calorimeter cells with $|\eta| < 4.5$, projected onto the transverse plane. Its magnitude is denoted $E_{\mathrm{T}}^{\mathrm{miss}}$. The hadronic energy scale is used for the energies of cells associated with jets; τ candidates are treated as jets. Contributions from cells associated with electrons employ the electromagnetic energy calibration. Contributions from the p_{T} of muon tracks are included, removing the contributions of any calorimeter cells associated with the muon.

5.1. τ reconstruction and identification

The reconstruction and identification of hadronically decaying τ leptons proceed as follows:

1. the τ candidate reconstruction starts by considering each jet as a τ candidate;
2. energy clusters in the calorimeter associated with the τ candidate are used to calculate kinematic quantities (such as E_{T}) and the associated tracks are found;
3. identification variables are calculated from the tracking and calorimeter information;
4. these variables are combined into multivariate discriminants and the outputs of the discriminants are used to separate jets and electrons misidentified as τ leptons decaying hadronically from τ leptons.

Details, including the variable definitions used in the multivariate discriminants, are given in Ref. [9]. In this analysis the outputs of BDT discriminants are used.

Reconstructed τ candidates are required to have 20 GeV $< E_{\mathrm{T}} <$ 100 GeV. They must also have $|\eta| < 2.3$, and one, two or three associated tracks. A track is associated with the τ candidate if it has $p_{\mathrm{T}} > 1$ GeV and is inside a cone of $\Delta R < 0.4$ around the jet axis. The associated track with highest p_{T} must have $p_{\mathrm{T}} > 4$ GeV. The charge is given by the sum of the charges of the associated tracks, and is required to be non-zero. The probability of misidentifying the τ lepton charge sign is about 1%. The charge misidentification rate for muons and electrons is negligible.

If the τ candidate overlaps with a muon (with $p_{\mathrm{T}} > 4$ GeV and without an isolation requirement) or an electron candidate within $\Delta R(\ell, \tau) < 0.4$, the τ candidate is removed. To remove electrons misidentified as τ leptons, an additional criterion is used that relies on a BDT trained to separate τ leptons and electrons (BDT_e) using seven variables shown to be well modelled by comparing $Z \to e^+e^-$ and $Z \to \tau^+\tau^-$ events in data and in MC simulation. The variables were chosen after ranking a large set by their effectiveness.[3] The most effective variables for BDT_e are E/p, the EM fraction (the ratio of the τ candidate energy measured in the EM calorimeter to the total τ candidate energy measured in the calorimeter), and the cluster-based shower width. The BDT output tends to be near 1 (0) if the τ candidate is a τ lepton (electron). BDT_e was trained using $Z \to e^+e^-$ and $Z \to \tau^+\tau^-$ Monte Carlo samples. The τ candidate is required to satisfy $\mathrm{BDT}_e > 0.51$; 85% of reconstructed τ leptons decaying hadronically satisfy this requirement, as measured in $Z \to \tau^+\tau^-$ events. The additional rejection for electrons is a factor of 60.

The majority of objects reconstructed as τ candidates in a multi-jet environment are jets misidentified as τ leptons. A jet or an electron misidentified as a τ lepton will be referred to as a fake τ. Another BDT (BDT_j) based on eight variables is used to separate τ leptons in τ candidates with one track (denoted τ_1) from such jets. For candidates with more than one track (denoted τ_3) BDT_j includes ten variables. The BDT_j was trained using multi-jet events as background and $Z \to \tau^+\tau^-$ Monte Carlo as signal. The most effective variables for BDT_j are calorimeter and track isolation, cluster-based jet mass, and the fraction of energy within $\Delta R = 0.1$ of the jet axis. The BDT_j distributions are fit with templates for background and signal to extract the number of τ leptons in the sample. Details are given in Section 7. The fake τ background in the τ_3 sample is significantly higher than in the τ_1 sample, leading to very different BDT_j distributions. Hence independent measurements are carried out for τ_1 and τ_3 candidate events and the results are combined at the end. If there is a τ_1 and a τ_3 candidate in the event, the τ_1 candidate is kept as the probability that the τ_1 is a τ lepton is much higher. If there are two τ_1 or τ_3 candidates, both are kept.

5.2. Event selection

For this analysis, events are selected using a single-muon trigger with a p_{T} threshold of 18 GeV or a single-electron trigger with a p_{T} threshold of 20 GeV, rising to 22 GeV during periods of high instantaneous luminosity. The offline requirements are based on data quality criteria and optimised using Monte Carlo simulation:

- a primary vertex with at least five tracks, each with $p_{\mathrm{T}} >$ 400 MeV, associated with it;
- one and only one isolated high-p_{T} muon and no identified electrons for the $\mu + \tau$ channel, or one and only one isolated electron and no isolated muons for the $e + \tau$ channel;
- at least one τ candidate (as defined in Section 5.1);
- at least two jets not overlapping with a τ candidate, i.e. $\Delta R(\tau, \mathrm{jet}) > 0.4$;
- $E_{\mathrm{T}}^{\mathrm{miss}} > 30$ GeV to reduce the multi-jet background, and the scalar sum of the p_{T} of the leptons (including τ), jets, and $E_{\mathrm{T}}^{\mathrm{miss}}$ must be greater then 200 GeV, to reduce the $W +$ jets background.

The $\ell + \tau$ samples are divided into events with no jets identified as a b-quark jet (0 b-tag control sample) and those with at least one such jet ($\geqslant$1 b-tag $t\bar{t}$ sample). The 0 b-tag sample is used to estimate the background in the $\geqslant$1 b-tag $t\bar{t}$ sample. Each sample is split into two, one with the τ candidate and ℓ having the opposite sign charge (OS), and the other one with τ and ℓ having the same sign charge (SS). While the τ candidates in the SS samples are almost all fake τ leptons, the OS samples have a mixture of τ leptons and fake τ leptons. The numbers of observed and expected events in the above samples are shown in Table 1. The $\ell +$ jets entry is the contribution from all processes with a ℓ and a τ candidate that is a jet misidentified as a τ lepton other than from $t\bar{t}$ ($\to \ell +$ jets). The τ entries require the reconstructed τ candidate be matched to a generated τ lepton. The matching criterion is $\Delta R < 0.1$ between the τ candidate and the observable component of the generated τ lepton.

To estimate the multi-jet background from data, an event selection identical to the $\mu + \tau$ ($e + \tau$) event selection except for an inverted muon (electron) isolation cut is used to obtain a multi-jet template for the shape of the transverse mass, $m_{\mathrm{T}} = \sqrt{(E_T^{\ell} + E_{\mathrm{T}}^{\mathrm{miss}})^2 - (p_x^{\ell} + E_x^{\mathrm{miss}})^2 - (p_y^{\ell} + E_y^{\mathrm{miss}})^2}$. The normalisation of each selected data sample is obtained by fitting the m_{T} distribution of the selected data samples with the multi-jet template and the sum of non-multi-jet processes predicted by MC, allowing the amount of both to float. The uncertainty on the multi-jet

[3] The effectiveness is quantified by quadratically summing over the change in the purity between the mother and daughter leaves for every node in which the given variable is used in a decision tree.

Table 1
Number of $\ell+\tau$ candidates for Monte Carlo samples and data. $t\bar{t}(\ell+e)$ are $t\bar{t}$ events with one identified lepton and an electron reconstructed as a τ candidate. $t\bar{t}(\ell+\text{jets})$ are $t\bar{t}$ events with one identified lepton and a jet reconstructed as a τ candidate. $\ell+\text{jets}$ are events with one identified lepton and a jet reconstructed as a τ candidate from sources other than $t\bar{t}(\ell+\text{jets})$ and multi-jets. Sources contributing to jet fakes are $W+\text{jets}$, $Z+\text{jets}$, single top quark, diboson events and $t\bar{t}$. $Wt(\ell+\tau)$ is $W+t$ production with one W decaying to ℓ and another to τ. The uncertainties are statistical only, except for the multi-jet estimates. MC samples are normalised to the data integrated luminosity.

background is estimated to be 30%. This estimate is only used to illustrate the background composition. The background models are derived from data (see Section 6) and do not depend on knowing the exact composition. All processes contribute more events to OS than SS because of the correlation between a leading-quark charge and the lepton charge, except for the multi-jet channel contribution which within uncertainties has equal numbers of OS and SS events. As one can see from Table 1, the τ leptons are almost all in the OS sample and come mainly from two sources: $Z\to\tau^+\tau^-$, which is the dominant source in the sample with 0 b-tag, and $t\bar{t}\to\ell+\tau+X$ which is the dominant source in the sample $\geqslant$1 b-tag. The sources of fake τ leptons are quite distinct between the 0 b-tag and the $\geqslant$1 b-tag samples: the first is mainly $W/Z+\text{jets}$ with small contributions from other channels, the second is mainly $t\bar{t}$.

6. Background models

The jet origin can strongly influence the τ-lepton fake probability. Due to their narrow shower width and lower track multiplicity, light-quark jets have a higher probability of faking a τ lepton than other jet types. Thus the BDT_j distributions have a strong dependence on the jet type. It is therefore crucial to build a background model which properly reflects the jet composition in order to correctly estimate the fake τ contamination in the signal region. Deriving this background model from control regions in data rather than MC simulation is preferable in order to avoid systematic effects related to jet composition in the MC models.

The gluon component of the fake τ leptons is charge symmetric; therefore it is expected to have the same shape in SS events as in OS events and should contribute the same number of fake τ leptons in each sample. The contribution of fake τ leptons from gluons can be removed by subtracting the distribution of any quantity for SS events from the corresponding distribution for OS events. The multi-jet background also cancels, as can be seen in Table 1. The resulting distributions are labelled OS-SS. Similarly, since each sample is expected to have an almost equal contribution from b-jets and $\bar{b}$-jets, the small b-jet component should also be removed by OS-SS (the asymmetry in b production, mainly from single top quark final states, is negligible). The only jet types remaining in the OS-SS distributions are light-quark jets. MC studies indicate that the BDT_j distributions of c-quark jets misidentified as τ leptons are not noticeably different from those of light-quark jets.

One can construct a background BDT_j distribution from the 0 b-tag data sample by subtracting the expected amount of τ-lepton signal. The signal is mainly from $Z\to\tau^+\tau^-$ and can be reliably predicted from MC. A control sample dominated by $W+\text{jets}$ events is considered as a check. The latter sample is selected by requiring events with a muon and a τ candidate, no additional jets, $E_{\text{T}}^{\text{miss}}>30$ GeV and 40 GeV $<m_{\text{T}}<100$ GeV. According to MC simulation, in $W+\text{jets}$ events where exactly one jet is required, 90% of the fake τ leptons are from light-quark jets and 10% from gluons. This sample is labelled $W+1$ jet.

The BDT_j background shapes for the OS-SS 0 b-tag and $\geqslant1$ b-tag data samples are not identical to the $W+1$ jet distributions for two reasons: (1) the shape depends on the jet multiplicity, (2) different OS/SS ratios are observed in the samples. The dependence on the OS/SS ratio comes from the differences in jet fragmentation producing a leading particle with the opposite charge and the same charge as the initial quark; thus the OS BDT_j shape from light-quark jets differs from the equivalent SS BDT_j shape. The ratio of OS-SS BDT_j background distributions derived from $W+1$ jet and $\geqslant1$ b-tag simulated events show that significant corrections are needed (30% for $\text{BDT}_j>0.8$, a region dominated by the true τ signal). For the 0 b-tag sample the corresponding corrections are much smaller (5% in the same region). Both the 0 b-tag and the $W+1$ jet data samples are used to obtain statistically independent estimates of the background in the $\geqslant1$ b-tag sample.

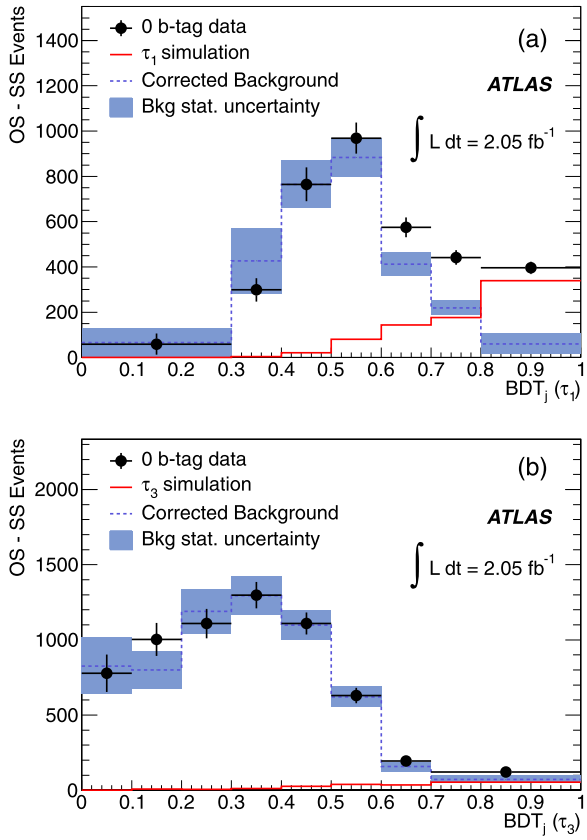

Fig. 1. BDT$_j$ (OS-SS) distributions of $\ell + \tau$ (e and μ combined) events in the 0 b-tag data (black points): (a) τ_1, (b) τ_3. The expected contributions from τ and e (sum of $Z \to \tau^+\tau^-$, single top and $t\bar{t} \to \ell + \tau + X$) are shown as a solid red line. The derived background templates after applying MC corrections are shown as dashed histogram with shaded/blue statistical uncertainty bands. The shapes of these background templates are used for the fits to the $\geqslant$1 b-tag distributions.

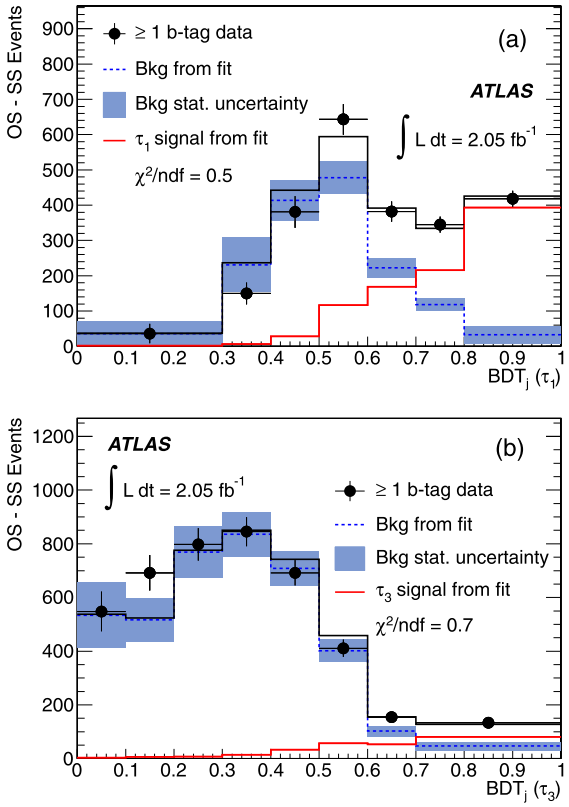

Fig. 2. BDT$_j$ (OS-SS) distributions of $\ell + \tau$ in the $\geqslant$1 b-tag sample; (a) τ_1, (b) τ_3. The normalisation of each template is derived from a fit to the data. The fitted contributions are shown as the light/red (signal), dashed/blue (background derived from 0 b-tag after applying MC corrections) and dark/black (total) lines. Shaded/blue bands are the statistical uncertainty of the background template.

Two different approaches are used for constructing backgrounds in the $\geqslant$1 b-tag data sample. One, used by the fit method (Section 7), is to reweight the BDT$_j$ distribution of the background bin-by-bin using the MC-based ratio of the $\geqslant$1 b-tag background to the background model. In this case the 0 b-tag sample is preferred as it requires smaller corrections derived from MC simulation; the $W + 1$ jet is used as a cross check. The other approach is to split the background into bins of some variable within which the shapes of BDT$_j$ distributions of the background model are close to those from the $\geqslant 1$ b-tag background. This approach, used in the matrix method cross check (Section 7.1), avoids using MC corrections, but assumes the data and MC simulation behave similarly as function of the binning variable.

7. Fits to BDT$_j$ distributions

The contribution from $t\bar{t} \to \ell + \tau + X$ signal is derived from the $\geqslant$1 b-tag data sample by a χ^2 fit to the OS-SS BDT$_j$ distribution with a background template and a signal template. The parameters of the fit are the amount of background and the amount of signal. The shapes of the templates are fixed.

Two statistically independent background templates corrected by MC, as discussed in Section 6, are used: one derived from 0 b-tag data, the other (purely as a check) derived from the $W + 1$ jet data sample. The signal BDT$_j$ templates for 0 b-tag and $\geqslant 1$ b-tag are derived from τ leptons in $t\bar{t}$ and $Z \to \tau^+\tau^-$ MC simulation. Contributions to the BDT$_j$ distributions from electrons passing the BDT$_e$ cut cannot be distinguished from τ leptons so they are treated as part of the signal.

The uncertainty on the background templates is determined by the numbers of data and MC simulated events. The signal template for the 0 b-tag control sample has a non-negligible statistical uncertainty (2% for τ_1, 5% for τ_3) because of the low acceptance.

The fitting procedure was tested extensively with MC simulation before applying it to data. In the fits to the $\geqslant$1 b-tag data, applying MC corrections to the 0 b-tag background template increases the statistical uncertainty because of the uncertainty due to the number of simulated events but raises the measured cross section by only 1%.

Fig. 1 shows the BDT$_j$ (OS-SS) distributions of $\ell + \tau$ events with 0 b-tag and the 0 b-tag background template after subtracting the expected number of τ leptons and applying the MC corrections. The τ signal is mostly $Z \to \tau^+\tau^-$ events with a small contamination of electrons faking τ leptons (from $t\bar{t} \to \ell + e + X$ and $Z \to e^+e^-$) and a small contribution from $t\bar{t} \to \ell + \tau + X$. The uncertainty on the background template includes the statistical uncertainty of the correction, the statistical uncertainty from MC and the 0 b-tag data uncertainty.

Fig. 2 shows the result of the fit to the $\geqslant$1 b-tag samples. The τ lepton signal is mostly $t\bar{t} \to \ell + \tau + X$ with a small contamination of misidentified electrons (estimated by applying fake probabilities derived from data), and small contributions from $Z \to \tau^+\tau^-$ events and single top quark events (estimated from MC simulation). These contributions are subtracted from the number of fitted τ lepton signal events before calculating the cross section. The fit results using the background templates derived from 0 b-tag data and $W + 1$ jet data are shown in Table 2. The results are consistent with each other within the statistical uncertainties of the background templates. The BDT$_j$ distributions for τ_1 and τ_3 are

Table 2
Results of template fits to $\mu+\tau$, $e+\tau$ and the combined BDT$_j$ distributions. The combined results are obtained by fitting the sum of the $\mu+\tau$ and $e+\tau$ BDT$_j$ distributions. The first column gives the channel and the second the τ type. The third column shows the extracted signal (sum of τ leptons and electrons misidentified as τ leptons) with the background template derived from 0 b-tag data distributions. The fourth column shows the extracted signal with the background template derived from $W+1$ jet. The uncertainties are from the uncertainties in the fit parameters and do not include the systematic uncertainties. The MC columns give the expected τ signal (includes the contribution of non-$t\bar{t}\to l+\tau$ events) and the expected number of $t\bar{t}\to l+\tau$ assuming the theoretical $t\bar{t}$ production cross section (164 pb).

		Background template		MC	
		0 b-tag	$W+1$ jet	Signal	$t\bar{t}$
$\mu+\tau$	τ_1	490 ± 40	456 ± 32	432	388
	τ_3	135 ± 33	130 ± 50	126	116
$e+\tau$	τ_1	440 ± 50	430 ± 50	388	338
	τ_3	116 ± 32	120 ± 28	114	101
Combined	τ_1	930 ± 70	860 ± 50	820	726
	τ_3	260 ± 60	260 ± 40	239	217

fitted separately. The combined $\ell+\tau_i$ results are obtained by fitting the sum of the distributions. After adding $\ell+\tau_1$ and $\ell+\tau_3$ signals obtained from a χ^2 fit to the combined $e+\tau$ and $\mu+\tau$ distributions and subtracting the small contributions to the signal from $Z\to\tau^+\tau^-$, $Z\to e^+e^-$ and $t\bar{t}\to e+\ell$ (given in Table 1), the results are 840 ± 70 (243 ± 60) $t\bar{t}\to\ell+\tau_1(\tau_3)+X$ events. The uncertainty is from the fit only and does not include systematic uncertainties. The results are in good agreement with the 780 ± 50 (243 ± 60) events obtained with the $W+1$ jet background template and consistent with the number expected from MC simulation, 726 ± 19 (217 ± 10). Note that the fit uncertainty is dominated by the uncertainties on the background template, thus the statistical uncertainties of the results with the two different background templates are not strongly correlated.

Fig. 3 shows the OS-SS distribution of the number of jets for $\geqslant 1$ b-tag events adding all channels for two BDT$_j$ regions: BDT$_j<0.7$, which is dominated by $t\bar{t}\to\ell+$jets, and BDT$_j>0.7$, in which the largest contribution is from $t\bar{t}\to\ell+\tau+X$. As expected, the multiplicity of jets peaks at four when BDT$_j<0.7$ and three when BDT$_j>0.7$ (the τ is counted as a jet). Fig. 4 shows the invariant mass of a selected jet with the τ candidate for BDT$_j<0.7$ and BDT$_j>0.7$ for events with a τ candidate and three or more jets. The selected jet is the highest p_{T} untagged jet in events with more than one b-tag and the second highest p_{T} untagged jet in events with one b-tag. The distribution shows clearly the presence of a W decaying to two jets in the BDT$_j<0.7$ region dominated by $t\bar{t}\to\ell+$ jets. The mass distribution in the BDT$_j>0.7$ signal region is significantly broader as expected for $t\bar{t}\to\ell+\tau+X$. The signal and background shown in these figures are based on the fit using the 0 b-tag background template.

7.1. Check with matrix method

From Figs. 3 and 4 one can see that a BDT$_j>0.7$ requirement separates well a region dominated by $t\bar{t}\to\ell+$jets from a region dominated by $t\bar{t}\to\ell+\tau+X$. One can extract the signal from the same OS-SS $\geqslant 1$ b-tag sample used by the fit method via a matrix method. All τ candidates are labelled "loose", and τ candidates with BDT$_j>0.7$ are labelled "tight". The probability that the loose τ candidates are also tight τ candidates, for both τ leptons and fake τ leptons, is defined as

$$\epsilon_{\mathrm{real}}=\frac{N^{\mathrm{tight}}_{\mathrm{real}}}{N^{\mathrm{loose}}_{\mathrm{real}}}\qquad \epsilon_{\mathrm{fake}}=\frac{N^{\mathrm{tight}}_{\mathrm{fake}}}{N^{\mathrm{loose}}_{\mathrm{fake}}}$$

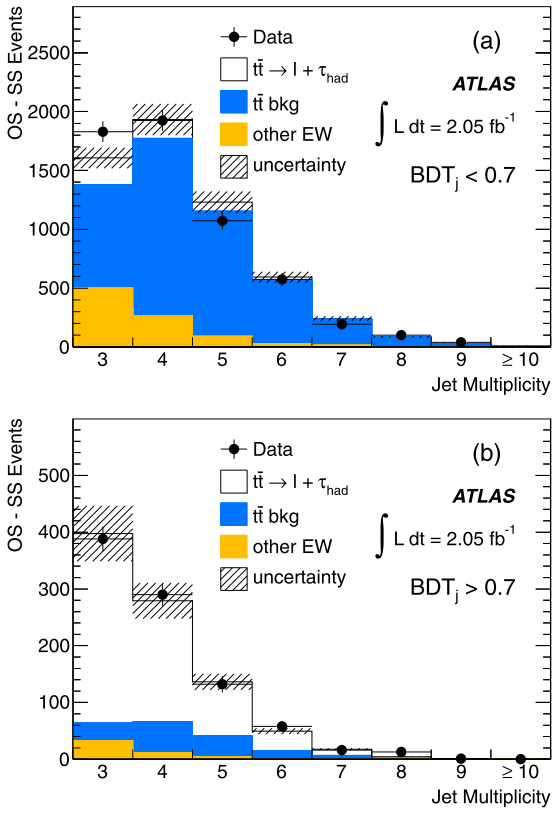

Fig. 3. OS-SS number of jets distributions for events with at least one b-tag. The $\mu+\tau$ and $e+\tau$ channels have been summed together. The solid circles indicate data and the histograms indicate the expected signal and backgrounds. The normalisation of the expected signal and the backgrounds are based on the fit result. The uncertainty includes statistical and systematic contributions. The fraction of each background is estimated from MC. (a) is for BDT$_j<0.7$, (b) for BDT$_j>0.7$.

where the "real" subscript denotes τ lepton, the "fake" subscript denotes fake τ and N is the number of τ candidates. The number of "tight" τ leptons is then given by

$$N^{\mathrm{tight}}_{\mathrm{real}}=N^{\mathrm{tight}}_{\mathrm{data}}-\frac{\epsilon_{\mathrm{fake}}}{\epsilon_{\mathrm{real}}-\epsilon_{\mathrm{fake}}}\left(N^{\mathrm{loose}}_{\mathrm{data}}\cdot\epsilon_{\mathrm{real}}-N^{\mathrm{tight}}_{\mathrm{data}}\right).$$

The value of ϵ_{fake} is measured utilising the OS-SS BDT$_j$ distributions from the background control samples; ϵ_{real} is derived from MC (including all processes that contribute a τ lepton or an electron misidentified as a τ lepton) and was tested using $Z\to\tau^+\tau^-$ events. This method uses the binning approach described in Section 6 to estimate the background. Values of ϵ_{fake} and ϵ_{real} are measured separately for three EM-fraction bins. The EM-fraction, the ratio of the energy measured in the EM calorimeter to the total τ candidate energy measured in the calorimeter, is an effective variable for splitting the data into regions where the shapes of MC OS-SS BDT$_j$ distributions for the $W+1$ jet background template and the $\geqslant 1$ b-tag background are similar. Table 3 shows the number of signal events obtained with the matrix method using the background derived from the 0 b-tag data sample and from the $W+1$ jet data sample. The numbers in each pair are in good agreement and consistent with the numbers obtained by fitting the OS-SS BDT$_j$ distributions.

7.2. Systematic uncertainty

Several experimental and theoretical sources of systematic uncertainty are considered. Lepton trigger, reconstruction and selection efficiencies are assessed by comparing the $Z\to\ell^+\ell^-$ events

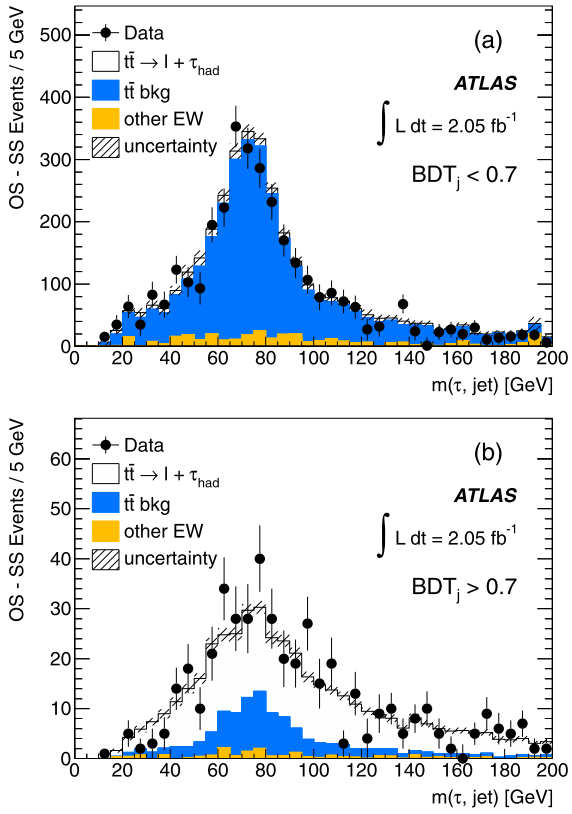

Fig. 4. OS-SS invariant mass of jet and τ candidate for events with at least one b-tag. The jet is the highest p_T untagged jet in events with more than one b-tag and the second highest p_T untagged jet in events with one b-tag. The $\mu+\tau$ and $e+\tau$ channels have been summed together. The solid circles indicate data and the histograms indicate the expected signal and backgrounds. The normalisation of the expected signal and the backgrounds are based on the fit result. The uncertainty includes statistical and systematic contributions. The fraction of each background is estimated from MC. (a) is for $\mathrm{BDT}_j < 0.7$, (b) for $\mathrm{BDT}_j > 0.7$.

Table 3
Number of signal events obtained with the matrix method for $\mu+\tau$, $e+\tau$ and the combined channels. The first column gives the channel and the second the τ type. The third column shows the extracted signal with the background template derived from 0 b-tag data distributions. The fourth column shows the extracted signal with the background template derived from $W+1$ jet. In order to compare the matrix method results to the fit results the number of signal events shown is $\sum N^{\mathrm{real}}_{\mathrm{tight}}/\bar{\epsilon}_{\mathrm{real}}$ where $\bar{\epsilon}_{\mathrm{real}}$ is the ϵ_{real} averaged over the three EM-fraction bins. The uncertainties are statistical only.

		Background template

selected with the same object criteria as used for the $t\bar{t}$ analysis in data and MC.

Scale factors are applied to $Z \to \tau^+\tau^-$ MC samples when calculating acceptances to account for any differences between predicted and observed efficiencies. The scale factors are evaluated by comparing the observed efficiencies with those determined with simulated Z boson events. Systematic uncertainties on these scale factors are evaluated by varying the selection of events used in the

Table 4
Relative systematic uncertainties, in %, for the cross-section measurement. The first column gives the source of systematic uncertainty, ID/Trigger stands for the combined uncertainty of lepton identification and lepton trigger. The τ ID uncertainty includes electrons misidentified as τ leptons. The second and third columns give the channel.

efficiency measurements and by checking the stability of the measurements over the course of data taking.

The modelling of the lepton momentum scale and resolution is studied using reconstructed invariant mass distributions of $Z \to \ell^+\ell^-$ candidate events and used to adjust the simulation accordingly [34,35].

The jet energy scale (JES) and its uncertainty are derived by combining information from test-beam data, LHC collision data and simulation [32]. For jets within the acceptance, the JES uncertainty varies in the range 4–8% as a function of jet p_{T} and η. Comparing MC and data the estimated systematic uncertainties are 10% and 1–2% for the jet energy resolution (JER) and the jet reconstruction efficiency, respectively. The uncertainty on the efficiency of the b-tagging algorithm has been estimated to be 6% for b-quark jets, based on b-tagging calibration studies [33].

The uncertainty in the kinematic distributions of the $t\bar{t}$ signal events gives rise to systematic uncertainties in the signal acceptance, with contributions from the choice of generator, the modelling of initial- and final-state radiation (ISR/FSR) and the choice of the PDF set. The generator uncertainty is evaluated by comparing the MC@NLO predictions with those of POWHEG [36–38] interfaced to either HERWIG or PYTHIA. The uncertainty due to ISR/FSR is evaluated using the AcerMC generator [39] (which relies on the MADGRAPH package [40]) interfaced to the PYTHIA shower model, and by varying the parameters controlling ISR and FSR in a range consistent with experimental data [19]. Finally, the PDF uncertainty is evaluated using a range of current PDF sets: NNPDF, CTEQ, and MSTW [41–43]. Each one comes with a set of error PDFs, the RMS of the variations was taken as the PDF uncertainty. The dominant uncertainty in this category of systematic uncertainties is the modelling of ISR/FSR.

The τ ID uncertainty is derived from a template fit to a $Z \to \tau^+\tau^-$ data sample selected with the same μ and τ candidate requirements as the sample for this analysis, but with fewer than two jets and $m_{\mathrm{T}} < 20$ GeV to remove $W+$jets events. The fit relies on the $W+1$ jet data sample for a background template and $Z \to \tau^+\tau^-$ MC events for a signal template. The uncertainty includes the statistical uncertainty of the data samples, the uncertainty in the Z/γ^* cross section measured by ATLAS [44] (excluding the luminosity uncertainty) and the jet energy scale uncertainty. It also includes the uncertainty on the number of misidentified electrons (<0.5%, determined from $Z \to e^+e^-$ data).

The effect of these variations on the final result is evaluated by varying each source of systematic uncertainty by $\pm 1\sigma$, applying the selection criteria to obtain new signal and background templates and recalculating the cross section.

Table 5
Measured cross section from the τ_1 and τ_3 samples, as well as the combination $(\tau_1+\tau_3)$ for each channel separately. The uncertainty in the integrated luminosity (3.7%) is not included.

	$\mu+\tau$
τ_1	189 ± 16 (stat.) ± 20 (syst.) pb
τ_3	180 ± 40 (stat.) ± 21 (syst.) pb
$\tau_1+\tau_3$	186 ± 15 (stat.) ± 20 (syst.) pb
	$e+\tau$
τ_1	190 ± 20 (stat.) ± 20 (syst.) pb
τ_3	170 ± 50 (stat.) ± 21 (syst.) pb
$\tau_1+\tau_3$	187 ± 18 (stat.) ± 20 (syst.) pb

The uncertainties obtained for the fit method using the 0 b-tag background template are shown in Table 4. The systematic uncertainties for the matrix method are very similar. The uncertainty on the measured integrated luminosity is 3.7% [45]. This translates into a 3.5% uncertainty on the cross section.

8. Measuring the $t\bar{t}$ cross section

The cross section is derived from the number of observed OS-SS signal events in the $\geqslant 1$ b-tag data sample assuming the only top quark decay mode is $t \to Wb$, and subtracting from that number the small contribution from $t\bar{t} \to e+\ell$ (from electrons faking τ leptons) and τ leptons from $Z \to \tau^+\tau^-$ (Table 1). The systematic uncertainties are estimated as the quadratic sum of all uncertainties given in Table 4, which includes the uncertainty from the subtraction.

The results are given separately for τ_1 and τ_3 and then combined (weighted by their statistical uncertainty and assuming all systematic uncertainties other than from τ ID are fully correlated). The results using the 0 b-tag background template are shown in Table 5.

The results for the $\mu+\tau$ and $e+\tau$ channels are combined taking into account the correlated uncertainties using the BLUE (Best Linear Unbiased Estimator) technique [46]. Combining them does not improve the systematic uncertainty as the systematic uncertainties are almost 100% correlated.

The results for each lepton type are:

$$\mu+\tau: \quad \sigma_{t\bar{t}} = 186 \pm 15\ (\text{stat.}) \pm 20\ (\text{syst.}) \pm 7\ (\text{lumi.})\ \text{pb},$$

$$e+\tau: \quad \sigma_{t\bar{t}} = 187 \pm 18\ (\text{stat.}) \pm 20\ (\text{syst.}) \pm 7\ (\text{lumi.})\ \text{pb},$$

Combining both channels one obtains:

$$\sigma_{t\bar{t}} = 186 \pm 13\ (\text{stat.}) \pm 20\ (\text{syst.}) \pm 7\ (\text{lumi.})\ \text{pb}.$$

To check the fit measurements, the cross sections can be calculated using the matrix method and the results obtained with the $W+1$ jet background to minimise the correlation with the fit results. The combination of the matrix method and the fit results with the BLUE method shows they are compatible at the 45% and 10% confidence level for $\mu+\tau$ and $e+\tau$, respectively.

9. Conclusions

The cross section for $t\bar{t}$ production in pp collisions at 7 TeV has been measured in the $\mu+\tau$ and the $e+\tau$ channels in which the τ decays hadronically. The number of τ leptons in these channels has been extracted using multivariate discriminators to separate τ leptons from electrons and jets misidentified as hadronically decaying τ leptons. These numbers were obtained by fitting the discriminator outputs and checked with a matrix method. Combining the measurements from $\mu+\tau$ and $e+\tau$ events, the cross section is measured to be

$$\sigma_{t\bar{t}} = 186 \pm 13\ (\text{stat.}) \pm 20\ (\text{syst.}) \pm 7\ (\text{lumi.})\ \text{pb},$$

in good agreement with the cross section measured by ATLAS in other channels [1,2], with the cross-section measurements by the CMS Collaboration [3–5,7] and with the SM prediction, 164^{+11}_{-16} pb [25].

Acknowledgements

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently.

We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWF, Austria; ANAS, Azerbaijan; SSTC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR and VSC CR, Czech Republic; DNRF, DNSRC and Lundbeck Foundation, Denmark; EPLANET and ERC, European Union; IN2P3-CNRS, CEA-DSM/IRFU, France; GNAS, Georgia; BMBF, DFG, HGF, MPG and AvH Foundation, Germany; GSRT, Greece; ISF, MINERVA, GIF, DIP and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; RCN, Norway; MNiSW, Poland; GRICES and FCT, Portugal; MERYS (MECTS), Romania; MES of Russia and ROSATOM, Russian Federation; JINR; MSTD, Serbia; MSSR, Slovakia; ARRS and MVZT, Slovenia; DST/NRF, South Africa; MICINN, Spain; SRC and Wallenberg Foundation, Sweden; SER, SNSF and Cantons of Bern and Geneva, Switzerland; NSC, Taiwan; TAEK, Turkey; STFC, the Royal Society and Leverhulme Trust, United Kingdom; DOE and NSF, United States of America.

The crucial computing support from all WLCG partners is acknowledged gratefully, in particular from CERN and the ATLAS Tier-1 facilities at TRIUMF (Canada), NDGF (Denmark, Norway, Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy), NL-T1 (Netherlands), PIC (Spain), ASGC (Taiwan), RAL (UK) and BNL (USA) and in the Tier-2 facilities worldwide.

Measurement of the cross section for top-quark pair production in pp collisions at $\sqrt{s} = 7$ TeV with the ATLAS detector using final states with two high-p_{T} leptons

The ATLAS collaboration

Abstract: A measurement is reported of the production cross section of top-quark pairs ($t\bar{t}$) in proton-proton collisions at a center-of-mass energy of 7 TeV recorded with the ATLAS detector at the LHC. Candidate events have a signature consistent with containing two isolated leptons, large missing transverse momentum, and at least two jets. Using a data sample corresponding to an integrated luminosity of $0.70\,\mathrm{fb}^{-1}$, a $t\bar{t}$ production cross section $\sigma_{t\bar{t}} = 176 \pm 5(\mathrm{stat.})^{+14}_{-11}(\mathrm{syst.}) \pm 8(\mathrm{lum.})$ pb is measured for an assumed top-quark mass of $m_t = 172.5$ GeV. This measurement is in good agreement with Standard Model predictions.

1 Introduction

As the heaviest known elementary particle, the top quark is a particularly interesting probe of the Standard Model (SM). The measurement of the $t\bar{t}$ production cross section in different decay modes is a sensitive test of perturbative QCD and the SM description of top-quark decay. The production cross section in proton-proton (pp) collisions at a center-of-mass energy $\sqrt{s} = 7$ TeV is calculated to be 165^{+11}_{-16} pb at approximate next-to-next-to-leading-order (NNLO) [1, 2], and the top quark is predicted to decay nearly 100% of the time to a W boson and a b quark. A measured cross section that differs from the SM prediction can be a sign of new physics. Furthermore, $t\bar{t}$ production is an important background in many searches for physics beyond the SM, and in searches for the SM Higgs boson.

The $t\bar{t}$ event topologies are determined by the decays of the two W bosons. In increasing order of $t\bar{t}$ branching fraction: dilepton final states occur when both W bosons decay to a charged lepton and a neutrino, 'lepton plus jets' final states when only one W boson decays leptonically while the other decays to a pair of quarks, and all-hadronic final states when both W bosons decay to pairs of quarks.

Top-quark production in dilepton final states has been studied using proton-antiproton collisions at $\sqrt{s} = 1.96$ TeV [3, 4] and Large Hadron Collider (LHC) measurements of the production cross section in proton-proton collisions at $\sqrt{s} = 7$ TeV in the same final state have recently been reported [5, 6]. A measurement is presented of the $t\bar{t}$ production cross

section using the dilepton channel, characterized by two opposite-sign leptons, unbalanced transverse momentum indicating the presence of neutrinos from the W-boson decays, and two b-quark jets. This result uses twenty times more data than the previous ATLAS measurement in the same final state, reported in ref. [6].

The $t\bar{t}$ dilepton final states can be selected with a good signal-to-background ratio using simple kinematic requirements. With the additional requirement of the presence of a jet consistent with a b quark ('b-tag'), the signal-to-background ratio can be further improved. Cross-section measurements with and without the b-tag requirement are reported here. Leptons are either well-identified electron or muon candidates that are selected using the full detector or, to reduce losses from lepton identification inefficiencies, isolated tracks. The well-identified electrons or muons are called 'identified leptons', and the isolated tracks are referred to as 'track leptons'. The term 'lepton' is used to refer to identified leptons and track leptons collectively. Events with one identified lepton and one track lepton are called 'lepton+track' events. Each dilepton channel is exclusive, i.e. has no overlap with the other channels. Channels with tau leptons are not explicitly reconstructed, but reconstructed leptons can arise from leptonic tau decays and a track lepton can arise from hadronic tau decay modes as well. The analysis with the b-tag requirement uses only identified leptons.

The measured cross section takes into account the $t\bar{t}$ signal acceptance and the expected background contributions from Z/γ^*+jets, single top quarks, WW, WZ, and ZZ events, and events with misidentified leptons (primarily W+jets events). Background contributions from $Z/\gamma^* \to ee$+jets, $Z/\gamma^* \to \mu\mu$+jets and events with misidentified leptons are evaluated directly from the data. All other background contributions are evaluated using Monte Carlo (MC) simulation samples.

2 Detector and data sample

The ATLAS detector [7] at the LHC covers nearly the entire solid angle around the collision point. It consists of an inner tracking detector (ID) comprising a silicon pixel detector, a silicon microstrip detector (SCT), and a transition radiation tracker. The ID is surrounded by a thin superconducting solenoid providing a 2 T magnetic field, and by liquid-argon electromagnetic sampling calorimeters (LAr) with high granularity. An iron-scintillator tile calorimeter provides hadronic energy measurements in the central pseudorapidity[1] range ($|\eta| < 1.7$). The end-cap and forward regions are instrumented with LAr calorimetry for both electromagnetic (EM) and hadronic energy measurements up to $|\eta| < 4.9$. The calorimeter system is surrounded by a muon spectrometer incorporating three superconducting toroid magnet assemblies, with bending power between 2.0 and 7.5 Tm.

A three-level trigger system is used to collect data. The first-level trigger is implemented in hardware and uses a subset of the detector information to reduce the rate to at

[1] In the right-handed ATLAS coordinate system, the pseudorapidity η is defined as $\eta = -\ln[\tan(\theta/2)]$, where the polar angle θ is measured with respect to the LHC beamline. The azimuthal angle ϕ is measured with respect to the x-axis, which points towards the centre of the LHC ring. The y-axis points up. Transverse momentum and energy are defined as $p_{\mathrm{T}} = p\sin\theta$ and $E_{\mathrm{T}} = E\sin\theta$, respectively.

JHEP05(2012)059

most 75 kHz. This is followed by two software-based trigger levels that together reduce the event rate to ~ 300 Hz.

The analysis uses collision data with a center-of-mass energy of $\sqrt{s} = 7$ TeV recorded in 2011, with an integrated luminosity of $0.70 \pm 0.03\,\text{fb}^{-1}$ [8, 9].

3 Simulated samples

Monte Carlo simulation samples are used to calculate the $t\bar{t}$ acceptance and to evaluate the background contributions from single top quarks, WW, WZ, and ZZ events, and $Z/\gamma^* \to \tau\tau$+jets. All MC samples are processed with the GEANT4 [10] simulation of the ATLAS detector [11] and events are passed through the same analysis chain as the data.

The generation of $t\bar{t}$ and single top-quark events uses the MC@NLO generator [12],[2] [13, 14] with the CTEQ6.6 [15] parton distribution function (PDF) set and a top-quark mass of 172.5 GeV. Expected $t\bar{t}$ yields are calculated with a cross section normalized to the prediction of HATHOR[16], which employs an NNLO perturbative QCD calculation. Single top-quark production with MC@NLO includes the s, t and Wt channels and the diagram-removal scheme [17] is used to reduce overlap with the $t\bar{t}$ final state.

Drell-Yan events (Z/γ^*+jets) are modeled with the ALPGEN generator, using the MLM matching scheme [18] and the CTEQ6L1 [19] PDF set. The Z/γ^*+jets samples, including both light and heavy flavor jets, are normalized to NNLO with a K-factor of 1.25. In the $Z/\gamma^* \to ee$ and $\mu\mu$ decay channels, the background from Z/γ^*+jets is evaluated using a data-driven technique that normalizes the MC expectation to the data observation near the Z pole. Background contributions from the W+jets final states come primarily from events where the W boson decays leptonically and the second lepton candidate is a misidentified jet or a heavy-flavor decay. Backgrounds from W+jets events are evaluated from the data.

All MC simulated events are hadronized using the HERWIG shower model [20, 21] supplemented by the JIMMY underlying event model [22]. Both hadronization programs are tuned to ATLAS data using the ATLAS MC10 tune [23]. Diboson events are modeled using the ALPGEN generator normalized with K-factors of 1.26 (WW), 1.28 (WZ) and 1.30 (ZZ) to match the total cross section from NLO QCD predictions using calculations with the MCFM program [24].

All Monte Carlo samples are generated taking into account that multiple pp interactions can occur in the same LHC bunch crossing within a given event ('pile-up'). The average number of interactions per crossing is 5.6 in this data set. The MC events are re-weighted so that the distribution of interactions per crossing in the MC matches that observed in the data.

4 Object selection

Leptons are required to be isolated and have high transverse momentum, p_{T}, consistent with originating from W-boson decay, with p_{T} thresholds chosen to ensure events are triggered with high efficiency.

[2] We use Version 3.41.

JHEP05(2012)059

Electron candidates are reconstructed from energy deposits (clusters) in the EM calorimeter, which are then associated to reconstructed tracks of charged particles in the inner detector. Stringent quality requirements on the conditions of the EM calorimeter at the time of data taking are applied to ensure a well measured reconstructed energy. A 'tight' selection [25] using calorimeter, tracking and combined variables, is employed to provide good separation between the signal electrons and background. Electron candidates are additionally required to have $p_{\mathrm{T}} > 25$ GeV and $|\eta_{cl}| < 2.47$, excluding electrons from the transition region between the barrel and endcap calorimeters defined by $1.37 < |\eta_{cl}| < 1.52$. The variable η_{cl} is the pseudorapidity of the energy cluster associated with the candidate.

Muon candidate reconstruction is begun by searching for track segments in layers of the muon chambers. These segments are combined starting from the outermost layer, fitted to account for material effects, and matched with tracks found in the inner detector. The candidates are refitted using the complete track information from both detector systems, and required to satisfy $p_{\mathrm{T}} > 20$ GeV and $|\eta| < 2.5$.

Lepton isolation requirements reduce backgrounds from misidentified jets and suppress the selection of leptons from heavy-flavor decays. For electron candidates, the transverse energy (E_{T}) deposited in the calorimeter not associated to the electron is summed in a cone of radius $\Delta R = 0.2$, where $\Delta R \equiv \sqrt{\Delta\eta^2 + \Delta\phi^2}$, around the electron and is required to be less than 3.5 GeV. For muon candidates, the isolation requirement is based on both calorimeter and track information. The track isolation requirement is based on the sum of the transverse momenta of tracks with $p_{\mathrm{T}} > 1\,\mathrm{GeV}$ in a cone $\Delta R = 0.3$ centered on the muon candidate, while the calorimeter isolation requirement is based on the sum of transverse energy in the same cone. Both the track and calorimeter sums are required to be less than 4 GeV. Additionally, muon candidates must have a distance $\Delta R > 0.4$ from any jet with $p_{\mathrm{T}} > 20\,\mathrm{GeV}$, further suppressing muon candidates from heavy flavor decays. Muon candidates arising from cosmic rays are rejected by removing candidate pairs that are back-to-back in the $r - \phi$ plane and with transverse impact parameters relative to the beam axis $|d_0| > 0.5$ mm.

Track-lepton (TL) candidates are defined by an ID track with $p_{\mathrm{T}} > 25$ GeV and a series of quality cuts optimized for high efficiency and a low rate of misidentification. The track must have at least six SCT hits and at least one hit in the innermost pixel layer. It also must have $|d_0| < 0.2$ mm and the uncertainty on the momentum measurement must be less than 20%. The track has to be isolated from other nearby tracks, following the track isolation defined above, in this case using tracks with $p_{\mathrm{T}} > 0.5$ GeV. The summed momentum cut is set to 2 GeV.

Jets are reconstructed with the anti-k$_t$ algorithm [26] with a radius parameter $R = 0.4$, starting from energy clusters in the calorimeter reconstructed using the scale established for electromagnetic objects. These jets are then calibrated to the hadronic energy scale using p_{T} and η dependent correction factors [27]. Jets are removed if they are within $\Delta R = 0.2$ of a well-identified electron candidate or a TL. The jets used in the analysis are required to have $p_{\mathrm{T}} > 25\,\mathrm{GeV}$ and $|\eta| < 2.5$.

Jets are identified as b-quark candidates ('b-tagged') by an algorithm that forms a likelihood ratio of b- and light-quark jet hypotheses using the following discriminating

JHEP05(2012)059

variables: the signed impact parameter significance of well measured tracks associated with a given jet, the decay length significance associated with a reconstructed secondary vertex, the invariant mass of all tracks associated to the secondary vertex, the ratio of the sum of the energies of the tracks associated with the secondary vertex to the sum of the energies of all tracks in the jet assuming a pion hypothesis, and the number of two-track vertices that can be formed at the secondary vertex [28]. The cut on the combined likelihood ratio has been chosen such that a b-tagging efficiency of $\approx 80\%$ per b-jet in $t\bar{t}$ candidate events is achieved.

The missing transverse momentum is formed from the negative vector sum of transverse momenta of all jets with $p_{\mathrm{T}} > 20\,\mathrm{GeV}$ and $|\eta| < 4.5$ [29]. The contribution from cells associated with electron candidates is replaced by the candidates' calibrated transverse energy. The contribution from all muon candidates and calorimeter clusters (including those not belonging to a reconstructed object) is also included. The symbol $E_{\mathrm{T}}^{\mathrm{miss}}$ is used to denote the magnitude of the missing transverse momentum.

5 Event selection

The analysis requires collision data selected by an inclusive single electron or muon trigger with offline-reconstructed candidates satisfying $p_{\mathrm{T}} > 25$ GeV for electrons, and $p_{\mathrm{T}} > 20$ GeV for muons, to ensure a constant trigger efficiency. To ensure that the event was triggered by the lepton candidates used in the analysis, one of the identified leptons and the triggered lepton are required to match within $\Delta R < 0.15$.

Events are required to have a primary interaction vertex with at least five tracks with $p_{\mathrm{T}} > 400$ MeV. The event is discarded if any jet with $p_{\mathrm{T}} > 20\,\mathrm{GeV}$ fails quality cuts designed to reject jets arising from calorimeter noise or activity inconsistent with the bunch-crossing time [27]. If an electron candidate and a muon candidate share a track, the event is also discarded.

The selection of events in the signal region consists of a series of kinematic requirements on the reconstructed objects. The requirements on $E_{\mathrm{T}}^{\mathrm{miss}}$, the lepton-lepton invariant mass ($m_{\ell\ell}$), and the scalar p_{T} sum of all selected jets and leptons (H_{T}) are optimized to minimize the expected total uncertainty on the cross-section measurement. The resulting event selection, referred to as the 'non-b-tag' selection, is listed below.

- Events must have exactly two oppositely-charged identified-lepton candidates (ee, $\mu\mu$, $e\mu$), satisfying the selection criteria of section 4, *or* if only one identified-lepton candidate is found, the event is retained if a track-lepton candidate is present, with opposite charge to the identified lepton, forming a lepton+track event (eTL or μTL).

- Events must have at least two jets with $p_{\mathrm{T}} > 25$ GeV and $|\eta| < 2.5$.

- Events in the ee, $\mu\mu$ eTL and μTL channels are required to have $m_{\ell\ell} > 15$ GeV in order to reject backgrounds from vector-meson decays. The requirement also helps to suppress backgrounds in these channels from b-quark production.

JHEP05(2012)059

- Events in the ee and $\mu\mu$ channels must satisfy $E_{\mathrm{T}}^{\mathrm{miss}} > 60$ GeV and $|m_{\ell\ell} - m_Z| > 10$ GeV, to suppress backgrounds from Z/γ^*+jets and multijets.

- Events in the $e\mu$ channel are required to satisfy $H_{\mathrm{T}} > 130$ GeV. No $E_{\mathrm{T}}^{\mathrm{miss}}$ or $m_{\ell\ell}$ cuts are applied.

- The lepton+track event candidates must have $E_{\mathrm{T}}^{\mathrm{miss}} > 45$ GeV, H_{T} (including the track lepton) > 150 GeV, and $|m_{\ell\ell} - m_Z| > 10$ GeV.

A parallel selection with the additional requirement of at least one b-tagged jet is made. Because of the enhanced background rejection afforded by the b-tag requirement, the selection is further optimized, resulting in an $E_{\mathrm{T}}^{\mathrm{miss}}$ requirement for ee and $\mu\mu$ events that is relaxed to $E_{\mathrm{T}}^{\mathrm{miss}} > 40$ GeV, while the H_{T} requirement for $e\mu$ events remains the same as for the non-b-tag selection, i.e. $H_{\mathrm{T}} > 130$ GeV. We refer to the analysis that requires at least one b-tagged jet as the 'b-tag analysis', and the events selected therein as the 'b-tagged sample'. The subset of the b-tagged sample with 40 GeV $< E_{\mathrm{T}}^{\mathrm{miss}} < 60$ GeV is referred to as the 'exclusive b-tagged sample' and has no overlap with the non-b-tag sample.

The acceptance times the branching fraction of $t\bar{t}$ to dileptons, for the selection described above, is 0.96% for the $ee + \mu\mu + e\mu$ channels without b-tagging, 0.11% for the exclusive b-tagged sample, and 0.19% for eTL + μTL channels.

6 Background evaluation

The $t\bar{t}$ event selection rejects Z/γ^*+jets events with ee and $\mu\mu$ invariant mass below 15 GeV, or within 10 GeV of the Z-boson mass. However, Z/γ^*+jets events with ee or $\mu\mu$ invariant mass outside of these regions can enter the signal sample when there is large $E_{\mathrm{T}}^{\mathrm{miss}}$, typically from mismeasurement. These events are difficult to properly model in simulations due to uncertainties on the non-Gaussian tails of the $E_{\mathrm{T}}^{\mathrm{miss}}$ distribution, on the cross section for Z boson production with multiple jets, and on the lepton energy resolution.

To evaluate the Z/γ^*+jets background in dielectron and dimuon events ($Z \to \tau\tau$ is considered below), the MC prediction for the number of events in the signal region is normalized to the data using the number of Z/γ^*+jets events measured in a control region [6]. The control region is formed by events with the same jet requirements as the signal region, but with $m_{\ell\ell}$ within 10 GeV of the Z-boson mass, and a $E_{\mathrm{T}}^{\mathrm{miss}}$ cut of $E_{\mathrm{T}}^{\mathrm{miss}} > 45$ GeV for the lepton+track candidates and $E_{\mathrm{T}}^{\mathrm{miss}} > 30$ GeV for the others. Contamination in the control region from other physics processes (signal and other background processes considered for the analysis) is subtracted according to MC predictions. The ratio of data events to MC expectation in the control region provides a scale factor that is used to correct the MC prediction for Z/γ^*+jets events in the signal region.

Other backgrounds mainly come from W+jets, $t\bar{t}$ lepton+jets, and single top-quark production with fake leptons. The term 'fake lepton' is used to refer to both misidentified and non-prompt lepton candidates, the latter category arising from hadron decays in

JHEP05(2012)059

flight. The yield of events with fake identified leptons is evaluated from the data using a matrix method [30]. In addition to the standard lepton selection requirements, a selection with a looser isolation requirement is defined. Dilepton events are selected using the loose isolation requirement and events are categorized according to whether each lepton passes the standard selection or the loose selection but not the standard selection. There are four such categories for the two leptons: loose-loose, loose-standard, standard-loose, and standard-standard. Each of the four categories is related to the number of events with two 'real' (prompt) leptons, two fake leptons, or one of each, through a set of linear equations with coefficients given by the products of probabilities for real or fake lepton satisfying the loose selection to also satisfy the standard selection. These linear expressions form a matrix that is inverted in order to extract the real and fake lepton content of the observed dilepton event sample. The probability for real leptons is measured as a function of jet multiplicity using data samples of $Z \to ee$ and $Z \to \mu\mu$ events. The corresponding probability for fake leptons is measured in a data sample dominated by dijet production, with events containing one lepton candidate passing the looser isolation cuts and having $E_{\mathrm{T}}^{\mathrm{miss}} < 20$ GeV. Contributions from real leptons due to W+jets final states are subtracted using simulated events.

For lepton+track events the largest background is from events with fake leptons, dominated by fake track leptons. The probability of a jet being reconstructed as a track lepton is determined from a γ+jets data sample selected with photon triggers. The fake probability is applied to a second sample enriched in W+jets events with exactly one identified lepton and no track leptons, but using the same kinematic cuts as for the signal sample. In this second sample the fake probabilities are summed for each jet in each event and the fake track-lepton contribution is calculated as a function of the number of jets.

The contributions from other electroweak background processes with two real leptons, such as single top quarks, $Z \to \tau\tau$, WW, ZZ and WZ production are determined from Monte Carlo simulations. The expected numbers of background events are given in table 1. The absence of Z/γ^*+jets background in the $e\mu$ channel, coupled with the larger branching fraction for the $e\mu$ signal, allows relatively loose selection criteria to be used in this channel.

The background contributions for the b-tag analysis are determined using the same techniques described above, with the additional requirement of a b-tagged jet.

The modeled acceptances, efficiencies and data-driven background evaluation methods are validated by comparing predictions from Monte Carlo simulations with data in control regions with kinematics similar to the signal region but dominated by backgrounds. In particular, the $E_{\mathrm{T}}^{\mathrm{miss}}$, $m_{\ell\ell}$ and jet multiplicity distributions are studied in a sample of Z-boson candidates, defined by requiring $|m_{\ell\ell} - m_Z| < 10$ GeV and $E_{\mathrm{T}}^{\mathrm{miss}} < 60\,\mathrm{GeV}$. The predictions from MC simulations in the control regions are in reasonable agreement with data, although small discrepancies exist in regions that do not affect the $t\bar{t}$ cross-section measurement.

Table 1. Breakdown of the expected $t\bar{t}$ signal and background events in the signal region compared to the observed event yields, for each of the dilepton channels. All systematic uncertainties are included, and correlations between different background sources are taken into account, when calculating the total background uncertainty. The largest contribution to the line labeled 'Fake leptons' comes from W+jets events.

7 Systematic uncertainties

A summary of the systematic uncertainties on the measured $t\bar{t}$ production cross section is given in table 2.

Lepton trigger efficiencies, and reconstruction and selection efficiencies for identified leptons and track leptons, are assessed using $Z \to ee$ and $Z \to \mu\mu$ events in the same data sample as used for the $t\bar{t}$ analyses. Scale factors are evaluated by comparing these efficiencies with those determined with simulated Z-boson events. The scale factors are applied to MC samples when calculating acceptances to account for any differences between predicted and observed efficiencies. Systematic uncertainties on these scale factors are evaluated by varying the selection of events used in the efficiency measurements and by checking the stability of the measurements over the course of the data-taking period.

The modeling of lepton momentum scale and resolution is studied using reconstructed dilepton invariant mass distributions of Z/γ^* candidate events, and the simulation is adjusted to match the data. Uncertainties in the scale and resolution are used to evaluate the systematic uncertainty due to these corrections. The acceptance uncertainty from the lepton modeling is dominated mostly by the electron selection efficiency uncertainty.

The jet energy scale (JES) and its uncertainty are derived by combining information from test-beam data, LHC collision data and simulation [27]. For jets within the acceptance, the JES uncertainty varies in the range 4–8% as a function of jet p_{T} and η. This uncertainty is higher than in the previous result [6] because of the additional uncertainty due to multiple pp interactions at high instantaneous luminosity. The jet energy resolution and jet reconstruction/identification efficiency measured in data and in simulation are in good agreement. The statistical uncertainties on the comparisons, 10% and 1–2% for the energy resolution and the efficiency, respectively, are taken as systematic uncertainties associated with these effects. The effect on the acceptance is dominated by the JES uncertainty.

JHEP05(2012)059

The systematic uncertainty on the efficiency of the b-tagging algorithm has been estimated to be 6% for b-quark jets, based on b-tagging calibration studies using inclusive lepton and multijet final states. The uncertainties on the tagging rates of jets from light and charm quarks are larger, but are not a significant source of uncertainty due to the intrinsically high signal-to-background ratios in the dilepton final states. The acceptance uncertainty due to b-tagging is about 3% for all three channels.

The uncertainty in the kinematic distributions of the $t\bar{t}$ signal events gives rise to systematic uncertainties in the signal acceptance, with contributions from the choice of generator, the modeling of initial- and final-state radiation (ISR/FSR) and the PDFs. The generator and parton-showering uncertainty (collectively labeled 'Generator' in table 2) are evaluated by comparing the MC@NLO predictions with those of POWHEG [31–33] interfaced to either HERWIG or PYTHIA. The uncertainty due to ISR/FSR is evaluated using the ACERMC generator [34] interfaced to the PYTHIA shower model, and by varying the parameters controlling ISR and FSR in a range consistent with those used in the Perugia Hard/Soft tune variations [35]. Finally, the PDF uncertainty is evaluated using a range of current PDF sets [19]. The dominant uncertainties in this category of systematics are the modeling of ISR/FSR and the generator choice.

The overall normalization uncertainties on the backgrounds from single top quark and diboson production are taken to be 8.6% [36] and 5% [37], respectively. The systematic uncertainties from the background evaluations derived from the data include the statistical uncertainties in these methods as well as the systematic uncertainties arising from lepton and jet identification and reconstruction, and the MC estimates that are used. An uncertainty on the data-driven Z/γ^*+jets evaluation, based on the expected $E_{\mathrm{T}}^{\mathrm{miss}}$ resolution in these events, is included by varying the $E_{\mathrm{T}}^{\mathrm{miss}}$ cut in the control region by ± 5 GeV for ee and $\mu\mu$ events, and ± 10 GeV in lepton+track events where the $E_{\mathrm{T}}^{\mathrm{miss}}$ resolution is poorer. The systematic uncertainty on the fake identified lepton background prediction is 50%, as measured using control regions with different flavor composition and photon conversion rates, as determined by Monte Carlo studies. A 20% systematic uncertainty is set on the prediction of the fake track-lepton background, derived from a comparison of predicted and observed fake track leptons in control regions defined as opposite-sign events with zero or one jet without an H_{T} cut, and same-sign events with more than one jet. The uncertainty on the measured integrated luminosity of the dataset is 3.7% [9].

Table 2 lists the contributions to the cross-section measurement of each of the systematic uncertainties considered, in percent, with the non-b-tag and the exclusive b-tag analyses combined in the ee and $\mu\mu$ columns. Only non-b-tag events are used in the $e\mu$ channel. The relatively large 'Generator' uncertainty for ee events is partly a result of the limited size of the MC data set. In the eTL and μTL columns the 'MC statistics' uncertainty is larger than in the ee, $\mu\mu$, and $e\mu$ case because the number of events available is reduced by the removal of events with two identified leptons. The combined uncertainty comes from the profile likelihood technique used to determine the cross section [6], and takes into account all correlations. The statistical uncertainty is determined by fixing all systematic uncertainties at their best-fit values in the likelihood function.

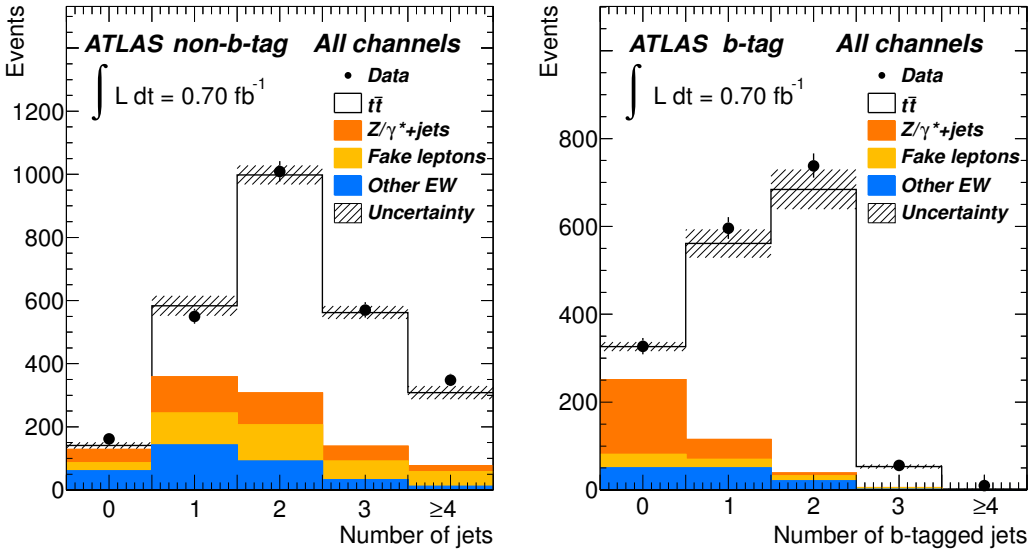
Table 2. Overview of the $t\bar{t}$ cross-section uncertainties.

8 Cross-section measurement

The expected and measured numbers of events in the signal region, after applying all selection cuts for each of the individual dilepton channels, are shown in table 1. A total of 1920 candidate events are observed for the analysis without b-tagging, and a total of 1400 candidate events are found for the b-tag analysis. There are 1221 events in common between the two selections, and 179 exclusive b-tagged events.

In figure 1 the number of selected jets and the expectation for 0.70 fb^{-1} are shown for the non-b-tag analysis with the five channels combined, and for the b-tag analysis with the three channels combined. In the non-b-tag case, all requirements except the jet multiplicity selection are applied, and in the b-tag case all requirements except the b-tag requirement are applied. The $E_{\mathrm{T}}^{\mathrm{miss}}$ distributions for the combination of the five non-b-tag and three b-tagged channels are shown in figure 2. All requirements except $E_{\mathrm{T}}^{\mathrm{miss}}$ are applied. The dominant backgrounds are Z/γ^*+jets and W+jets production with a fake lepton and, for the b-tag analysis, single-top events.

The cross-section results are obtained with a profile likelihood technique, as described in ref. [6]. The branching fraction for $t \to Wb$ is taken to be 100% and the acceptance is calculated for a top mass of 172.5 GeV.



The top-quark pair production cross section measured by combining the seven channels, the non-b-tagged ee, $\mu\mu$, $e\mu$, eTL and μTL and the exclusive b-tagged ee and $\mu\mu$, is

$$\sigma_{t\bar{t}} = 176 \pm 5(\mathrm{stat.})^{+14}_{-11}(\mathrm{syst.}) \pm 8(\mathrm{lumi.})\ \mathrm{pb}.$$

Figure 3 summarizes the cross sections for the individual channels, and the combination of the non-b-tag and the exclusive b-tagged data sets.

The measured cross section is in good agreement with a similar measurement made with 2010 data by the CMS collaboration [5], with an ATLAS measurement in the dilepton channel with earlier data [6], and with the SM prediction of 165^{+11}_{-16} pb. Compared to the earlier ATLAS measurement in the dilepton channel, the statistical uncertainty of the measurement has been reduced by a factor of four with the addition of more data, and a small reduction in the systematic uncertainty, which now dominates, has been achieved.

JHEP05(2012)059

(a) (b)

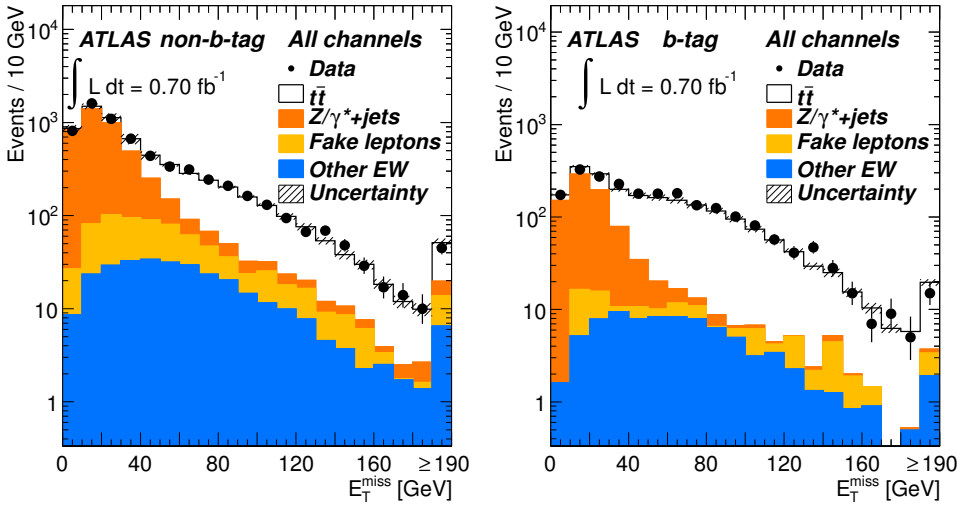


Figure 1. (a) Jet multiplicity distribution for ee+$\mu\mu$+$e\mu$+eTL+μTL events without a b-tagging requirement. (b) Multiplicity distribution of b-tagged jets in the ee+$\mu\mu$+$e\mu$ channels. Contributions from diboson and single top-quark events are summarized as 'Other EW'. The events in (b) are not a simple subset of those in (a) because the event selections for the b-tag and non-b-tag analyses differ. Uncertainties shown are statistical and systematic combined. The distributions are shown as stacked histograms.

Acknowledgments

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently.

計画研究 A05 班

課題名「テラスケール物理の理論的研究」

研究組織

(1) 研究代表者

野尻美保子　（NOJIRI, Mihoko）
大学共同利用機関法人・高エネルギー加速器研究機構・素粒子原子核機構・教授
研究者番号：30222201

(2) 研究分担者

兼村晋哉（KANEMURA, Shinya）
富山大学・大学院理工学研究部・准教授
研究者番号： 10362609

(3) 連携研究者

阿部智広（ABE, Tomohiro）
大学共同利用機関法人高エネルギー加速器研究機構素粒子原子核研究機構　素粒子原子核研究所
研究員
研究者番号：　70712727

交付決定額

計画研究 A05 班に配分された交付額を表 1 に示す。

表 1. 交付決定額（配分額）　（金額単位：円）

年度	直接経費	間接経費	合計
平成 23 年度	8,300,000	2,490,000	10,790,000
平成 24 年度	7,400,000	2,220,000	9,620,000
平成 25 年度	7,500,000	2,250,000	9,750,000
平成 26 年度	7,100,000	2,130,000	9,230,000
平成 27 年度	7,100,000	2,130,000	9,230,000
総計	37,400,000	11,220,000	48,620,000

研究成果

研究開始当初の背景

素粒子の標準理論の最大の謎である、ゲージ対称性の自発的破れや宇宙における暗黒物質の存在などは、テラスケールに新しい自然法則が存在することを示唆している。このテラスケール物理によって、ゲージ対称性が破れ、超高エネルギーでの力の統一理論から現在の自然界の多様性が生み出されたと考えられている。この研究計画実施時にこのテラスケール物理を探る LHC (Large Hadron Collider)実験が CERN で開始された。

LHC 実験では Higgs 粒子の発見によって、標準理論を完成させるほか、最大で数 TeV までの新粒子の探索することができる。このように高い成果が期待される LHC 実験ではあるが、ハドロンコライダーであるために、非常に多くのバックグラウンドがあり、たとえ新しい現象が存在しても、その発見は容易ではない。(LHC でのバックグラウンドの特徴は、多数のジェットが同時に生成される事象が多く、LHC での最新の実験結果をふまえた研究を理論・実験グループが緊密な連携をとって行う必要があった。　LHC で発見が期待されている新しい素粒子現象は、標準理論からの分布のズレである。様々な分布を精密に検討することで、発見された事象の背景にある素粒子現象を理解し、テラスケールの新しい物理を解明することが二つ目の目的である。まだ、LHC で発見が確実と考えられる Higgs 粒子についてはその性質をより幅広い視点から検討する必要があった。

2．研究の目的

本研究の目的は以下の３つである。(1)　QCD の理論的研究を行い LHC 実験での寺スケール物理探索のバックグラウンドを解明する。この研究により計画研究 A01~A04 が LHC 実験で新しい現象を確実に発見することをサポートする.(2) 標準模型からの分布のズレから新粒子の断面積、崩壊パターン、スピン、質量を測定する新しい解析方法を考案する。(3) テラスケールでの新物理を新しいパラダイム（時空、宇宙、宇宙 など）に転換する研究を行い、この実験的検証にむけた現象論的研究を行う。

3．研究の方法

高次補正を取り入れた QCD の研究を行う。特に摂動部と非摂動部の切り分けを理論的に行い理論的に安定な予言を導きデータとの比較を行う。
様々なモデルやパラメータが予言する信号のトポロジーを研究して信号から背後の物理を逆にたどることができる様にする。
運動量分布、不変質量分布やその組み合わせの分布やエッジから、新粒子の質量、スピン、崩壊分岐比を決める方法を複数確立する。
ヒッグス粒子の発見能力や測定精度を向上させるため、H23 年度の QCD の研究を基に、サブジェット解析等の研究を行う。標準理論を超えたヒッグス粒子の研究を行い発見されたヒッグスの性質を探る。
発見された新現象の背後に潜む原理や理論を探る. 特に暗黒物質の物理や、ヒッグス粒子の決定する真空の構造や安定性と関わる物理を研究する。
上記のような研究を行うためには最新の計算機の存在が必須であり、コア数の多い計算機の購入を行った。また、最初の 2 年は暗黒物質の物理に詳しい長尾氏、最後の 3 年間はヒッグス粒子の性質や複合模型に明るい阿部氏を雇用し連携研究者とした。また高ネエルギー加速器研究機構の萩原教授を連携として、Madgraph 等の高エネルギー物理関連ツールの利用や、QCD の高次計算について、適切な助言が受けられるようにした。研究体制としては、KEK の学生の久保田と Higgs 粒子と Radion 粒子の混合模型についての研究、KEK の学生の坂木氏と Jet の内部構造について研究を行った。また、IPMU では、学生の飛岡氏（現 Weisman 研究員） 張ヶ谷氏(現 バークレー研究員)、福田氏(現東大院生) IPMU　准教授の松本氏、PD の　Mandal, Mukhopadhyay, Bhattacherjee, 竹内、Han 各氏と暗黒物質や、ジェット構造についての共同研究を行った。

また、兼村は Higgs 粒子の発見を受けて、2011 年から 2015 年の期間に、富山大学でヒッグス物理やテラスケール物理に関する研究会と国際会議を 4 回主催した。また新ヒッグス勉強会(New Higgs Working Group)を主宰し 2012 年以降 2015 年までに 16 回の定例会を富山大学で開催してレポートを

まとめるとともに、多くの論文を執筆し発表を行った。

LHC 実験の理論的研究をしている研究者は欧米に多数いるため、研究会を開催したり、外国人ビジターを招聘する等した。特に、研究代表者が関わった主たる研究会として B4 班と共同で開催した “Physics Opportunities at LHC”201 2 年 2 月 16 日—18 日(KEK で開催) “Higgs as a Probe of New Physics 2013” 2013 年 2 月 13 日-16 日がある。

また、LHC の物理現象をモデル化する MC simulation は大変重要であるため、国際的なスクールを開催した。研究代表者が世話人として関わったものに、Monte Carlo Tools for LHC” School and Workshop を 2011 年 9 月 5 日-10 日に京都で開催), School on the Future of Collider Physics (16-19 July 2013, 東京大学 KIPMU) 2015 年には LHC RunII の開始をうけ、LHC 関係のツールの講習会(Collider 勉強会)を東京大学の諸井氏等（B05 班）の協力を得て 5 回開催した。

4．研究成果

野尻は科研費の研究期間中に１８件の原著論文を発表した。

[top partner の探索と性質の解明]

スカラートップ粒子崩壊から生成されトップ粒子の偏曲を利用して、スカラートップ粒子の右左混合を図る方法をを研究した。特にジェットの内部構造を利用した再構成方法の枠内でハドロニックなトップの崩壊についても偏曲の測定が可能であることを示した。

多くの標準模型を超える物理において、top 粒子のパートナー粒子であるフェルミオンの存在が予想される。このような粒子は、ht, Zt, bW といった終状態に崩壊することが期待されるが multi b-jet の final state に 着目することが、このような信号を取り出すことができることを明らかにした

[Higgs 粒子の性質]

LHC RUN1 でヒッグス粒子の分岐比にたいして標準模型からのずれがある可能性が指摘されたため、余剰次元模型の予言する Radion 粒子とヒッグス粒子の混合によってこのような異常がおこりうることを指摘した。その後この研究を発展させ、より高い精度の測定が期待できる ILC 実験によって Radion の質量が 10TeV をはるかに超える場合でも、標準模型からのずれを測定できることを示した。

LHC 実験の成功にともなって、ILC 実験が LHC 実験の後でも新物理探索に有効であるかを検討する必要が生じた。Higgs 粒子の精密測定によって明らかになる標準模型を超える物理の例として、超対象模型に着目し、スカラートップ粒子が LHC 実験で発見できないような場合でも、Higgs 粒子の分岐比の標準模型からのずれが ILC で観測できることをあきらかにするとともに, 真空の安定性の制限や、B の希少崩壊からの制限が Higgs 分岐比の標準模型からのずれを制限していることを明らかにした。

[jet の物理の研究]

quark から生成されるジェットと gluon から生成されるジェットでは、charged track の数やジェットの広さなどの性質が異なっている。このような性質を捉えて jet の起源を解明すれば new physics への感度を向上できると期待されるため、アルゴリズムの改善を行うとともに、縮退領域にある超対称模型において、実際に感度向上に役に立つことを指摘した。
[LHC 実験での新物理の兆候の研究]
LHC Run I 実験において 2TeV の gauge boson 信号に過剰があるという報告がなされた。この粒子は、主に W, Z の 2 体粒子に崩壊すると考えられた。この粒子の 13TeV での探索感度について検討を行うとともに、jet substructure を使った方法で, jet 内の number of charged track を background の評価に加えると background rejection の効率に大きな不定性がある問題を指摘した。
LHC Run II 実験のデータにおいて Diphoton イベントの過剰が報告された。重たいカラーをもつ粒子と暗黒物質が Z2 parity odd であるような模型において、heavy quark が束縛状態として生成され、それが、2 photon に消滅する場合に、このような信号が得られることを指摘した。さらに暗黒物質密度が適切な値であるためには、質量が縮退している必要があることを示し、LHC において、このような模型のパラメーターが mono jet search によって制限されていることを指摘した。また、750 GeV の信号を説明することができるパラメータがこのような制限のもとで、exclude されていないことを示した。

兼村は以下のような研究を行った。

発見されたヒッグス粒子の性質からヒッグスセクターの構造、ひいては新物理学の方向性を決定するための理論研究：
2012 年に LHC でヒッグス粒子は一つ発見されたが、ヒッグスセクターの構造は未知であり様々な拡張されたヒッグスセクターの可能性がある。本研究では、超対称性や複合ヒッグス模型等の新物理モデルに基づくヒッグスセクターや、一般の拡張ヒッグスセクターを考えた時、ヒッグス粒子の結合定数がどのようなパターンでずれるかを系統的に研究した。特に標準理論のヒッグス２重項場に付加的なヒッグス場が一個加わった拡張ヒッグスセクターに基づいてヒッグス結合に対する輻射補正を研究し、将来の加速器実験でヒッグス結合が精密に測定され、標準理論からのズレが検出された時に、そのズレのパターンからヒッグスセクターの構造、ひいては新物理理論の方向性を決定する可能性を明らかにした。
(2)第２のヒッグス粒子の探索に関する理論 研究：
様々な新物理モデルに導入される拡張ヒッグスセクターには特徴のある付加的ヒッグス場が現れる。本研究では、超対称性模型等に現れる輻射シーソーモデルなどに現れるヒッグス２重項場が２個あるモデルに出てくる第２のヒッグス粒子の LHC や ILC での探索可能性について系統的に研究した。また、タイプ２シーソー模型に現れるトリプレット場は複荷電ヒッグス場を予言する

が、このようなエキゾチックな場が LHC でどのように検証されるかを研究し、ダイボソン崩壊が支配的なシナリオにおける LHC からの質量のバウンドを正解で初めて求めた。
(3)様々な新物理パラダイムにおけるヒッグスポテンシャルの研究と、
実験での検証可能性の研究：
ヒッグス粒子の発見によって、ヒッグス機構や湯川相互作用等の標準理論の質量生成機構は実証された。しかし、電弱対称性の破れを担うヒッグスポテンシャルや背後のダイナミクスは依然として未知である。本研究では、軽いヒッグスを予言するが高エネルギーでヒッグスダイナミクスが強結合になる模型の詳細を研究し、ランダウポールの上の UV 理論の構築、低エネルギーでの現象論、ニュートリノ輻射生成や電弱バリオン数生成のシナリオの実現可能性を調べた。また古典的共形不変性に基づく電弱対称性の破れのモデルを研究し、そのヒッグスセクターの一般的性質を明らかにした。さらに最小複合ヒッグス理論のヒッグスセクターの性質を詳細に検討し、その現象論と加速器実験での検証可能性を明らかにした。
(4)ニュートリノ質量、暗黒物質、バリオン数生成に関する模型構築 とその現象論の研究：
B－L ゲージ対称性の自発的破れが引き金となって暗黒物質質量やニュートリノ質量が生成されるモデルを構築しその現象論を研究した。超対称性の枠組みで輻射シーソー模型を構築し、この模型に現れるマルチコンポネント暗黒物質の性質を調べ、検証可能性を研究した。電弱バリオン数生成のモデルを研究し、このシナリオの一般的特徴である強い一次的電弱相転移の実験的検証に関して、HL-LHC や ILC 等の将来加速器実験におけるヒッグス自己結合の測定と eLISA 計画などの将来重力波実験でのスペクトル測定による検証を研究し、その相補性を明らかにした。

5 年間のこれらの成果は、約 50 報の査読付き論文として出版するとともに多数の学会、国際会議で発表した。

科研費研究員として雇用したのは長尾氏と阿部智弘氏であり、このうち長尾氏の雇用期間中の論文は 2 件　阿部氏の雇用期間中の原著論文は 6 件であり、このうちの一件は野尻との共著である。阿部氏の研究のなかで、主たる成果は以下の通りである。
部分的に複合模型である模型を構築し、その現象論的特性を明らかにし、とくに、Higgs 発見当初に話題になっていた、Higgs 粒子が 2photon mode に崩壊する分岐比率にみられる excess が説明可能であることをあきらかにした。また 2TeV の diphoton についても、実験データの示唆する信号をこの模型で説明できるかを精密測定の制限をいれて調べ、13TeV の LHC 実験での検証可能性を明らかにした。
two Higgs doublet 模型で期待される EDM 模型の two loop の寄与を求めた
Higgs 粒子にのみ暗黒物質が結合するような模型を暗黒物質となる粒子のスピンによって分類し、暗黒物質が LHC や ILC で探索可能かを調べるとともに、暗黒物質密度や、その相互作用などをあきらかにした。

Type X の two Higgs doublet 模型の実験的な制限を詳細に調べ、LHC 等でのシグナルを検討した。なおこの研究によって阿部氏は素粒子メダル奨励賞を受賞した http://www2.yukawa.kyoto-u.ac.jp/~sg.www/syorei_s/result15/Smedal15.html

Abstract: Motivated by ATLAS diboson excess around 2 TeV, we investigate a phenomenology of spin-1 resonances in a model where electroweak sector in the SM is weakly coupled to strong dynamics. The spin-1 resonances, W' and Z', are introduced as effective degrees of freedom of the dynamical sector. We explore several theoretical constraints by investigating the scalar potential of the model as well as the current bounds from the LHC and precision measurements. It is found that the main decay modes are $V' \to VV$ and $V' \to Vh$, and the V' width is narrow enough so that the ATLAS diboson excess can be explained. In order to investigate future prospects, we also perform collider simulations at $\sqrt{s} = 13\,\text{TeV}$ LHC, and obtain a model independent expected exclusion limit for $\sigma(pp \to W' \to WZ \to JJ)$. We find a parameter space where the diboson excess can be explained, and are within a reach of the LHC at $\int dt\mathcal{L} = 10\,\text{fb}^{-1}$ and $\sqrt{s} = 13\,\text{TeV}$.

1 Introduction

The ATLAS experiment recently reported an excess of the events in the search for the diboson resonance, in the $pp \to (WW, WZ, \text{and } ZZ) \to JJ$ channels, where J is a fat-jet formed by boosted W or Z boson [1]. The largest local significance is 3.4 σ around 2 TeV in the WZ channel, and the global significance is 2.5 σ. The CMS experiment also studied the same channels. The largest deviation they found is 1.4 σ at $\sim$ 1.9 TeV [2]. Although we cannot conclude that there is a new particle with the mass around 2 TeV from this data, it is worthwhile to consider models which can explain this excess, and many papers have already appeared discussing interpretations of the excess [3–18]. As discussed in these references, a simple candidate is a spin-1 particle.

New vector resonances often appear in the models with dynamical symmetry breaking. Such spin-1 resonances appear in the composite Higgs scenario [19–22] with the dynamics

at TeV scale to account for the naturalness problem. Since the models are based on the non-Linear sigma models, the effective theory involves many operators whose coefficients are unknown. They possibly affect to the couplings of the new spin-1 particles to the standard model (SM) particles, and thus there is uncertainty in the prediction of the W' couplings.

Another way to include spin-1 particles is to extend the electroweak gauge symmetry. We can easily introduce new spin-1 particles in renormalizable manner. In that case, the models are calculable and we can avoid the operators whose coefficients are unknown, in contrast to the models based on the non-linear sigma models. Besides, some renormalizable models with extended gauge sector can be regarded as the low energy effective theory of UV theory with some dynamics.

Such renormalizable models have been discussed in the context of the left-right (LR) symmetric model [8, 17, 18] and the leptophobic G221 model [11]. These models contain the right-handed SM fermions which are not singlet under the new gauge symmetry. In such case, the couplings of the SM fermions to the new gauge boson are not suppressed, and the new gauge bosons mainly decay into the SM fermions.

It is also possible to use linear sigma model, instead of non-linear sigma models, for models emerged from the dynamics at TeV scale. An example was proposed in ref. [23]. This model, called the partially composite standard model, has three Higgs fields. Two of them are regarded as effective degrees of freedom below the dynamical scale. The other one is an elementary field. Spin-1 resonances are introduced as new gauge bosons *a la* Hidden local symmetry [24–27]. A feature of the model is that the SM fermion are singlet under the new gauge symmetry, and thus all the fermion couplings to the new gauge bosons are suppressed by the mixing angle in the gauge sector. As a result, the new gauge bosons mainly decay into the SM gauge bosons. This is an important feature of this model.

In this paper, we investigate the possibility to explain the diboson excess by the partially composite standard model, and also the future prospects of W' and Z' bosons searches at the LHC Run-2, where $\sqrt{s} = 13\,\text{TeV}$. We perform a comprehensive study to find the parameter space which has not been excluded from current experimental data. The constraints on the model parameters come from the LHC searches and the electroweak precision measurements. We also require theoretical constraints such as perturbativity condition, bounded below condition, global minimum vacuum condition, and stability condition of the scalar potential. We find a parameter space where the diboson excess can be explained.

We further investigate a model-independent sensitivity at the LHC Run-2 by generating both signal $pp \to W' \to WZ$ and dijet background events, and performing detector simulations.

We organize the rest of this paper as follows. We briefly review the partially composite standard model in section 2. In section 3, we show the constraints to the model, and find that there are parameter regions where are consistent with the ATLAS excess. In section 4, we perform the collider simulations for the signal and the background, and obtain the sensitivity at the LHC Run-2. In section 5, we investigate the future prospects of the spin-1 resonances search using our simulation results. Section 6 is devoted for conclusion.

JHEP02(2016)084

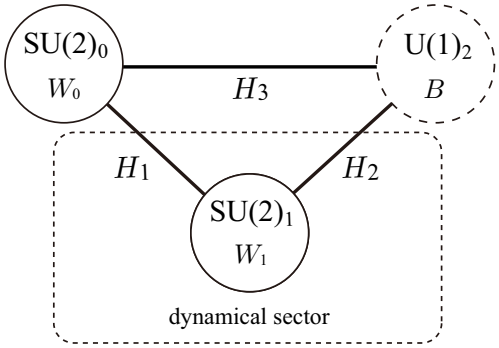

Figure 1. The moose diagram of this setup: the circles represent the gauge groups, and the thick lines that connect two circles are the Higgs fields. The Higgs fields H_1, H_2, and $\mathrm{SU}(2)_1$ gauge group can be regarded as the operators originated from the dynamical sector.

2 The partially composite standard model

2.1 The model setup

In the partially composite standard model, the gauge symmetry of the electroweak sector is $\mathrm{SU}(2)_0 \times \mathrm{SU}(2)_1 \times \mathrm{U}(1)_2$, and three Higgs fields (H_1, H_2, H_3) are introduced for the symmetry breaking, $\mathrm{SU}(2)_0 \times \mathrm{SU}(2)_1 \times \mathrm{U}(1)_2 \to \mathrm{U}(1)_{EM}$. We denote the gauge couplings g_0, g_1, and g_2, respectively. The three gauge couplings are related to the QED coupling as

$$\frac{1}{e^2} = \frac{1}{g_0^2} + \frac{1}{g_1^2} + \frac{1}{g_2^2}. \tag{2.1}$$

Here, we assume that the $\mathrm{SU}(2)_1$ gauge symmetry belongs to a dynamical sector, and $g_1 \gg g_0, g_2$. Under this assumption, g_0 and g_2 are approximately g_W and g_Y which are the gauge couplings of $\mathrm{SU}(2)_L$ and $\mathrm{U}(1)_Y$, respectively. We regard the gauge field associated with $\mathrm{SU}(2)_1$ as the vector resonance originated from unknown dynamics above TeV scale. This implies that fields transformed under the $\mathrm{SU}(2)_1$ gauge symmetry also belong to the dynamical sector. We take H_1 and H_2 as such fields, and regard H_3 as an elementary field. All the fermions are also elementary, and they are singlet under $\mathrm{SU}(2)_1$. We schematically show the model structure in the moose notation [28] in figure 1, and also summarize the field contents and their charge assignments in table 1.

The scalar potential is given as[1]

$$\begin{aligned} V(H_1, H_2, H_3) = {} & \mu_1^2 \mathrm{tr}(H_1 H_1^\dagger) + \mu_2^2 \mathrm{tr}(H_2 H_2^\dagger) + \mu_3^2 \mathrm{tr}(H_3 H_3^\dagger) \\ & + \kappa \mathrm{tr}(H_1 H_2 H_3^\dagger) \\ & + \lambda_1 (\mathrm{tr}(H_1 H_1^\dagger))^2 + \lambda_2 (\mathrm{tr}(H_2 H_2^\dagger))^2 + \lambda_3 (\mathrm{tr}(H_3 H_3^\dagger))^2 \\ & + \lambda_{12} \mathrm{tr}(H_1 H_1^\dagger) \mathrm{tr}(H_2 H_2^\dagger) + \lambda_{23} \mathrm{tr}(H_2 H_2^\dagger) \mathrm{tr}(H_3 H_3^\dagger) \\ & + \lambda_{31} \mathrm{tr}(H_3 H_3^\dagger) \mathrm{tr}(H_1 H_1^\dagger) \,. \end{aligned} \tag{2.2}$$

[1]We omit the term $i\kappa' \mathrm{tr}(H_1 H_2 H_3^\dagger \tau^3)$ in this paper because this term can be eliminated by the field redefinition [23].

L	**2**	-1/2	**1**	**1**
e_R	**1**	-1	**1**	**1**

Table 1. The charge assignment of the partially composite standard model. Only H_1 and H_2 are the representations of the $SU(2)_1$ gauge symmetry.

Here all the Higgs fields are represented by two-by-two matrices, and they are real, namely

$$\epsilon H_i^* \epsilon = -H_i, \quad \text{where } \epsilon = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}. \tag{2.3}$$

All parameters in the Higgs potenbibtial are also real. We assume that all the vacuum expectation values (VEVs) of the Higgs fields are diagonal, real and positive to realize desired electroweak symmetry breaking. The Higgs fields are expanded around their VEVs, $v_1,\ v_2$ and v_3,

$$H_i = \frac{v_i}{2} + \frac{1}{2}\left(h_i + i\tau^a \pi_i^a\right), \tag{2.4}$$

where τ^a is the Pauli matrices, and $h_i,\ \pi_i^a$ are the four real scalar component fields. The covariant derivatives of the Higgs fields are given as

$$D_\mu H_1 = \partial_\mu H_1 + ig_0 \frac{\tau^a}{2} W_{0\mu}^a H_1 - ig_1 H_1 \frac{\tau^a}{2} W_{1\mu}^a, \tag{2.5}$$

$$D_\mu H_2 = \partial_\mu H_2 + ig_1 \frac{\tau^a}{2} W_{1\mu}^a H_2 - ig_2 H_2 \frac{\tau^3}{2} B_\mu, \tag{2.6}$$

$$D_\mu H_3 = \partial_\mu H_3 + ig_0 \frac{\tau^a}{2} W_{0\mu}^a H_3 - ig_2 H_3 \frac{\tau^3}{2} B_\mu. \tag{2.7}$$

By calculating the muon life time in this model at the tree level, we find the relation between the Fermi constant and the VEVs in this model as

$$v_3^2 + \frac{1}{\frac{1}{v_1^2} + \frac{1}{v_2^2}} = v^2 \equiv \left(\sqrt{2} G_F\right)^{-1}, \tag{2.8}$$

where $v \simeq 246\,\text{GeV}$. For the later convenience, we introduce a new parameter r,

$$r \equiv \frac{v_2}{v_1}. \tag{2.9}$$

Thus v_1 and v_2 are expressed by r, v_3, and v,

$$v_1^2 = (1 + r^{-2})(v^2 - v_3^2), \qquad v_2^2 = (1 + r^2)(v^2 - v_3^2). \tag{2.10}$$

JHEP02(2016)084

There are twelve scalars in this model, and six of them are eaten by the gauge bosons. Thus this model has six physical scalars: three CP-even Higgs bosons ($h,\ H,\ H'$), one CP-odd Higgs boson (A), and two charged Higgs bosons ($H^{\pm}$). We identify h as the SM-like 125 GeV Higgs bosons. The masses of the CP-odd and the charged Higgs bosons are the same at the tree level and given by

$$m_A^2 = m_{H^\pm}^2 = -\frac{1}{4}\frac{\kappa}{v_3}\frac{1+r^2}{r}v^2. \tag{2.11}$$

The mass eigenstates of the CP-even Higgs bosons are related to the gauge eigenstates through the mixing angles $\theta_1,\ \theta_2$, and θ_3 as follows,

$$\begin{pmatrix} H' \\ H \\ h \end{pmatrix} = \begin{pmatrix} s_1s_2 - c_1c_2s_3 & -s_1c_2 - c_1s_2s_3 & c_1c_3 \\ -c_1s_2 - s_1c_2s_3 & c_1c_2 - s_1s_2s_3 & s_1c_3 \\ c_2c_3 & s_2c_3 & s_3 \end{pmatrix} \begin{pmatrix} h_1 \\ h_2 \\ h_3 \end{pmatrix} \tag{2.12}$$

where s_i (c_i) stands for $\sin\theta_i$ ($\cos\theta_i$) for $i = 1,\ 2,\ 3$.

The Yukawa interactions are given as

$$\mathcal{L}^{\text{Yukawa}} = -\bar{Q}^i H_3 \begin{pmatrix} y_u^{ij} & 0 \\ 0 & y_d^{ij} \end{pmatrix} \begin{pmatrix} u_R^j \\ d_R^j \end{pmatrix} - \bar{L}^i H_3 \begin{pmatrix} 0 & 0 \\ 0 & y_e^{ij} \end{pmatrix} \begin{pmatrix} 0 \\ e_R^j \end{pmatrix} + H.c., \tag{2.13}$$

where i and j are the generation indices. We introduce a parameter κ_F which is the ratio of the couplings between the lightest CP-even Higgs boson and the fermions to its SM value,

$$\kappa_F \equiv \frac{g_{hff}}{m_f/v} = \frac{v}{v_3}s_3. \tag{2.14}$$

Since $|s_3| \leq 1$ and $v/v_3 > 1$, κ_F can be larger than one. We will discuss the viable range of κ_F in the next subsection. The fermion masses are given as

$$m_f = y_f\frac{v_3}{2} = y_f\frac{v_3}{v}\frac{v}{2}, \tag{2.15}$$

and the Yukawa couplings are enhanced by v/v_3 compared to their SM values. Large Yukawa couplings could make the Higgs potential unstable above the electroweak scale. We discuss this point in section 3.2.

In addition to the SM gauge bosons, we have extra three vector bosons, $W'^{\pm}$ and Z'. In the $g_1 \gg g_0$ regime, the mass eigenvalues of the gauge bosons are given as

$$m_W^2 \simeq \frac{1}{4}g_0^2v^2\left(1 - \frac{g_0^2}{g_1^2}\frac{1}{(1+r^2)^2}\right), \tag{2.16}$$

$$m_{W'}^2 \simeq \frac{1}{4}g_1^2(v_1^2+v_2^2)\left(1 + \frac{g_0^2}{g_1^2}\frac{1}{(1+r^2)^2}\right), \tag{2.17}$$

$$m_Z^2 \simeq \frac{1}{4}(g_0^2+g_2^2)v^2\left(1 - \frac{(g_0^2-g_2^2r^2)^2}{g_1^2(g_0^2+g_2^2)}\frac{1}{(1+r^2)^2}\right), \tag{2.18}$$

$$m_{Z'}^2 \simeq \frac{1}{4}g_1^2(v_1^2+v_2^2)\left(1 + \frac{g_0^2+g_2^2r^4}{g_1^2}\frac{1}{(1+r^2)^2}\right). \tag{2.19}$$

JHEP02(2016)084

We find $m_{W'} \simeq m_{Z'}$ except in the large r regime. We need to find the relation between the gauge eigenstates and the mass eigenstates to evaluate the couplings, and they are given as

$$W_\mu^\pm \simeq \left(1 - \frac{1}{2(1+r^2)^2}\frac{g_0^2}{g_1^2}\right) W_{0\mu}^\pm + \left(\frac{1}{1+r^2}\frac{g_0}{g_1}\right) W_{1\mu}^\pm, \tag{2.20}$$

$$W_\mu'^\pm \simeq -\left(\frac{1}{1+r^2}\frac{g_0}{g_1}\right) W_{0\mu}^\pm + \left(1 - \frac{1}{2(1+r^2)^2}\frac{g_0^2}{g_1^2}\right) W_{1\mu}^\pm, \tag{2.21}$$

$$A_\mu = \frac{e}{g_0} W_{0\mu}^3 + \frac{e}{g_1} W_{1\mu}^3 + \frac{e}{g_2} W_{2\mu}^3, \tag{2.22}$$

$$\begin{aligned} Z_\mu \simeq\ & c_W \left(1 - \frac{1-2r^2t_W^2}{2(1+r^2)^2}\frac{g_0^2}{g_1^2}\right) W_{0\mu}^3 + c_W \left(\frac{1-r^2t_W^2}{(1+r^2)}\frac{g_0}{g_1}\right) W_{1\mu}^3 \\ & - s_W \left(1 - \frac{r^4 t_W^2}{2(1+r^2)^2}\frac{g_0^2}{g_1^2}\right) W_{2\mu}^3, \end{aligned} \tag{2.23}$$

$$Z'_\mu \simeq -\frac{1}{1+r^2}\frac{g_0}{g_1} W_{0\mu}^3 + \left(1 - \frac{1+r^4t_W^2}{2(1+r^2)^2}\frac{g_0^2}{g_1^2}\right) W_{1\mu}^3 - \frac{r^2 t_W}{(1+r^2)}\frac{g_0}{g_1} W_{2\mu}^3, \tag{2.24}$$

where $c_W = m_W/m_Z$, $s_W = \sqrt{1-c_W^2}$, and $t_W = s_W/c_W$. The typical size of the mixing angles is $\mathcal{O}(g_0/g_1)$, and the gauge filed W_0 (W_1) is the main component of the mass eigenstate W (W'). It is worth noting that the mixing angles for W' and Z' become the same in the small r regime, which means the custodial symmetry is enhanced.

The approximate expressions for some couplings of the W' and Z' to the SM particles are given as

$$\frac{g_{W'ff}}{g_{Wff}^{\rm SM}} \simeq -\frac{m_W}{m_{W'}}\sqrt{1-\frac{v_3^2}{v^2}}\frac{1}{r}, \tag{2.25}$$

$$\frac{g_{W'WZ}}{g_{WWZ}^{SM}} \simeq -\frac{m_W}{m_{W'}}\sqrt{1-\frac{v_3^2}{v^2}}\frac{1}{c_W^2}\frac{r}{1+r^2}, \tag{2.26}$$

$$\frac{g_{WWZ'}}{g_{WWZ}^{SM}} \simeq -\frac{m_W}{m_{W'}}\sqrt{1-\frac{v_3^2}{v^2}}\frac{1}{c_W}\frac{r}{1+r^2}. \tag{2.27}$$

Compare to the benchmark model (sequential standard model (SSM) [29–31]) used by the ATLAS/CMS, the W' couplings to the SM fermions are smaller. All couplings have a suppression factor of $(m_W/m_{W'})\sqrt{1-v_3^2/v^2}$, because the W' boson couples to the elementary fermion through W_0-W_1 mixing, so that the width is narrow. Since $g_{W'ff}$ is proportional to r^{-1}, the production cross section of the Drell-Yan process is proportional to r^{-2}. The W' boson could not be produced in the large r region. In section 3, we will find a parameter space in small r regions where a signal rate is consistent with the ATLAS diboson excess. Some numerical results are given in section 3.3

The gauge boson couplings to the scalars are also important in our analysis. We give their approximated expressions here. Due to the mixing between the two SU(2) gauge eigenstates, the WWh and ZZh couplings differ from the SM values. We denote these coupling ratios to the SM values by $\kappa_{W,Z}$,

$$\kappa_W \equiv \frac{g_{hWW}}{2m_W^2/v}, \quad \kappa_Z \equiv \frac{g_{hZZ}}{2m_Z^2/v}, \tag{2.28}$$

JHEP02(2016)084

and their approximated formulae in the $g_1 \gg g_0, g_2$ regime are

$$\kappa_W \simeq \kappa_Z \simeq \frac{r^3}{(1+r^2)^{3/2}}\sqrt{1-\frac{v_3^2}{v^2}}c_2c_3 + \frac{1}{(1+r^2)^{3/2}}\sqrt{1-\frac{v_3^2}{v^2}}s_2c_3 + \frac{v_3}{v}s_3. \tag{2.29}$$

The couplings relevant to the W'/Z' decay are

$$g_{WW'h} \simeq g_{ZZ'h} \simeq \frac{2m_W m_{W'}}{v}\left(-\frac{r^2}{(1+r^2)^{3/2}}c_2c_3 + \frac{r}{(1+r^2)^{3/2}}s_2c_3 - \frac{1}{r}\frac{m_W^2}{m_{W'}^2}\frac{v_3}{v}\sqrt{1-\frac{v_3^2}{v^2}}s_3\right), \tag{2.30}$$

$$g_{WW'H} \simeq g_{ZZ'H} \simeq \frac{2m_W m_{W'}}{v}\left(-\frac{r^2}{(1+r^2)^{3/2}}(-c_1s_2 - s_1c_2s_3)\right. \tag{2.31}$$
$$\left. + \frac{r}{(1+r^2)^{3/2}}(c_1c_2 - s_1s_2s_3) - \frac{1}{r}\frac{m_W^2}{m_{W'}^2}\frac{v_3}{v}\sqrt{1-\frac{v_3^2}{v^2}}s_1c_3\right),$$

$$g_{WW'H'} \simeq g_{ZZ'H'} \simeq \frac{2m_W m_{W'}}{v}\left(-\frac{r^2}{(1+r^2)^{3/2}}(s_1s_2 - c_1c_2s_3)\right. \tag{2.32}$$
$$\left. + \frac{r}{(1+r^2)^{3/2}}(-s_1c_2 - c_1s_2s_3) - \frac{1}{r}\frac{m_W^2}{m_{W'}^2}\frac{v_3}{v}\sqrt{1-\frac{v_3^2}{v^2}}c_1c_3\right).$$

2.2 Model parameters

In the electroweak sector of the model, there are 13 real parameters,

$$\mu_1^2,\ \mu_2^2,\ \mu_3^2,\ \kappa,\ \lambda_1,\ \lambda_2,\ \lambda_3,\ \lambda_{12},\ \lambda_{23},\ \lambda_{31},\ g_0,\ g_1,\ g_2. \tag{2.33}$$

It is convenient to use a different set of the parameters instead of these parameters. We use the following 13 parameters to fix the parameters in the electroweak sector,

$$r,\ v_3,\ v,\ \alpha,\ m_Z,\ m_{Z'},\ m_h,\ m_{H'},\ m_H,\ m_A,\ \kappa_F,\ \kappa_Z,\ g_{WW'H'}. \tag{2.34}$$

Here, we use r, v_3, v instead of the three μ parameters. κ is fixed by the charged Higgs mass or the CP-odd Higgs mass. The six λ's have the same information as the three CP-even Higgs masses and their mixing angles (m_h, m_H, $m_{H'}$, θ_1, θ_2, θ_3). We can use m_Z, $m_{Z'}$, and $\alpha(= e^2/4\pi)$ instead of the gauge couplings. In addition, we can replace (θ_1, θ_2, θ_3) with (κ_F, κ_Z, $g_{WW'H'}$).

The values of the four parameters, v, m_Z, α, and m_h are already known very precisely. We take $m_h = 125\,\text{GeV}$. We find κ_F is severely constrained close to 1 in the $m_A \gg m_h$ regime. When the heavy Higgs masses are universal, $m_A = m_{H'} = m_H$, λ_3 is simply expressed as

$$\lambda_3(\mu = m_{Z'}) = \frac{\kappa_F^2}{2}\frac{m_h^2}{v^2} + \frac{1-\kappa_F^2}{2}\frac{m_A^2}{v^2}. \tag{2.35}$$

Thus, λ_3 is very large except for κ_F =1. Similarly, the coupling ratio κ_Z is also severely constrained close to its maximal value in $m_A \gg m_h$ regime. Typically, the allowed value of κ_Z is $1-\mathcal{O}(1)\%$. The detailed description is given in appendix A. In the following discussion, we take $\kappa_F \simeq 1$, $m_A = m_H = m_{H'} = \mathcal{O}(1)\,\text{TeV}$, $g_{WW'H'} = 0$, and we always choose κ_Z to be its maximal value. For most of our numerical analysis, κ_Z is set to 0.95–1.00.

JHEP02(2016)084

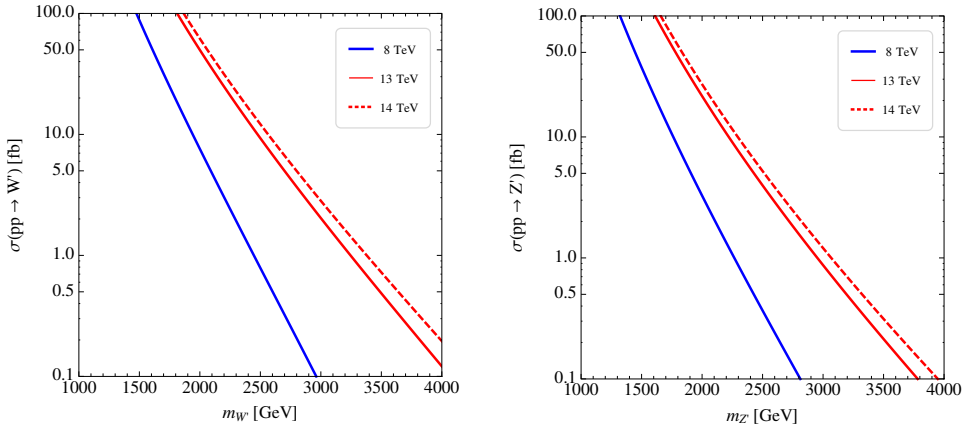

Figure 2. The production cross sections of the extra vector bosons, W' and Z'. We take $v_3 = 200\,\text{GeV}$, $r = 0.13$.

3 Phenomenology of spin-1 resonances

In this section, we discuss the properties of the W' and Z' bosons such as the production cross sections and the decay branching ratios. And we also discuss both the theoretical and experimental constraints. In the following, we show some formulae with approximation, which help to understand the parameter dependence. However, we use the exact formulae in our numerical calculations.

3.1 Properties of the extra vector bosons

The main production mode of W' and Z' in pp collisions is the Drell-Yan process. They are proportional to r^{-2} as we can see from eq. (2.25).[2] We consider small r in order to make the cross section large. In figure 2, we show the production cross sections for W' ($W'^{+} + W'^{-}$) and Z'. Here we take $v_3 = 200\,\text{GeV}$, $r = 0.13$ and $\kappa_F = 1.00$. We use the CTEQ6L parton distribution functions [32]. The production cross section of W' is approximately twice that of Z' for small r because the custodial SU(2) symmetry is recovered in the region.

The partial decay widths of W' and Z' into the SM particles are given as

$$\Gamma(W' \to WZ) \simeq \frac{1}{48\pi}\frac{m_{W'}^3}{v^2}\frac{r^2}{(1+r^2)^2}\left(1-\frac{v_3^2}{v^2}\right), \tag{3.1}$$

$$\Gamma(W' \to Wh) \simeq \frac{1}{48\pi}\frac{m_{W'}^3}{v^2}\frac{r^2}{(1+r^2)^3}\left(-rc_2c_3+s_2c_3\right)^2, \tag{3.2}$$

$$\Gamma(W' \to f\bar{f}) \simeq \frac{N_c}{48\pi}\frac{m_W^2}{m_{W'}}\frac{e^2}{s_W^2}\frac{1}{r^2}\left(1-\frac{v_3^2}{v^2}\right), \tag{3.3}$$

$$\Gamma(Z' \to WW) \simeq \frac{1}{48\pi}\frac{m_{W'}^3}{v^2}\frac{r^2}{(1+r^2)^2}\left(1-\frac{v_3^2}{v^2}\right), \tag{3.4}$$

$$\Gamma(Z' \to Zh) \simeq \frac{1}{48\pi}\frac{m_{W'}^3}{v^2}\frac{r^2}{(1+r^2)^3}\left(-rc_2c_3+s_2c_3\right)^2, \tag{3.5}$$

[2]For more details on the formulae, see appendix B.

JHEP02(2016)084

$$\Gamma(Z' \to f\bar{f}) \simeq \frac{N_c}{24\pi}\frac{m_W^2}{m_{W'}}\frac{e^2}{s_W^2}\frac{1}{r^2}\left(1-\frac{v_3^2}{v^2}\right) \times \left(\left(\left(1-r^2\frac{s_W^2}{c_W^2}\right)T_f^3 + r^2\frac{s_W^2}{c_W^2}Q_f\right)^2 + \left(r^2\frac{s_W^2}{c_W^2}Q_f\right)^2\right), \tag{3.6}$$

where $T_f^3 = 1/2$ $(-1/2)$ for the up-type (down-type) fermions, Q_f is the electric charge of the fermion, and N_c is the color factor, $N_c = 3$. Note that the bosonic channels are dominant among their decay channels due to an enhancement factor from the wave function of the longitudinally polarized gauge bosons in the final states. Therefore the dominant decay modes of W' (Z') are $W' \to WZ$ and $W' \to Wh$ $(Z' \to WW$ and $Z' \to Zh)$.

There are also decay modes with a heavy scalar in the final states. For example, $W' \to WH$ and $W' \to hH$ exist and their approximated formulae are

$$\Gamma(W' \to WH) \simeq \frac{1}{48\pi}\left(\frac{g_{WW'H}}{2m_W m_{W'}/v}\right)^2 \frac{m_{W'}^3}{v^2}\left(8\frac{m_W^2}{m_{W'}^2} + \left(1-\frac{m_H^2}{m_{W'}^2}+\frac{m_W^2}{m_{W'}^2}\right)^2\right)\left(1-\frac{m_H^2}{m_{W'}^2}\right), \tag{3.7}$$

$$\Gamma(W' \to hH) \simeq \frac{1}{48\pi}\frac{m_{W'}^4}{v^2-v_3^2}\frac{v_3^2}{v^2}\frac{2}{(1+r^2)^3}(-rc_2c_3+s_2c_3)^2\left(1-\frac{m_{H^+}^2}{m_{W'}^2}\right)^3, \tag{3.8}$$

where $g_{WW'H}$ is given in eq. (2.31), and $g_{WW'H}/(2m_W m_{W'}/v)$ is $\mathcal{O}(1)$ in large regions of the parameter space. These decay widths are comparable to those of the SM final states. The decay channels including only the heavy states, such as $W' \to H^\pm H$, also have the same feature. Once these modes are open, they would be dominant decay modes.

In figure 3, we show the total widths and the branching ratios of W' and Z'. Here we take $v_3 = 200\,\text{GeV}$, $r = 0.13$ and $\kappa_F = 1.00$, $m_A = m_{H'} = m_H = 2\,\text{TeV}$. We also take $g_{WW'H'} = 0$ as we mentioned in section 2.2, thus $W' \to WH'$ and $Z' \to ZH'$ are absent in the figure. We find that the dominant decay channels are $V' \to VV$ and $V' \to Vh$ for large $m_{V'}$. However, the decay branching ratio reduces once $V' \to HX$ decay modes are open.

In figure 3, we find $\text{Br}(W' \to WZ) = \text{Br}(W' \to Wh) \simeq 40$ % at $m_{W'} = 2\,\text{TeV}$. The relation is easily understood by the equivalence theorem, $\text{Br}(W' \to W_L Z_L) = \text{Br}(W' \to \pi_{SM}\pi_{SM})$ in the heavy W' mass limit, where π_{SM} is the SM Nambu-Goldstone boson. In the SM limit, $\text{Br}(W' \to \pi_{SM}\pi_{SM})$ is equivalent to $\text{Br}(W' \to \pi_{SM}h)$. Thus, $\text{Br}(W' \to WZ) \simeq \text{Br}(W' \to Wh)$ is realized. In addition, when one takes $g_{WW'H'} = 0$, the heavy Higgses H, A, $H^\pm$ form a multiplet, and $\text{Br}(W' \to ZH^\pm) \simeq \text{Br}(W' \to WA) \simeq \text{Br}(W' \to WH)$ is realized.

We also find the total widths are narrow, namely $\Gamma/m \sim 1$–5 %, because the resonances decay into the SM particles with suppressed couplings due to the mixing between the elementary and the composite sectors. Another remark is that the decay properties of W' and Z' are similar due to the enhanced SU(2) custodial symmetry in small r regime.[3]

In figure 4, we take different scalar masses, $m_A = m_{H'} = m_H = 1\,\text{TeV}$. The other parameter choice is the same as in figure 3. The decay channels to the non-SM particles,

[3]In the large r region, the branching ratio $Z' \to f\bar{f}$ and the production cross section of Z' become larger (see eqs. (3.6), (B.2)), while the production cross section of W' is suppressed.

JHEP02(2016)084

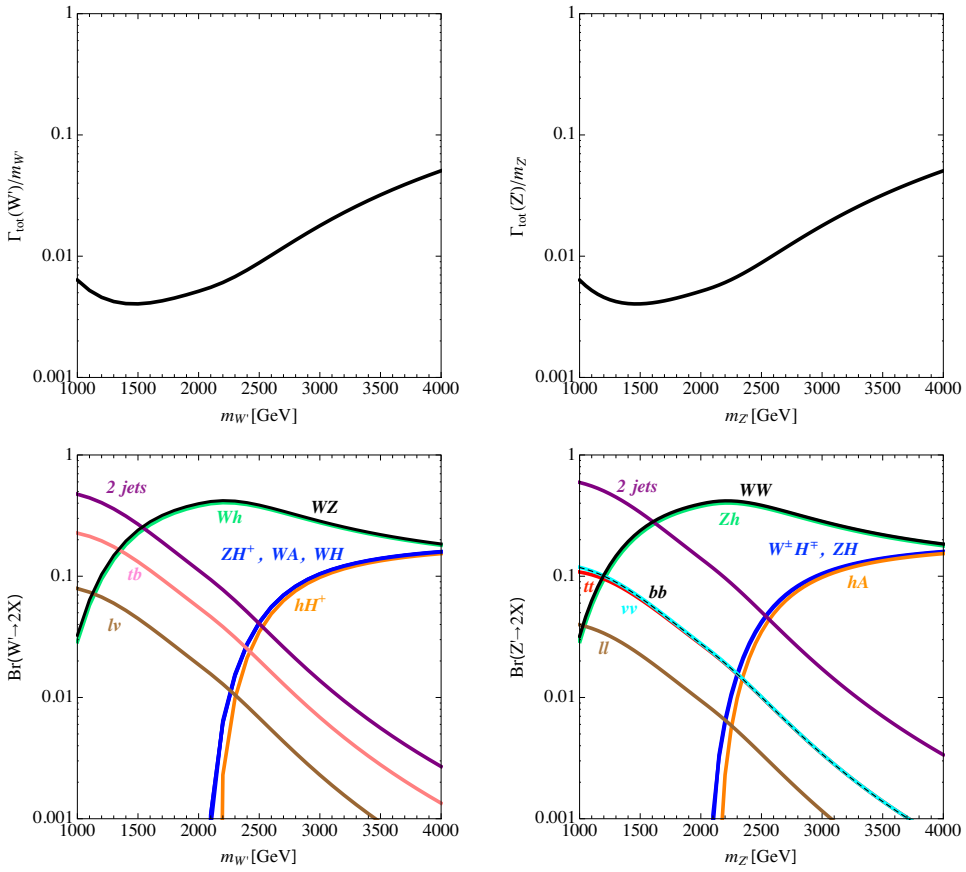

Figure 3. The total widths and the branching ratios of the extra vector bosons, W' and Z'. We take $v_3 = 200\,\text{GeV}$, $r = 0.13$, $\kappa_F = 1.00$, and $m_A = m_{H'} = m_H = 2\,\text{TeV}$. Here, 2jets means $\text{Br}(W' \to ud)$+$\text{Br}(W' \to sc)$ or $\text{Br}(Z' \to uu)$+$\text{Br}(Z' \to dd)$+$\text{Br}(Z' \to ss)$+$\text{Br}(Z' \to cc)$, $\ell\nu$ means $\text{Br}(W' \to e\nu_e)$ ($=\text{Br}(W' \to \mu\nu_\mu) = \text{Br}(W' \to \tau\nu_\tau)$), $\ell\ell$ means $\text{Br}(Z' \to ee)$ ($=\text{Br}(Z' \to \mu\mu) = \text{Br}(Z' \to \tau\tau)$), $\nu\nu$ means $\text{Br}(Z' \to \nu_e\nu_e)$+$\text{Br}(Z' \to \nu_\mu\nu_\mu)$+$\text{Br}(Z' \to \nu_\tau\nu_\tau)$, and $W^\pm H^\mp$ means $\text{Br}(W' \to W^+H^-) = \text{Br}(W' \to W^-H^+)$.

namely $\text{Br}(W' \to H^+H)$, $\text{Br}(W' \to H^+A)$, $\text{Br}(Z' \to HA)$, and $\text{Br}(Z' \to H^+H^-)$, are open. We took the parameter so that the channels to H' is absent, $g_{WW'H'} = 0$.

As mentioned above, these channels are comparable to the decay modes to the SM particles. As a result, the decay modes $V' \to VV$ and $V' \to Vh$ searched at the ATLAS and the CMS experiments are suppressed compared to figure 3. This implies that the decay channels with heavy scalars should not be open if we try to explain the excess at the ATLAS experiment. Hereafter, we consider the situation that the heavy scalars are as heavy as the extra gauge bosons.

3.2 Constraints on the model

In this subsection, we show theoretical and experimental constraints on the model parameters. In order to perform a reliable perturbative calculation, we demand perturbativity condition, bounded below condition, global minimum vacuum condition, and stability condition. In addition, we take into account the LHC bounds and the electroweak precision measurements.

JHEP02(2016)084

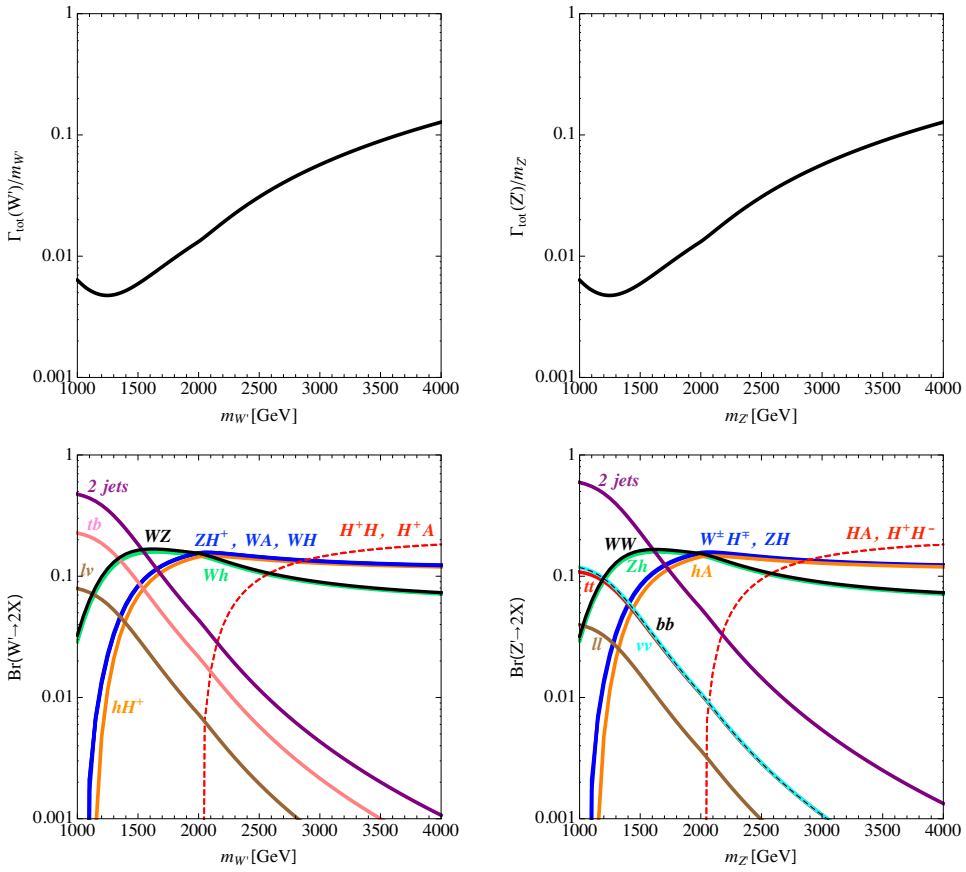

Figure 4. The total widths and the branching ratios of W' and Z' for $m_A = m_{H'} = m_H = 1\,\text{TeV}$. Other parameter choice and the notations are the same as in figure 3.

3.2.1 Theoretical constraints

Perturbativity condition for the gauge coupling g_1. We require that all the absolute values of the gauge couplings and the Higgs quartic couplings are smaller than 4π and $(4\pi)^2$ in order to keep the reliability of our analysis based on the perturbative calculation.

For the gauge couplings, g_0 and g_2 are almost the same value as the SM gauge couplings, but g_1 can be very large. Since $\text{SU}(2)_1$ is asymptotic free in our setup, g_1 becomes smaller at high energy due to the quantum effects. Thus the maximum value of the g_1 is given at Z' mass scale, and we require $|g_1(\mu = m_{Z'})| < 4\pi$. The regions where $|g_1(m_{Z'})| > 4\pi$ are filled with yellow in figures 5 and 6.

Perturbativity condition for the Higgs quartic couplings. The scalar quartic couplings are large when the mass differences between the SM-like Higgs and the other heavy scalar bosons are large. Since we take $m_h \ll m_A = m_H = m_{H'} \sim \mathcal{O}(1)\,\text{TeV}$ in our analysis, the quartic couplings tend to be large. In addition, due to the renormalization group effects, they can be even larger at high energy. The renormalization group equations for

JHEP02(2016)084

this model are given in appendix C. We define a cutoff scale Λ by

$$|\lambda_i(\mu = \Lambda)| = (4\pi)^2\,, \tag{3.9}$$

and require $|\lambda_i(\mu < \Lambda)| < (4\pi)^2$.

This constraint highly depends on our choice of Λ. We require that Λ should be significantly higher than a few TeV, otherwise we have to take account of interaction terms from higher dimensional operators whose coefficients are unknown, and some uncertainty is introduced to our analysis. For example, there are operators which modifies the W' coupling to the SM fermions such as $(c/\Lambda^2)\bar{Q}i\gamma^\mu(H_1 iD_\mu H_1^\dagger)Q$. This operator brings unknown parameter c, and thus brings uncertainty to our calculations such as the production cross section of W'. Typically, such higher dimensional operators with $c \sim 1$ bring 1% (10%) uncertainty if $\Lambda = 100\,\text{TeV}(10\,\text{TeV})$. To avoid such uncertainty from unknown parameters, we restrict ourselves for the case $\Lambda > 100\,\text{TeV}$. The parameter regions where $|\lambda(\Lambda)| > (4\pi)^2$ are filled with the lighter (darker) gray for $\Lambda = 100(10)$ TeV in figures 5 and 6 for reference.

Bounded below condition. Here we consider the conditions that the Higgs potential at the tree level is bounded below. For the purpose, it is enough to check that the potential value at the large field values, and thus we consider only the quartic terms in the potential. We rewrite the quartic terms as

$$V_{\text{quartic}} = R^4\left(\lambda_1 n_1^2 + \lambda_2 n_2^2 + \lambda_3 n_3^2 + \lambda_{12} n_1 n_2 + \lambda_{23} n_2 n_3 + \lambda_{31} n_3 n_1\right), \tag{3.10}$$

with

$$R^2 n_i \equiv \text{tr}(H_i H_i^\dagger) = \frac{1}{2}(h_i^2 + \pi_i^a \pi_i^a), \tag{3.11}$$

where n_i satisfies $0 \le n_{1,2,3} \le 1$, and $n_1^2 + n_2^2 + n_3^2 = 1$. In order to avoid run-away vacua, we demand the following conditions for the Higgs quartic couplings at $m_{Z'}$ scale $(\lambda_i(\mu = m_{Z'}))$,

$$\text{Min}\left[\lambda_1 n_1^2 + \lambda_2 n_2^2 + \lambda_3 n_3^2 + \lambda_{12} n_1 n_2 + \lambda_{23} n_2 n_3 + \lambda_{31} n_3 n_1\right] > 0, \quad \text{for } 0 \le n_{1,2,3} \le 1. \tag{3.12}$$

The parameter regions where this condition is not satisfied are filled with cyan in figures 5 and 6. Especially, one can solve the above inequality analytically in specific directions as

$$\begin{aligned} \lambda_1 > 0 \ \text{ for } n_2 = n_3 = 0, \qquad & \lambda_2 > 0 \ \text{ for } n_1 = n_3 = 0, \\ \lambda_3 > 0 \ \text{ for } n_1 = n_2 = 0, \qquad & \lambda_{23} + 2\sqrt{\lambda_2\lambda_3} > 0 \ \text{ for } n_1 = 0, \\ \lambda_{31} + 2\sqrt{\lambda_3\lambda_1} > 0 \ \text{ for } n_2 = 0, \qquad & \lambda_{12} + 2\sqrt{\lambda_1\lambda_2} > 0 \ \text{ for } n_3 = 0. \end{aligned} \tag{3.13}$$

Global minimum vacuum condition. We demand the electroweak vacuum to be a global minimum of the Higgs potential at $\mu = m_{Z'}$. The parameter regions where this condition is not satisfied are filled with green in figures 5 and 6.

JHEP02(2016)084

Stability condition. Among the quartic couplings, λ_3 can be very small when κ_F is very close to 1, see eq. (2.35), and especially it takes the same value as the quartic coupling in the SM for $\kappa_F = 1$. In that case, λ_3 can be negative at a high energy scale due to the contribution from the Yukawa interaction to the renormalization group equations, and the Higgs potential becomes unstable. The VEV giving masses to the fermions are v_3, see eq. (2.15). Thus the Yukawa coupling in our setup is larger than the coupling in the SM by v/v_3, and the Higgs potential can become unstable at a few TeV scale for the small v_3 region. We define the scale $\bar{\Lambda}$ at which λ_3 becomes negative,

$$\lambda_3(\mu = \bar{\Lambda}) = 0, \tag{3.14}$$

and we demand $\bar{\Lambda} \gtrsim 100\,\text{TeV}$, as we demand for the perturbativity condition. We fill the regions where this condition is not satisfied with magenta in figures 5 and 6.

This bound is conservative because we do not allow a meta-stable vacuum. Note that we do not take into account higher loop corrections. In the SM, the constraints become significantly weaker if higher loop corrections are taken into account [33, 34].

3.2.2 Experimental constraints

Constraints from the direct search for W' and Z'. Since the production cross sections of the extra vector bosons are relatively large, this model is constrained from current results of the exotic resonance searches of various decay channels at the $\sqrt{s} = 8\,\text{TeV}$ LHC. We take account of the following constraints: $W' \to \ell\nu$ searches [35, 36], $Z' \to \ell\ell$ searches [37, 38], Vh resonance searches ($V' \to Vh$) [39–42], and the diboson searches ($V' \to VV$) using dijets [1, 2], $\ell\ell jj$ [43], $\ell\nu jj$ [44], and $\ell\nu\ell\ell$ channel [45]. The searches for the other channels do not constrain this model. We fill the excluded regions with blue in figures 5 and 6. Among the constraints, $V' \to Vh$ and $V' \to WZ \to \ell\nu jj$ give severe bound, and exclude a part of the parameter regions in which we can explain the diboson excess reported by the ATLAS experiment.

Constraints from the electroweak precision measurements. The electroweak precision parameters, $\hat{S}$, $\hat{T}$, W and Y, defined in ref. [46], are severely restricted from the electroweak precision observables. Since the interactions of W' and Z' to the light fermions affect the low energy observables, the light W' and Z' are severely constrained. They are calculated at the tree level in ref. [23],

$$\hat{S} = \frac{g_0^2 v_1^2 v_2^2}{g_1^2(v_1^2+v_2^2)^2 + g_0^2 v_1^4} \simeq \frac{m_W^2}{m_{W'}^2}\left(1 - \frac{v_3^2}{v^2}\right), \tag{3.15}$$

$$\hat{T} = 0, \tag{3.16}$$

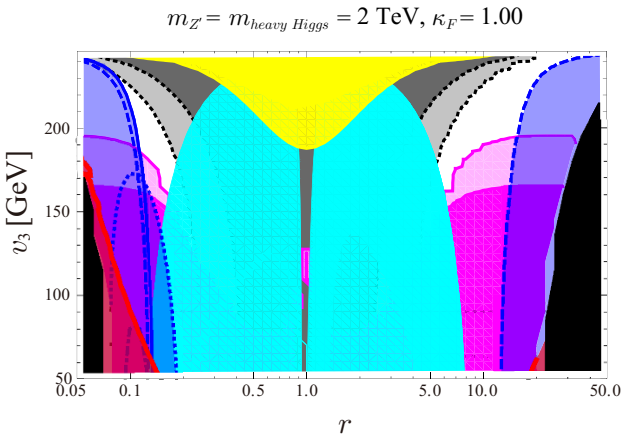
$$W = 4m_W^2 \frac{g_0^2}{g_1^2}\frac{1}{v_1^2+v_2^2}\frac{v_1^4}{g_1^2(v_1^2+v_2^2)^2 + g_0^2 v_1^4} \simeq \frac{m_W^4}{m_{W'}^4}\frac{1}{r^2}\left(1 - \frac{v_3^2}{v^2}\right), \tag{3.17}$$

$$Y = 4m_W^2 \frac{g_2^2}{g_1^2}\frac{1}{v_1^2+v_2^2}\frac{v_2^4}{g_1^2(v_1^2+v_2^2)^2 + g_0^2 v_1^4} \simeq r^2 t_W^2 \frac{m_W^4}{m_{W'}^4}\left(1 - \frac{v_3^2}{v^2}\right). \tag{3.18}$$

We use them to find the constraint on the parameter space. The parameter regions constrained at 95% C.L. are filled with red in figures 5 and 6. The small v_3, the small r as well as the light W' regions are constrained.

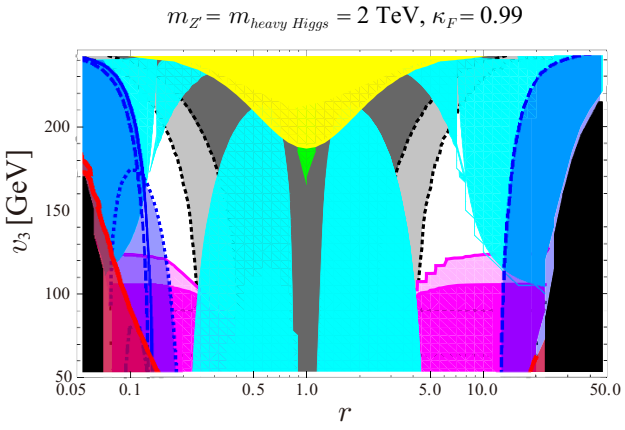
JHEP02(2016)084

We also consider constraints from flavor physics, and find they are weaker than the constraints from $\hat{S}$ and/or the current LHC bound. For example, K^0-$\bar{K}^0$ mixing in this model is almost the same as that in the SM. This is because the contributions from W' is sufficiently suppressed due to the suppression of the couplings to the SM fermions, and also the the modification of the W couplings to the fermions is very small, $\mathcal{O}(m_W^4/m_{W'}^4)$. Therefore, we do not show the constraints in the figures.



3.2.3 Summary of the constraints

In figure 5, we plot all the constraints in r–v_3 planes with three different parameter sets, $(m_{Z'}, m_A, \kappa_F) = (2\,\text{TeV}, 2\,\text{TeV}, 1.00)$, $(2\,\text{TeV}, 2\,\text{TeV}, 0.99)$, and $(2\,\text{TeV}, 1\,\text{TeV}, 1.00)$. Here we take all the heavy scalar bosons are degenerate, $m_A = m_{H'} = m_H$. The colored regions are excluded or constrained, and the white regions are allowed from all constraints. The gray regions surrounded by the black dotted lines represent the perturbativity condition of the Higgs quartic couplings for $\Lambda = 10$ (darker) and 100 TeV (lighter), and the yellow regions are that of g_1. The bounded below condition excludes the cyan region. The global minimum vacuum condition excludes the green region. The magenta regions are excluded by the stability condition for $\bar{\Lambda} = 10$ (darker) and 100 TeV (lighter). The LHC results exclude blue regions, where the solid blue lines represent $W' \to \ell\nu$ searches [35, 36], the dashed lines represent $Z' \to \ell\ell$ searches [37, 38], the dotted lines represent Vh resonance searches [39–42], and the dot-dashed lines represent diboson searches ($V' \to VV$) [1, 2, 43–45]. The regions filled with the red color are excluded by the electroweak precision measurements. No physical solutions are found in the black region, namely the gauge couplings and/or the VEVs become complex numbers there.



By comparing all the panels, we find the experimental bounds (the LHC and the electroweak precision measurements) are almost insensitive to the heavy Higgs bosons. The theoretical bounds are very sensitive to the κ_F, as we can see from the panels (a) and (b). This is because the deviation of κ_F from 1 leads to the large λ_3 (cf. $\lambda_3 \sim 0.13$ (0.78) at $\kappa_F = 1.00$ (0.99)) (see eq. (2.35)), which changes the regions excluded by the bounded below condition (see eq. (3.13)) and stability condition (see eq. (3.14)). We find that perturbativity condition is weaker in the panel (c) ($m_A = 1\,\text{TeV}$) compared with the panel (a) ($m_A = 2\,\text{TeV}$). This is because the lighter m_A leads to the smaller quartic couplings.

Figure 6 shows the constraints in $m_{Z'}$–r plane with the same color notation in figure 5. We take the universal masses $m_{Z'} = m_A = m_{H'} = m_H$, and three different choices for v_3 and κ_F, $(v_3, \kappa_F) =$(200 GeV, 1.00), (180 GeV, 1.00), and (180 GeV, 0.99). The perturbativity condition for the Higgs quartic couplings gives severe bounds in the heavy Higgs mass region. This is because the large mass differences in the CP-even Higgs mass spectra require the large Higgs quartic couplings, and they become non-perturbative eventually. We also find in the panel (c) that when κ_F deviates from 1, the bounded below condition gives stringent constraint. This is because that the Higgs quartic couplings λ_i are sensitive to the small deviation of κ_F, see appendix A.

Figure 5. The theoretical and experimental constraints in r–v_3 planes. We take three different parameter choices for $(m_{Z'}, m_A, \kappa_F)$. The colored regions are constrained, **Gray**: the perturbativity conditions for the Higgs quartic couplings, **Yellow**: the perturbativity conditions for g_1, **Cyan**: the bounded below condition, **Green**: the global minimum vacuum condition, **Magenta**: the stability condition, **Blue**: the LHC bounds, **Red**: constraints from the electroweak precision measurements, **Black**: no physical solutions. See also the explanations in the text.

JHEP02(2016)084

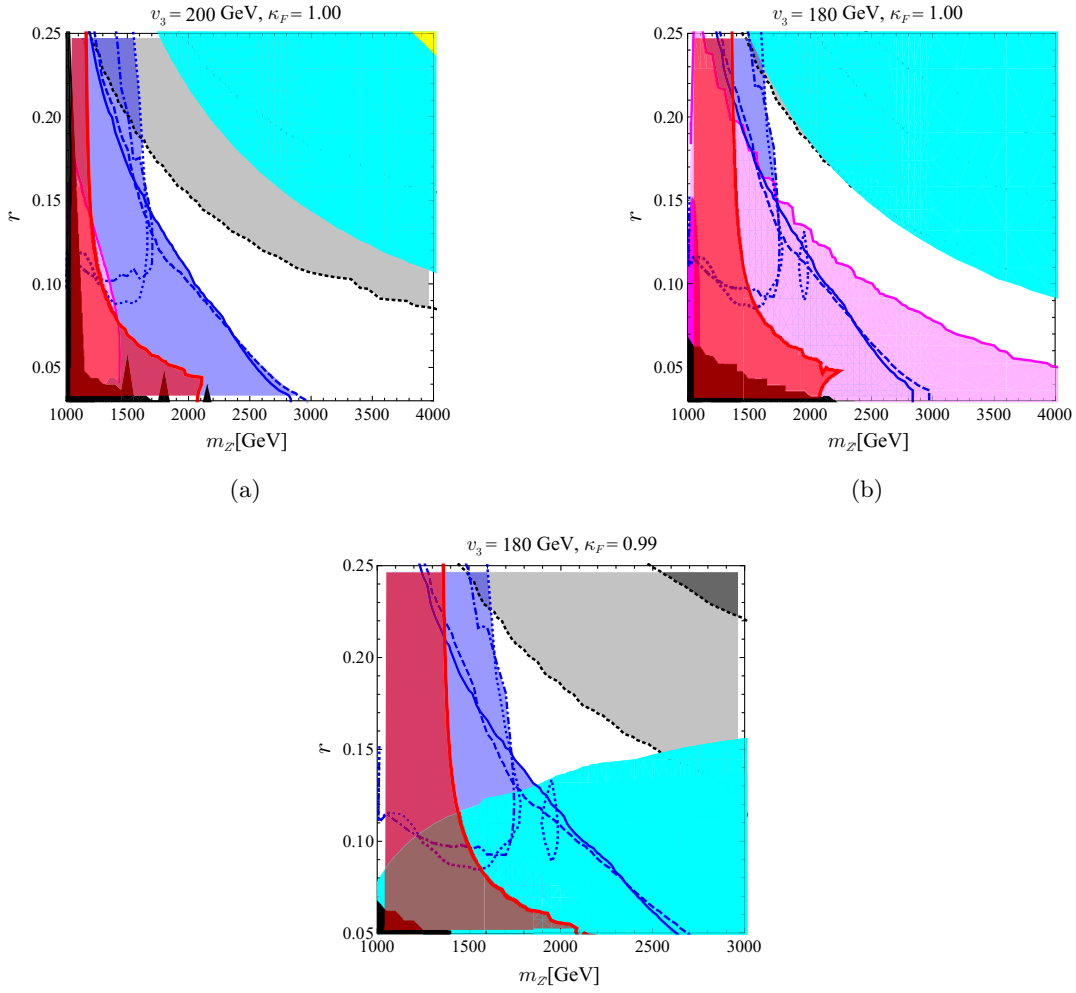

Figure 6. The theoretical and experimental constraints in the $m_{Z'}$–r planes. We take three different parameter choices for $(v_3,\ \kappa_F)$, and the universal masses $m_{Z'} = m_A = m_{H'} = m_H$ are taken. A color notation is the same as in figure 5.

3.3 Current status: 8 TeV analyses

In this subsection, we focus on the cross section times branching ratios of V' at the LHC 8 TeV. Inspired by the recent ATLAS diboson excess [1], we concentrate on the case that the masses of the extra vector bosons are around 2 TeV.

Since the separation of the WW, WZ, and ZZ channels are not good and there are significant overlap among them [1], we investigate the total cross section $\sigma(pp \to W')\mathrm{Br}(W' \to WZ) + \sigma(pp \to Z')\mathrm{Br}(Z' \to WW)$ at $\sqrt{s} = 8\,\mathrm{TeV}$ in figure 7. In this figure, $m_{Z'} = m_A = m_{H'} = m_H = 2\,\mathrm{TeV}$, $\kappa_F = 1.00$ are taken. The blue regions are excluded by the current experimental bounds discussed in section 3.2, and the regions of $g_1(\mu = m_{Z'}) > 4\pi$ is filled with yellow. Here we do not show the constraints from the Higgs sector.

JHEP02(2016)084

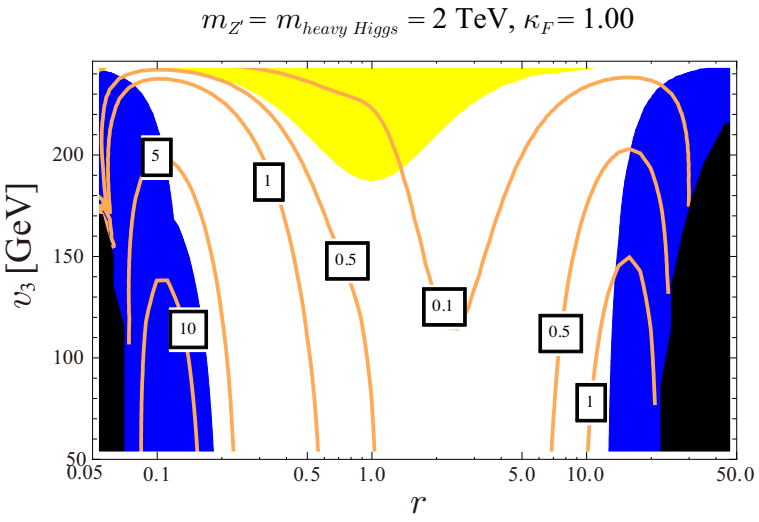

Figure 7. Contours of the cross section $\sigma(pp \to W')\mathrm{Br}(W' \to WZ) + \sigma(pp \to Z')\mathrm{Br}(Z' \to WW)$ at the LHC $\sqrt{s} = 8\,\mathrm{TeV}$ in fb unit. We take $m_{Z'} = m_A = m_{H'} = m_H = 2\,\mathrm{TeV}$, $\kappa_F = 1.00$. The blue regions are excluded by the current experimental bounds, and the regions of $g_1(\mu = m_{Z'}) > 4\pi$ are filled with yellow.

We have to estimate the cross section value, $\sigma(pp \to V' \to VV)$, required for the explanation of the diboson excess. We find $\sigma = 6\,\mathrm{fb}$ with large error when we use the event numbers between 1.85 and 2.15 TeV bins, the estimated background, and the efficiency given in ref. [1]. Hereafter we require $\sigma = 6\,\mathrm{fb}$ for the explanation of the diboson excess.

This cross section value can be achieved in the regions where r is much smaller than 1. This is because the production cross section is enhanced by r^{-2}. Hence, we focus on $r \ll 1$ regions in the rest of this paper.

Note that the strongest LHC constraint to the parameter regions where the ATLAS diboson excess can be explained comes from the hadronic channel of $\sigma(pp \to V' \to Vh)$ [42], e.g. $\sigma(pp \to V' \to Vh) \lesssim 7\,\mathrm{fb}$ for $m_{Z'} = 2\,\mathrm{TeV}$. This implies $\sigma(pp \to V' \to VV) < 7\,\mathrm{fb}$ as we discussed in section 3.1. If the coupling ratio κ_Z deviates from 1, this LHC bound becomes weaker, because the relation between $\sigma(pp \to V' \to VV)$ and $\sigma(pp \to V' \to Vh)$ are modified. However, in this model κ_Z is severely constrained close to 1 in the $m_A \gg m_h$ regime (see appendix A).

We show $\sigma(pp \to V' \to VV)$ in figure 8, for $m_{Z'} = 1.9$, 2.0, and 2.1 TeV. We take $\kappa_F = 1.00$, and all heavy scalar masses to be the same as $m_{Z'}$, $m_{Z'} = m_A = m_{H'} = m_H$. The color filled regions are excluded or constrained. The color notation is given in the caption. We find that the cross section is sensitive to the mass. For example, by changing $m_{Z'}$ from 1.9 to 2 TeV (5 % mass difference), the cross section is decreased by about 40 %. This is because the PDF rapidly changes in the heavier mass regions (see figure 2).

Below the thick orange line the cross section $\sigma(pp \to V' \to VV)$ is consistent with the ATLAS result. Here we apply the event selection efficiencies for the extended gauge model (cf. 10–16 % at $m_{JJ} = 2\,\mathrm{TeV}$) [1]. Note that a part of these regions are constrained from the stability condition at $\bar{\Lambda} = 100\,\mathrm{TeV}$ filled with light green. However, once we take

JHEP02(2016)084

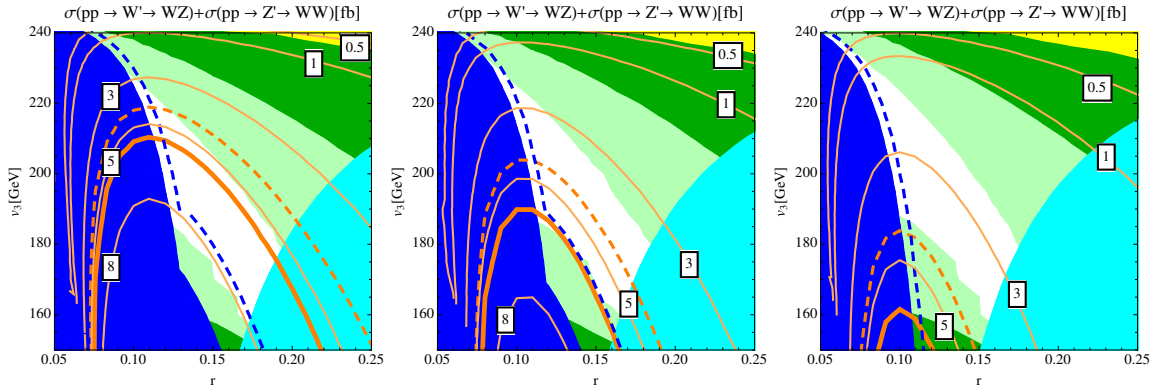

Figure 8. The cross sections of W' and Z' with two gauge bosons in their final states. We take $m_{Z'} = 1.9\,\text{TeV}$ (the left panel), 2.0 TeV (the middle panel), and 2.1 TeV (the right panel). The color filled regions are excluded or constrained. The blue regions are excluded by the experimental bounds. The regions of $g_1(\mu = m_{Z'}) > 4\pi$ are represented by yellow. The cyan regions are excluded by the bounded below condition. The green regions are constrained from the perturbativity and stability conditions where their cut off scale is 100 (10) TeV in the lighter green (darker green) regions. Below the thick orange line the cross section $\sigma(pp \to V' \to VV)$ is consistent with the ATLAS result. After taking account of the K-factor, the boundaries of the regions change into the dashed orange lines, and the regions below the dashed blue lines are excluded by the LHC bounds.

account of the higher order correction, these constraint would be weaker as we discussed in section 3.2.1. In the parameter regions shown in the figure, $\sigma(pp \to W' \to WZ)/\sigma(pp \to Z' \to WW) \simeq 2$. This is because the custodial symmetry is enhanced in the small r regime.

In the figure we show the leading order (LO) production cross sections. Next-to-leading order and next-to-leading logarithmic (NLO+NLL) corrections to the production cross sections of W' and Z' are evaluated in ref. [47, 48], and the K-factor $(\sigma/\sigma_{\text{LO}})$ is about 1.3. This means that once we consider the QCD corrections, the production cross sections in the figures should be scaled by about 30 %, and the LHC bounds become severer, while the theoretical constraints do not change. After taking account of the K-factor, the LHC diboson excess can be explained for the regions below dashed orange lines, and the regions below the dashed blue lines are excluded by the LHC bounds.

Figure 9 shows $\sigma(pp \to W' \to Wh)$.[4] The parameter choices and the color notations are the same as figure 8. We find that $\sigma(pp \to W' \to Wh)/\sigma(pp \to Z' \to Zh) \simeq 2$ due to the enhancement of the custodial symmetry. We find $\sigma(pp \to W' \to Wh) \times 20\,\text{fb}^{-1} \times \text{Br}(h \to b\bar{b})\ \text{Br}(W \to e\nu + \mu\nu) \sim 9$ events with $\sigma \sim 4\,\text{fb}$ in the regions where the ATLAS diboson excess can be explained. This is consistent with the excess of the event for the 1.8–1.9 TeV bins at the CMS with a local significance of 2.2σ for $W' \to Wh \to \ell\nu b\bar{b}$ search [41], although the detail of the event selection has not been reported.

We show $\Gamma_{\text{tot}}(W')$, κ_Z, $(g_{W'WZ}/g^{\text{SM}}_{WWZ}) \times (m_{W'}/m_W)^2$ and $g_{W'ff}/g^{\text{SM}}_{Wff}$ in figure 10. We fix $m_{Z'} = 2\,\text{TeV}$ because they are not sensitive to the Z' mass. The choices of other parameters and the color notations are the same as in figure 8. The width of W' is shown

[4] Detailed studies of this process are found in refs. [49, 50].

JHEP02(2016)084

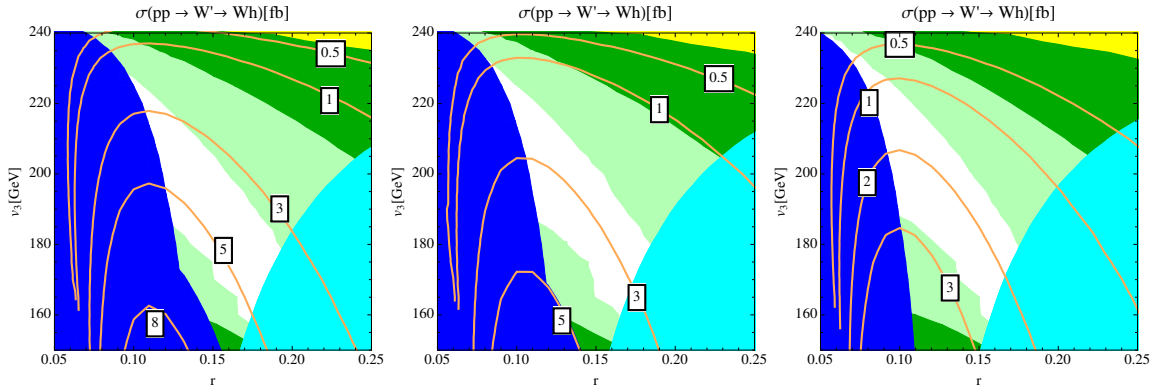

Figure 9. The cross sections of the diboson channels with h. We take $m_{W'} \simeq 1.9\,\text{TeV}$ (the left panel), 2.0 TeV (the middle panel), and 2.1 TeV (the right panel). The colored regions are experimental and theoretical constraints.

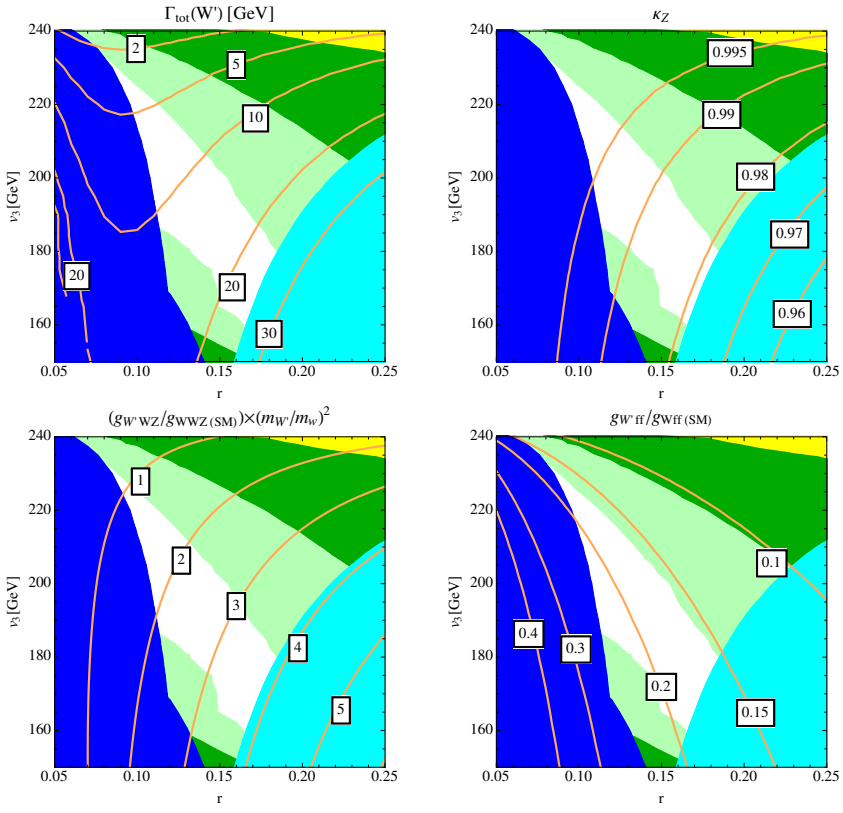

Figure 10. $\Gamma_{\text{tot}}(W')$, κ_Z, $(g_{W'WZ}/g^{\text{SM}}_{WWZ}) \times (m_{W'}/m_W)^2$, and $g_{W'ff}/g^{\text{SM}}_{Wff}$ for $m_{Z'} = 2\,\text{TeV}$. They are insensitive to small difference of $m_{Z'}$. The color notations are the same as in figure 8.

.

JHEP02(2016)084

in the top-left panel in the figure. We find that it is narrow and is less than 1 % of its mass, because the W' couplings to the SM particles are suppressed by powers of $m_W/m_{W'}$ and the decay into the heavy scalars are suppressed kinematically. The observable related to the Higgs couplings κ_Z defined in eq. (2.28) is shown in the top-right panels. The deviation from the SM prediction is small and the model is consistent with the current LHC data [51, 52]. Since the International Linear Collider (ILC) can measure the κ_Z at 1% level [53], some parameter points are within the reach of the proposed ILC. We show $g_{W'WZ}/g^{\rm SM}_{WWZ}$ and $g_{W'ff}/g^{\rm SM}_{Wff}$ at the lower panels in the figure. In the benchmark model used in ref. [1], $g_{W'WZ}/g^{\rm SM}_{WWZ} = m_W^2/m_{W'}^2$ and $g_{W'ff}/g^{\rm SM}_{Wff} = 1$. In our model, we find, due to the extra suppression by $\sqrt{1-v_3^2/v^2}$ and small r, $g_{W'WZ}/g^{\rm SM}_{WWZ}$ is numerically the same order as the benchmark model although its $m_{W'}$ dependence is $m_W/m_{W'}$ (see eq. (2.27)). On the other hand, $g_{W'ff}/g^{\rm SM}_{Wff}$ is about 10% of the benchmark model.

4 MC simulation of $W' \to WZ$ at $\sqrt{s} = 13\,\text{TeV}$

In this section, we perform a collider simulation of $pp \to W' \to WZ$ at $\sqrt{s} = 13\,\text{TeV}$. To study a discovery potential, we generate both QCD dijet background and $pp \to W' \to WZ$ signal events.

We generate 1.73×10^6 QCD dijet events as the dominant background by using Pythia 8.205 [54] with the generation cut so that the parton-parton center of mass energy must exceed 1 TeV and $p_T > 400\,\text{GeV}$ at $\sqrt{s} = 13\,\text{TeV}$. The tree level production cross section is 350 pb. Our sample therefore corresponds to roughly $\int dt\mathcal{L} = 5\,\text{fb}^{-1}$. We use the Tune 4C for fragmentation and hadronization [55]. We also generate 10^4 signal events ($pp \to W'(W'^+ + W'^-) \to WZ$) for the mass between 1800 and 3200 GeV, and take $\Gamma_{\rm tot}(W')$ to be 25 GeV in the simulation. Note that the total width of W' is less than about 30 GeV in the allowed region of this model (see figure 10). We also generate the signal and background events at $\sqrt{s} = 8\,\text{TeV}$ and compare them with the ATLAS plots [1].

The simple detector simulator Delphes3 [56] is modified using FastJet3 [57, 58] so that the mass drop and the grooming cuts used in the ATLAS study can be applied to the jets. We apply the cluster track matching algorithm of Delphes3 so that information of tracks inside jets can be used, otherwise the default ATLAS card is used.

Reconstruction of boosted objects using jet substructure was originally proposed in refs. [59, 60]. See recent developments in refs. [61, 62]. In our simulation, we closely follow the ATLAS analysis. The Cambridge-Aachen algorithm with $R = 1.2$ is used [63, 64] for the jet clustering. Then, $p_{T_1} > 600\,\text{GeV}$, $p_{T_2} > 540\,\text{GeV}$, $(p_{T_1} - p_{T_2})/(p_{T_1} + p_{T_2}) < 0.15$, $|y_1 - y_2| < 1.2$, $|\eta_1| < 2$ and $|\eta_2| < 2$ are required for the jets. In addition, we require $E_{Tmiss} < 350\,\text{GeV}$, and veto events with isolated electrons and muons with $p_T > 20\,\text{GeV}$. For each jet, the pair of the subjets which satisfies the subjet momentum balance criteria $\sqrt{y} > \sqrt{y_f} = 0.45$ are selected, where

$$\sqrt{y} = \min(p_{T_{j1}}, p_{T_{j2}})\frac{\Delta R_{(j1,j2)}}{m_0}. \tag{4.1}$$

Here, $p_{T_{j1}}$ and $p_{T_{j2}}$ are the transverse momenta of subjets j_1 and j_2, $\Delta R_{(j1,j2)}$ is the distance between the subjets j_1 and j_2, and m_0 is the mass of the parent jet. Then the constituents

JHEP02(2016)084

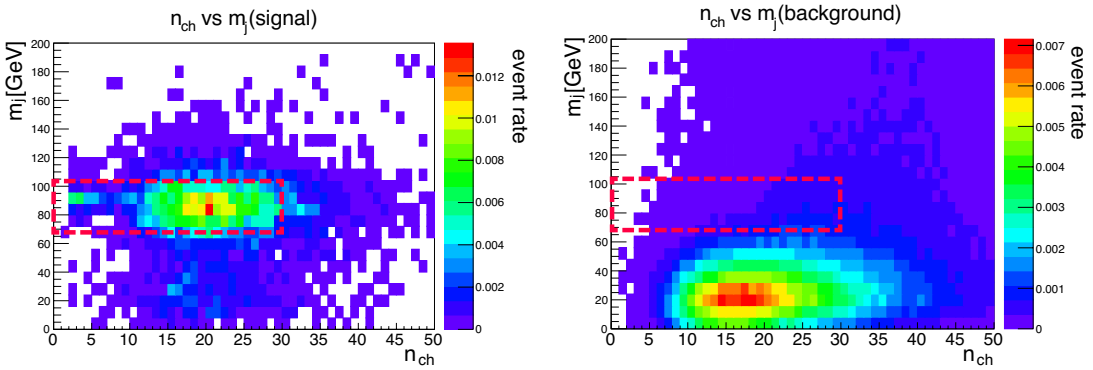

Figure 11. The distributions of the signal ($m_{W'} = 1800\,\text{GeV}$ and $\Gamma_{\text{tot}}(W') = 25\,\text{GeV}$) and the dijet background in n_{ch} and m_j plane. All the cut except for n_{ch} and m_j are applied, and we required $m_{jj} > 1500\,\text{GeV}$. The ATLAS signal regions are marked by squares.

of the selected pair of subjets are filtered. Namely the constituents are clustered with the radius parameter $R = 0.3$, and up to the highest 3 jets are taken to calculate the groomed jet mass and momentum. We require $|m_V - m_j| < 13\,\text{GeV}$, where m_V is m_Z or m_W, and m_j is an invariant mass of the groomed jet. Finally, the number of charged-particle tracks which are associated with the jet is required to be $n_{ch} < 30$. In figure 11, we show the distribution in n_{ch} and m_j plane for the events with $m_{jj} > 1500\,\text{GeV}$ where all the cuts except for n_{ch} and m_j are applied. The ATLAS signal regions are marked by squares. The figure shows very good separation between the signal and the background events.

To check our simulation, we compare the distributions of our $\sqrt{s} = 8\,\text{TeV}$ samples to the ATLAS ones. The figure 12 shows the reconstruction efficiency of the signal for various input W' mass. Our result at $\sqrt{s} = 13\,\text{TeV}$ is also shown. We find that the signal selection efficiency agrees with the ATLAS one. Since the jets get narrower with increasing p_T, the signal efficiency becomes lower for higher W' mass.

On the other hand, we find that the number of the background events after all the selection cuts are twice as large as that of the ATLAS final result. The discrepancy in the total background events might arise from several sources. The number of charged tracks of QCD jets are controlled by soft physics and varies significantly depending on Monte Carlo (MC) generators and tunes of the parton shower parameters especially for gluon jets. The distributions are shown in the left panel of figure 13, under the cut of figure 1 of ref. [1], $1.62\,\text{TeV} < m_{jj} < 1.98\,\text{TeV}$ and $60\,\text{GeV} < m_j < 110\,\text{GeV}$ together with the selection cuts listed above except that for n_{ch}, where m_{jj} is the dijet invariant mass. The signal distribution which is represented in the blue line agrees quite well with the ATLAS ones. However, the average number of charged tracks of dijet event is significantly higher than the ATLAS ones. To see the MC dependence, we also show the distribution of the MC sample generated by Herwig++ with default tunes by the black line [65], which predicts slightly small $\langle n_{ch} \rangle$ compared with Pythia8 Tune C4, but higher than ATLAS CT10 Tune.[5]

[5]In the study of quark-gluon separation [66], Herwig++ reproduces high gluon p_T jet nature well.

JHEP02(2016)084

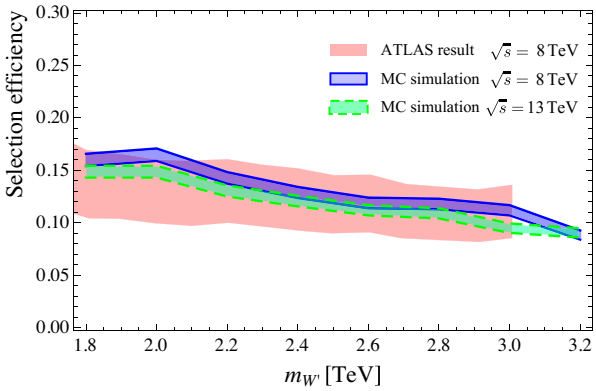

Figure 12. The event selection efficiencies for $W' \to WZ \to JJ$ simulated events generated by PYTHIA 8 as a function of the W' mass at $\sqrt{s} = 8$ and 13 TeV. The red band is the result of the ATLAS [1], where the thickness corresponds to $\pm$ 1 σ statistical and systematical errors. Our result of MC simulation at $\sqrt{s} = 8$ (13) TeV is represented in the blue (green) band where the thickness corresponds to $\pm$ 1 σ statistical error.

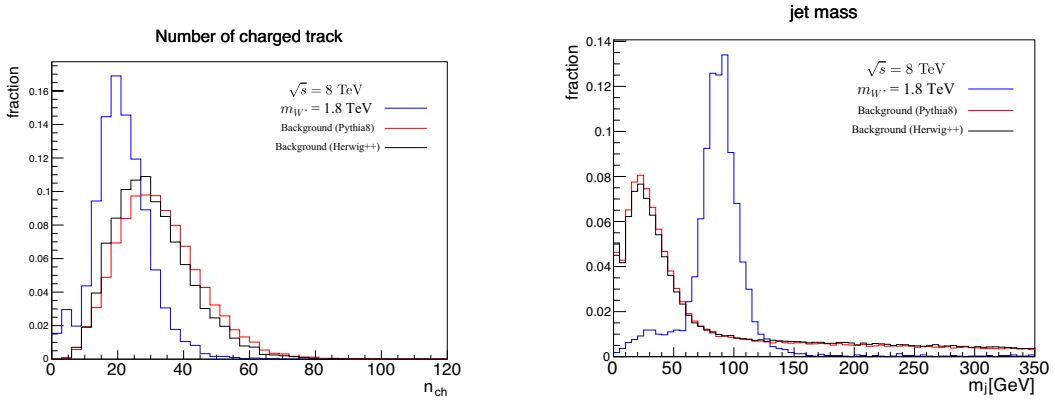

Figure 13. The distributions of the number of charged tracks $n_{\rm ch}$ (left) and the jet mass m_j (right) for the signal (Blue) and background events (Black and Red). We take $m_{W'} = 1800\,\text{GeV}$ and $\Gamma_{\rm tot}(W') = 25\,\text{GeV}$. We simulate the background events using PYTHIA8 (Red) and HERWIG++ (Black).

In the right panel of figure 13, we also show the m_j distributions for the signal and background. The signal distribution agrees quite well with the ATLAS MC results again. For the background distribution, we find that the number of events above $m_j > 50\,\text{GeV}$ is smaller compared with figure 1 of ref. [1]. This is because we do not generate underlying events together with the dijet events.

In the experimental side, ATLAS counts the well reconstructed track inside the jet. The efficiencies are not implemented in our simulation. Naively speaking, the efficiency is expected to be lower for the jets with high charged track multiplicity. For jet clustering, ATLAS selects calorimeter towers using Topocluster algorithm and does not use cluster-track matching which is only crudely implemented in our simulation. In any case, data driven approaches are adopted in ref. [1] to estimate the selection efficiency, and reproducing

JHEP02(2016)084

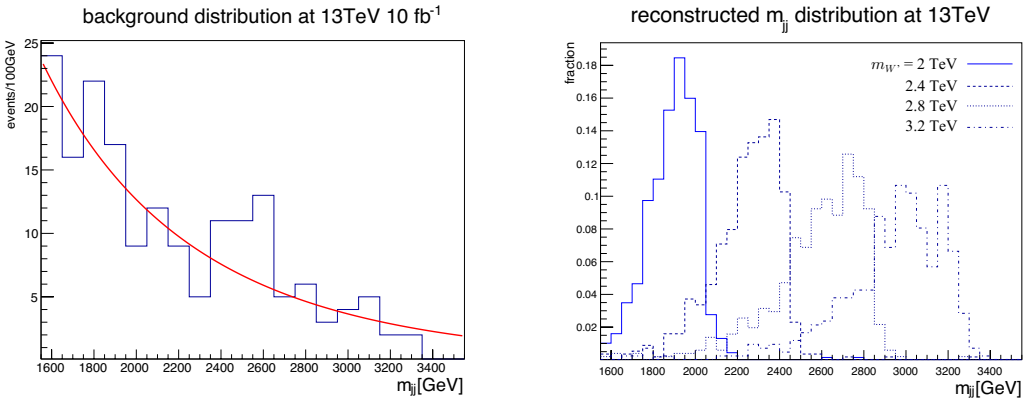

Figure 14. The m_{jj} distributions for the background (left) and the signal (right) at $\sqrt{s} = 13\,\text{TeV}$. The background distribution is for $10\,\text{fb}^{-1}$, and the signal distributions are normalized to be 1 for various input W' mass.

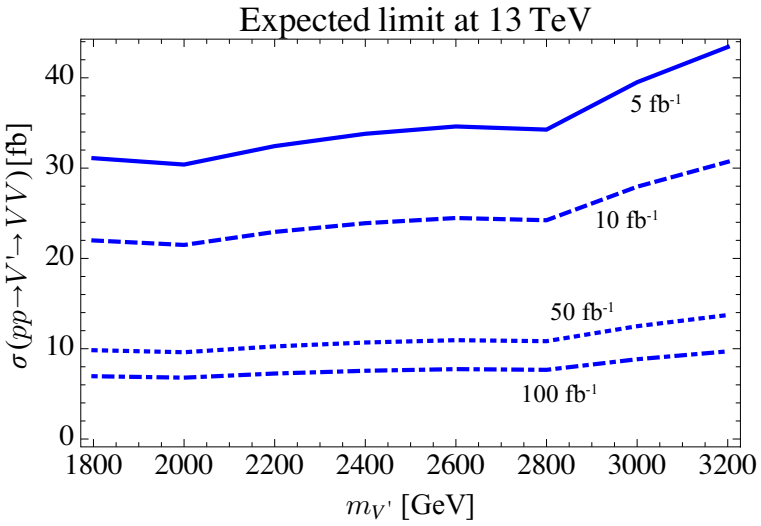

Figure 15. Expected limit on $\sigma(pp \to V' \to VV)$ at $\sqrt{s} = 13\,\text{TeV}$. We take $\Gamma_{\text{tot}}(V') = 25\,\text{GeV}$.

the result precisely is beyond the scope of this paper. It is probably worth doing more dedicated theoretical and experimental studies on jet nature relevant to the boosted W and Z bosons reconstruction in future.

Keeping crudeness of our simulation in mind, we estimate the signal efficiency at $\sqrt{s} = 13\,\text{TeV}$ using our signal MC and detector simulation without rescaling, while the number of the background events obtained from our MC is rescaled by factor of $1/2$ which is needed to reproduce the ATLAS results at $\sqrt{s} = 8\,\text{TeV}$. The scaling approach comes from an assumption that the change in the center of mass energy from 8 TeV to 13 TeV does not alter the structure inside jets of the same p_T jets. Note that gluon jets are involved in the QCD background at $\sqrt{s} = 13\,\text{TeV}$ but this effect is not taken into account. Under this assumption, the background is fitted to estimate the distribution, and the result is shown

JHEP02(2016)084

in the left panel of figure 14. We found 169 events/10 fb^{-1} for 1550 GeV $< m_{jj} <$ 3550 GeV after rescaling. We also show the dijet invariant mass distributions of the signal for various input W' mass in the right panel of figure 14.

Figure 15 shows expected the exclusion limit at 95 % C.L. for $\sigma(pp \to V' \to VV)$ at $\sqrt{s} = 13$ TeV.[6] We calculated $\Delta\chi^2$ of the signal plus background distributions to the background distribution. For the signal, we generate 10^4 signal events to obtain the result for each $m_{W'}$, and take the number of events in the bins $i_{\max} - 3 \leq i \leq i_{\max} + 3$, where $i_{\max}$ is the highest signal event bin and the bin size is 50 GeV. Then, we rescale them by the cross section and luminosity. The selection efficiency of the signal event is shown in figure 12. For the background, we use our fit and rescaled it by the luminosity. Here y-axis means $\sigma(pp \to W' \to WZ) + \sigma(pp \to Z' \to WW)$ with the mass at $m_{V'}$. We find that the region where $\sigma(pp \to V' \to VV)$ is larger than 20 fb may be excluded at $\int dt\mathcal{L} = 10\,\text{fb}^{-1}$ and $\sqrt{s} = 13$ TeV.

5 Future prospects: 13 TeV analyses

In this section, we analyze the future prospects of W' and Z' searches by applying result in section 4.

We investigate the prospects for the $\sqrt{s} = 13$ TeV collision in the case of $m_{Z'} = 2$ TeV. In figure 16, we show contours of the several cross sections by orange dashed lines in r–v_3 planes: $\sigma(pp \to W')\text{Br}(W' \to WZ) + \sigma(pp \to Z')\text{Br}(Z' \to WW)$, $\sigma(pp \to W')\text{Br}(W' \to Wh)$, $\sigma(pp \to W')\text{Br}(W' \to \ell\nu)$, $\sigma(pp \to W')\text{Br}(W' \to jj) + \sigma(pp \to Z')\text{Br}(Z' \to jj)$, and $\sigma(pp \to Z')\text{Br}(Z' \to \ell\ell)$. The color filled regions are excluded and constrained as we discussed in section 3.3. The color notations are the same as in figure 8.

The expected exclusion limit at $\sqrt{s} = 13$ TeV provided in figure 15 is shown by the red (dashed) line for $\int dt\mathcal{L} = 10$ (100) fb^{-1}. The masses of W' and Z' are highly degenerate in the small r regime, and we assume that the signal efficiency for $Z' \to WW$ event is equivalent to the one for $W' \to WZ$ which is simulated in the previous section. Thus we can apply the prospect shown in figure 15 to $\sigma(pp \to W' \to WZ) + \sigma(pp \to Z' \to WW)$. The region where the ATLAS diboson excess can be explained is within the reach of the LHC at $\int dt\mathcal{L} = 10\,\text{fb}^{-1}$ and $\sqrt{s} = 13$ TeV. In addition, the cross sections of the other channels are also large, so that the spin-1 resonances could be probed in the channels as well.

We plot the $\sqrt{s} = 13$ TeV cross sections as a function of spin-1 resonance mass in figure 17. We take the universal mass $m_{Z'} = m_A = m_{H'} = m_H$, $v_3 = 200$ GeV, and $\kappa_F = 1.00$ in figure 17. The color notation is the same as in figure 8. The mass of W' is highly degenerate with the mass of Z' in this figure. We find that the spin-1 resonances lighter than 2.1 (2.6) TeV can be excluded by the diboson search at the LHC with $\int dt\mathcal{L} = 10$ (100) fb^{-1}. Figure 18 shows the same cross sections for another parameter set ($v_3 = 150$ GeV and $\kappa_F = 0.99$). With the consideration of the bounded below condition, we find that the spin-1 resonances up to masses of 2.3 (2.6) TeV can be excluded with $\int dt\mathcal{L} = 10$ (100) fb^{-1}.

[6] Prospects for the electroweak gauge boson scattering which can also probe W' are discussed in, for example, ref. [67].

JHEP02(2016)084

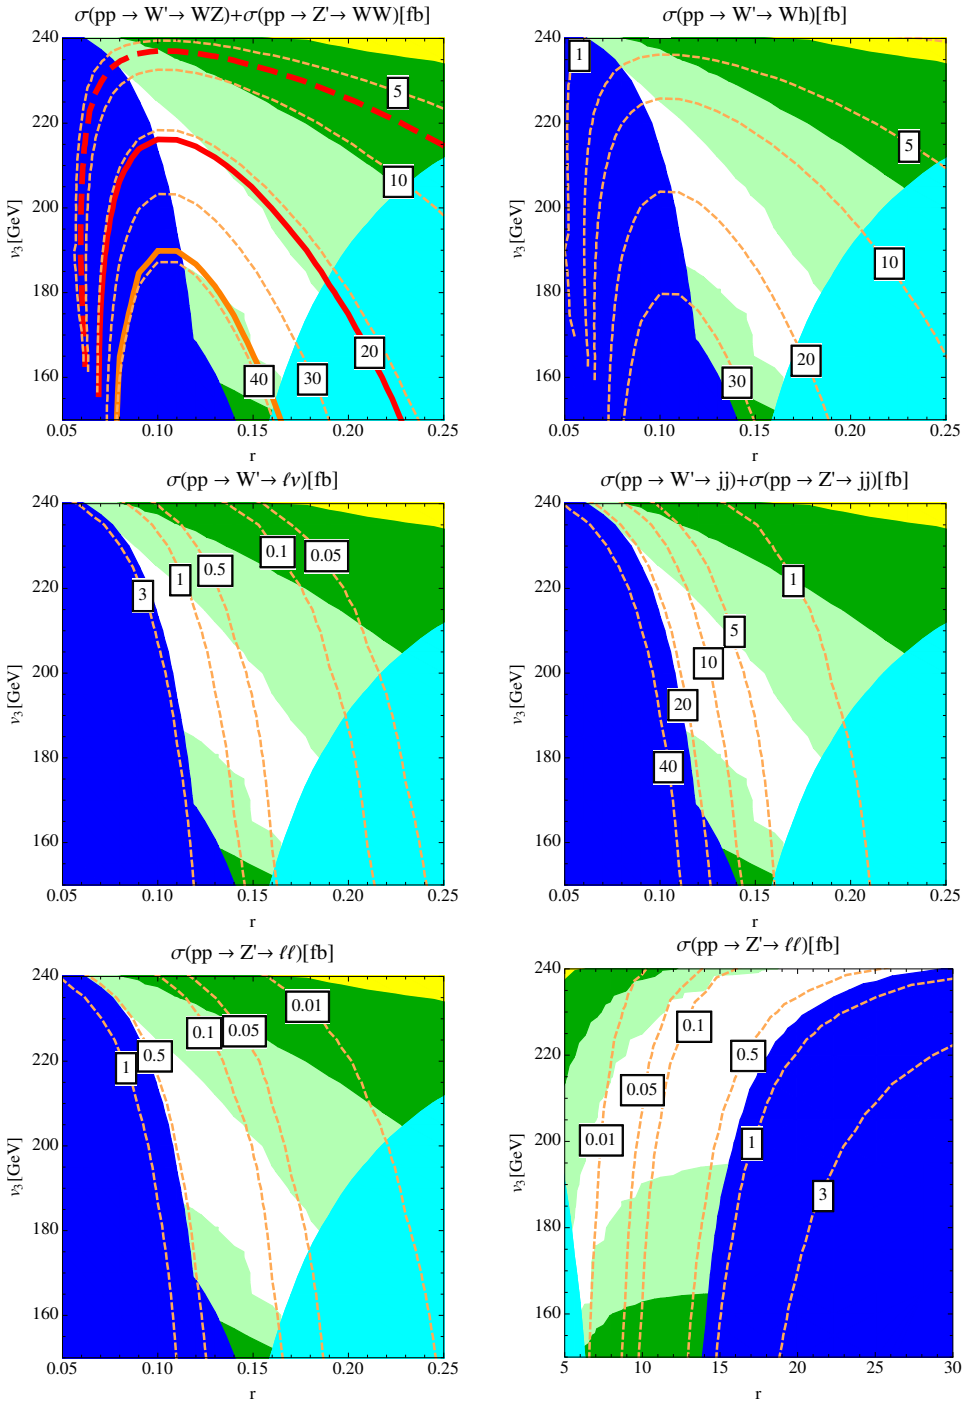

Figure 16. The prospects for the $\sqrt{s} = 13\,\text{TeV}$ collision. We take $m_{Z'} = m_A = m_{H'} = m_H = 2000\,\text{GeV}$, $\kappa_F = 1.00$. The color notation is the same as in figure 8. Below the thick orange line, the cross section $\sigma(pp \to V' \to VV)$ is enough to explain the diboson excess at ATLAS. Below the (dashed) red line is expected to be excluded with $\int dt\mathcal{L} = 10\ (100)\,\text{fb}^{-1}$.

JHEP02(2016)084

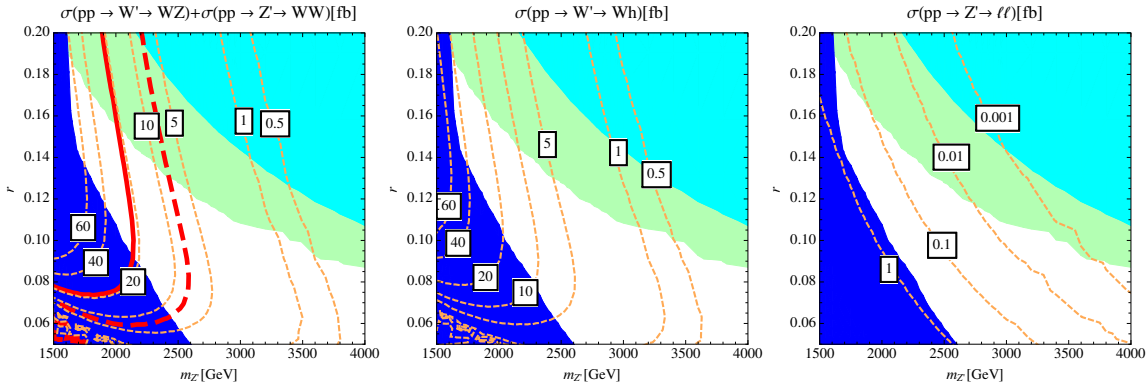

Figure 17. The prospects of the discovery as a function of $m_{Z'}$ and r for the LHC Run-2. We take $v_3 = 200\,\text{GeV}$ and $\kappa_F = 1.00$. The color notation is the same as in figure 8. The (dashed) red is the future expected exclusion limit for $\int dt\mathcal{L} = 10\ (100)\,\text{fb}^{-1}$.

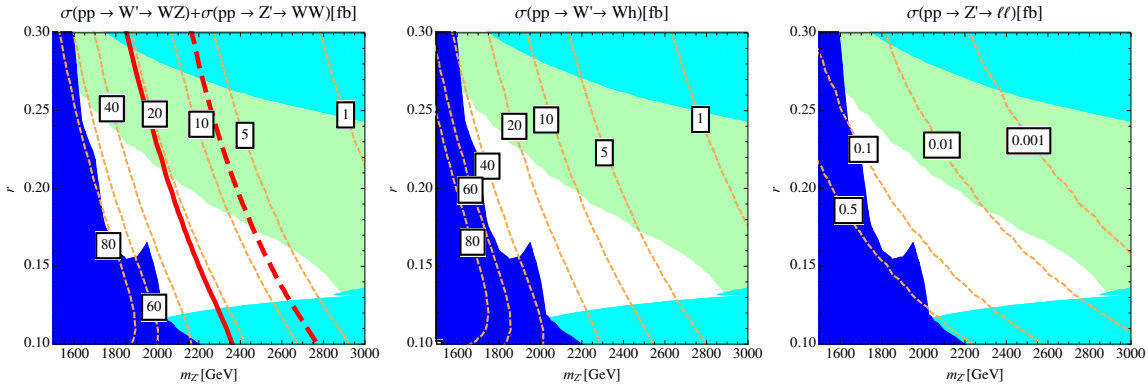

Figure 18. The prospects of the discovery as a function of $m_{Z'}$ and r for the LHC Run-2. We take $v_3 = 150\,\text{GeV}$ and $\kappa_F = 0.99$. Below the (dashed) red line is expected to be excluded with $\int dt\mathcal{L} = 10\ (100)\,\text{fb}^{-1}$.

Before closing this section, we briefly comment on the prospect for the large r region. Under the several theoretical bounds, this model has two allowed regions, namely small r and large r regions (see figure 5). The cross section of $pp \to Z' \to \ell\ell$ is enhanced by r^2 factor in large r regime (see eq. (B.2)). ATLAS study found $m_{Z'}$ around 3 TeV with the cross section around 0.01 fb is accessible with the high luminosity LHC at $\sqrt{s} = 14\,\text{TeV}$ with integrated luminosity $3000\,\text{fb}^{-1}$ [68]. Thus we can expect that the cross section for the large r region in the model is accessible at the LHC Run-2 as we can see in figure 16. However, the r regime would be constrained from the electroweak precision parameters at one-loop level due to the custodial symmetry breaking.

6 Conclusion

Motivated by the ATLAS diboson excess around 2 TeV, we have investigated the phenomenology of the spin-1 resonances (W' and Z') in the partially composite standard model. In this model, W' and Z' couple to the SM fermions weakly through the mixing

JHEP02(2016)084

to the elementary gauge bosons. We find that the main decay modes of the resonances are $V' \to VV$ and $V' \to Vh$, and the width is narrow enough so that the ATLAS diboson excess can be explained. The couplings of the spin-1 resonances with the SM sector can be controlled by the ratio of the Higgs VEVs so that the ATLAS diboson excess can be explained.

We have explored not only the current bounds from the LHC and the precision measurements but also the theoretical constraints, i.e. perturbativity condition, bounded below condition, global minimum vacuum condition, and stability condition of the scalar potential. The parameter regions where the diboson excess at the ATLAS can be explained are still allowed after including those constraints.

In order to investigate future prospects of the spin-1 resonance search, we have performed the simulation at $\sqrt{s} = 13\,\text{TeV}$ LHC, and estimated model independent exclusion limit for $\sigma(pp \to V' \to VV \to JJ)$ shown in figure 15. Applying our simulation result, we find that the parameter regions consistent with the ATLAS diboson excess will be excluded at $\int dt\mathcal{L} = 10\,\text{fb}^{-1}$ and $\sqrt{s} = 13\,\text{TeV}$.

Finally, we have investigated future prospects of diboson resonance search in our model. The spin-1 resonances up to a mass of 2.6 TeV can be probed at $\sqrt{s} = 13\,\text{TeV}$ and $\int dt\mathcal{L} = 100\,\text{fb}^{-1}$.

A Viable range of the coupling ratio κ_Z

In this appendix, we show κ_Z is very restricted to be one. We first replace the Higgs quartic couplings λ_i by the other parameters eq. (2.34). Here we take $m_A = m_{H'} = m_H$ for simplicity, and work in $m_A \gg m_h$ regime. For $r \ll 1$ regime, we find

$$\lambda_1 \simeq 0, \tag{A.1}$$

$$\lambda_2 \simeq f_1(\kappa_F, \kappa_Z), \tag{A.2}$$

$$\lambda_3 \simeq \frac{m_h^2}{2v^2}\kappa_F^2 + \frac{m_A^2}{2v^2}(1-\kappa_F^2), \tag{A.3}$$

$$\lambda_{12} \simeq 0, \tag{A.4}$$

$$\lambda_{23} \simeq f_2(\kappa_F, \kappa_Z), \tag{A.5}$$

$$\lambda_{31} \simeq 0, \tag{A.6}$$

JHEP02(2016)084

and for $r \gg 1$ regime,

$$\lambda_1 \simeq f_1(\kappa_F, \kappa_Z), \tag{A.7}$$

$$\lambda_2 \simeq 0, \tag{A.8}$$

$$\lambda_3 \simeq \frac{m_h^2}{2v^2}\kappa_F^2 + \frac{m_A^2}{2v^2}(1-\kappa_F^2), \tag{A.9}$$

$$\lambda_{12} \simeq 0, \tag{A.10}$$

$$\lambda_{23} \simeq 0, \tag{A.11}$$

$$\lambda_{31} \simeq f_2(\kappa_F, \kappa_Z), \tag{A.12}$$

$$\tag{A.13}$$

where

$$f_1(\kappa_F, \kappa_Z) \simeq \frac{m_h^2}{2v^2} - (1-\kappa_F)\frac{v_3^2}{v^2}\frac{2(m_A^2 - m_h^2)}{v^2 - v_3^2} + (1-\kappa_Z)\frac{m_A^2 - m_h^2}{v^2 - v_3^2}, \tag{A.14}$$

$$f_2(\kappa_F, \kappa_Z) \simeq \frac{m_h^2}{v^2} + (1-\kappa_F)\frac{v^2 - 3v_3^2}{v^2}\frac{m_A^2 - m_h^2}{v^2 - v_3^2} + (1-\kappa_Z)\frac{m_A^2 - m_h^2}{v^2 - v_3^2}. \tag{A.15}$$

1In eqs. (A.14) and (A.15), we make an expansion around $\kappa_F \simeq 1$ and $\kappa_Z \simeq 1$. Since both coefficients of $(1-\kappa_F)$ and $(1-\kappa_Z)$ are large enough in $m_A \gg v$ regime, even the small deviations of κ_F and κ_Z from 1 change the Higgs quartic couplings λ_i drastically.

Let us consider the case of $\kappa_F = 1$. The largest Higgs quartic coupling is λ_{23} (λ_{31}) in the $r \ll 1$ ($r \gg 1$) regime. We further demand λ_{23} (λ_{31}) $< (4\pi)^2$, namely

$$\kappa_Z > 1 - \frac{(16\pi^2 v^2 - m_h^2)}{(m_A^2 - m_h^2)}\left(1 - \frac{v_3^2}{v^2}\right). \tag{A.16}$$

Due to the running effects, these quartic couplings can be even larger at the high scale, so that the lower bound on κ_Z is actually severer than above estimation.

In figure 19, we show that the viable range of the coupling ratio κ_Z, where we take $v_3 = 200\,\text{GeV}$, $m_{Z'} = m_A = m_{H'} = m_H = 2\,\text{TeV}$, and $\kappa_F = 1.00$. The regions where $\lambda_i(\mu = 10\ (100)\,\text{TeV}) > (4\pi)^2$ are filled with green (light green), and there is no physical solution in the gray region. The maximal value of κ_Z is achieved at a boundary of the gray region. The white area represents the allowed region of parameter space. Thus we find κ_Z is severely constrained close to its maximized value for $m_A \gg m_h$.

B Production cross sections of W' and Z'

The leading order production cross sections of W' and Z' are given as follows.

$$\begin{aligned}\sigma(pp \to W'^{\pm}X) \simeq\ & \frac{\pi}{12s}\frac{m_W^2}{m_{W'}^2}\frac{e^2}{s_W^2}\frac{1}{r^2}\left(1 - \frac{v_3^2}{v^2}\right)\int_{m_{W'}^2/s}^1 \frac{dx}{x} \\ & \times \left(f_u(x, m_{W'}) f_{\bar{d}}\left(\frac{m_{W'}^2}{sx}, m_{W'}\right) + f_{\bar{d}}(x, m_{W'}) f_u\left(\frac{m_{W'}^2}{sx}, m_{W'}\right)\right. \\ & + f_d(x, m_{W'}) f_{\bar{u}}\left(\frac{m_{W'}^2}{sx}, m_{W'}\right) + f_{\bar{u}}(x, m_{W'}) f_d\left(\frac{m_{W'}^2}{sx}, m_{W'}\right) \\ & \left. + (u \leftrightarrow c, d \leftrightarrow s)\right),\end{aligned} \tag{B.1}$$

JHEP02(2016)084

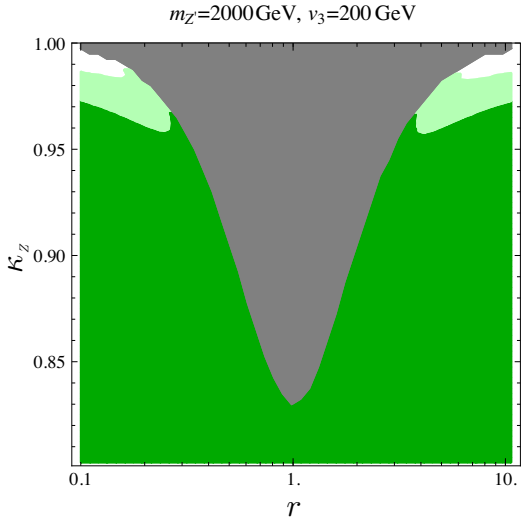

Figure 19. The viable range of the coupling ratio κ_Z, where we take $v_3 = 200\,\text{GeV}$, $m_{Z'} = m_A = m_{H'} = m_H = 2\,\text{TeV}$, and $\kappa_F = 1.00$. The regions where $\lambda_i(\mu = 10\ (100)\,\text{TeV}) > (4\pi)^2$ are filled with green (light green).

$$\begin{aligned}\sigma(pp \to Z'X) \simeq\ & \frac{\pi}{6s}\frac{m_W^2}{m_{W'}^2}\frac{e^2}{s_W^2}\frac{1}{r^2}\left(1-\frac{v_3^2}{v^2}\right) \\ & \times\left(\left(\left(1-r^2\frac{s_Z^2}{c_Z^2}\right)T_f^3+r^2\frac{s_Z^2}{c_Z^2}Q_f\right)^2+\left(r^2\frac{s_Z^2}{c_Z^2}Q_f\right)^2\right)\int_{m_{Z'}^2/s}^1\frac{dx}{x} \\ & \times\left(f_u(x,m_{Z'})f_{\bar{u}}\left(\frac{m_{Z'}^2}{sx},m_{Z'}\right)+f_{\bar{u}}(x,m_{Z'})f_u\left(\frac{m_{Z'}^2}{sx},m_{Z'}\right)\right. \\ & \left.+(u\leftrightarrow d,\ s,\ c,\ b)\right),\end{aligned} \tag{B.2}$$

where s is a square of the center of mass energy of the pp collider and $f_q(x,\ Q)$ is the parton distributions inside the p at the factorization scale Q for quark flavor q. Note that eq. (B.1) is a sum of production cross section of W'^+ and W'^-.

C Renormalization group equations

We derive the one-loop β functions for this model [69, 70], and obtain,

$$\beta_{g_0} = -3g_0^3, \tag{C.1}$$
$$\beta_{g_1} = -7g_1^3, \tag{C.2}$$
$$\beta_{g_2} = 7g_2^3, \tag{C.3}$$
$$\beta_{g_s} = -7g_s^3, \tag{C.4}$$
$$\beta_{\lambda_1} = 24\lambda_1^2 + 2\lambda_{12}^2 + 2\lambda_{31}^2 - 9\lambda_1(g_0^2+g_1^2) + \frac{9}{8}g_0^4 + \frac{9}{8}g_1^4 + \frac{9}{4}g_0^2g_1^2, \tag{C.5}$$
$$\beta_{\lambda_2} = 24\lambda_2^2 + 2\lambda_{12}^2 + 2\lambda_{23}^2 - 3\lambda_2(3g_1^2+g_2^2) + \frac{9}{8}g_1^4 + \frac{3}{8}g_2^4 + \frac{3}{4}g_1^2g_2^2, \tag{C.6}$$

JHEP02(2016)084

$$\beta_{\lambda_3} = 24\lambda_3^2 + 2\lambda_{23}^2 + 2\lambda_{31}^2 - 3\lambda_3(3g_0^2 + g_2^2) + \frac{9}{8}g_0^4 + \frac{3}{8}g_2^4 + \frac{3}{4}g_0^2 g_2^2 + 2\lambda_3(3y_t^2 + 3y_b^2 + y_\tau^2) - \frac{3}{2}y_t^4 - \frac{3}{2}y_b^4 - \frac{1}{2}y_\tau^4, \tag{C.7}$$

$$\beta_{\lambda_{12}} = 4\lambda_{12}^2 + 12\lambda_{12}(\lambda_1 + \lambda_2) + 4\lambda_{23}\lambda_{31} - \frac{3}{2}\lambda_{12}(3g_0^2 + 6g_1^2 + g_2^2) + \frac{9}{4}g_1^4, \tag{C.8}$$

$$\beta_{\lambda_{23}} = 4\lambda_{23}^2 + 12\lambda_{23}(\lambda_2 + \lambda_3) + 4\lambda_{12}\lambda_{31} - \frac{3}{2}\lambda_{23}(3g_0^2 + 3g_1^2 + 2g_2^2) + \frac{3}{4}g_2^4 + \lambda_{23}(3y_t^2 + 3y_b^2 + y_\tau^2), \tag{C.9}$$

$$\beta_{\lambda_{31}} = 4\lambda_{31}^2 + 12\lambda_{31}(\lambda_1 + \lambda_3) + 4\lambda_{12}\lambda_{23} - \frac{3}{2}\lambda_{31}(6g_0^2 + 3g_1^2 + g_2^2) + \frac{9}{4}g_0^4 + \lambda_{31}(3y_t^2 + 3y_b^2 + y_\tau^2), \tag{C.10}$$

$$\beta_{y_t} = y_t\left(-\frac{9}{4}g_0^2 - \frac{17}{12}g_2^2 - 8g_s^2 + \frac{9}{4}y_t^2 + \frac{3}{4}y_b^2 + \frac{1}{2}y_\tau^2\right), \tag{C.11}$$

$$\beta_{y_b} = y_b\left(-\frac{9}{4}g_0^2 - \frac{5}{12}g_2^2 - 8g_s^2 + \frac{3}{4}y_t^2 + \frac{9}{4}y_b^2 + \frac{1}{2}y_\tau^2\right), \tag{C.12}$$

$$\beta_{y_\tau} = y_\tau\left(-\frac{9}{4}g_0^2 - \frac{15}{4}g_2^2 + \frac{3}{2}y_t^2 + \frac{3}{2}y_b^2 + \frac{5}{4}y_\tau^2\right), \tag{C.13}$$

where β functions are defined in the following notation,

$$\frac{d(\text{coupling})}{d\ln\mu} = \frac{\beta_{(\text{coupling})}}{(4\pi)^2}. \tag{C.14}$$

Abstract: We discuss the Type-X (lepton-specific) two Higgs doublet model as a solution of the anomaly of the muon $g-2$. We consider various experimental constraints on the parameter space such as direct searches for extra Higgs bosons at the LEP II and the LHC Run-I, electroweak precision observables, the decay of $B_s \to \mu^+\mu^-$, and the leptonic decay of the tau lepton. We find that the measurement of the tau decay provides the most important constraint, which excludes the parameter region that can explain the muon $g-2$ anomaly at the 1σ level. We then discuss the phenomenology of extra Higgs bosons and the standard model-like Higgs boson (h) to probe the scenario favored by the $g-2$ data at the collider experiments. We find that the 4τ, 3τ and $4\tau + W/Z$ signatures are expected as the main signal of the extra Higgs bosons at the LHC. In addition, we clarify that the value of the $h\tau\tau$ coupling is predicted to be the standard model value times about -1.6 to -1.0, and the branching fraction of the $h \to \gamma\gamma$ mode deviates from the standard model prediction by -30% to -15%. Furthermore, we find that the exotic decay mode, h decaying into the Z boson and a light CP-odd scalar boson, is allowed, and its branching fraction can be a few percent. These deviations in the property of h will be tested by the precision measurements at future collider experiments.

1 Introduction

The anomalous magnetic moment of the muon $a_\mu \equiv (g-2)/2$, so-called muon $g-2$, is a very precisely measured observable. The latest measurement of a_μ by the E821 collaboration [1] gives

$$a_\mu^{\rm exp} = 11\ 659\ 208.0\ (5.4)(3.3) \times 10^{-10}. \tag{1.1}$$

As it has been well known that there is a discrepancy between the experimental value and the prediction of the standard model (SM). According to the calculation evaluated in

JHEP07(2015)064

refs. [2, 3]

$$a_\mu^{\rm exp} - a_\mu^{\rm SM} = (28.7 \pm 8.0) \times 10^{-10}, \qquad \text{(Davier et al.)}$$
$$a_\mu^{\rm exp} - a_\mu^{\rm SM} = (26.1 \pm 8.0) \times 10^{-10}, \qquad \text{(Hagiwara et al.)}$$

the discrepancy is more than the 3σ level, which can be considered as an indirect evidence of the existence of a new physics model. This discrepancy will be further probed at Fermilab [4] and J-PARC [5] in the near future. Since the size of the deviation is the same order as the electroweak contribution $a_\mu^{\rm EW} = 15.4 \times 10^{-10}$ [6], we expect that new physics exists at the electroweak scale if the strength of new interactions is as large as that of the weak interaction. In such a new physics scenario, new particles are expected to be light enough to be directly discovered at the LHC. Therefore, it is quite interesting to consider models beyond the SM as a solution of the muon $g-2$ anomaly.

Among various models which can explain the anomaly (for a review, e.g., see ref. [7]), two Higgs doublet models (2HDMs) give simple solutions. In 2HDMs, there are extra Higgs bosons (H, A, and $H^\pm$) in addition to the SM-like Higgs boson (h), and they can give new contributions to a_μ. Usually, a softly-broken discrete Z_2 symmetry is imposed [8] to avoid flavor changing neutral current (FCNC) processes at the tree level. Under the Z_2 symmetry, four independent types of Yukawa interactions are allowed depending on the assignment of the Z_2 charge to the SM fermion [9, 10], which are called as Type-I, Type-II, Type-X (or lepton specific) and Type-Y (or flipped) [11]. In all the types of Yukawa interactions, the lepton couplings to the extra Higgs bosons can be sizable enough to explain a_μ. In the Type-I and Type-Y 2HDMs, however, the top Yukawa coupling also becomes large together with the enhancement of the lepton couplings. This is disfavored from the view point of perturbativity. Thus, the Type-II and Type-X 2HDMs are suitable to solve the muon $g-2$ anomaly.

The muon $g-2$ has been calculated in a number of papers within 2HDMs [12–22]. In the early 2000s, this was calculated at the one-loop level in the Type-II 2HDM in ref. [12]. After that, it was pointed out in refs. [13, 14] that the two-loop Barr-Zee type diagrams [23, 24] give a significant contribution to a_μ if a mass of A is $\mathcal{O}$(10-100) GeV and if there is large $Ab\bar{b}$ or $A\tau^+\tau^-$ couplings. In ref. [19], the implication on collider signatures was discussed in the Type-X 2HDM, namely, the $h \to AA \to 4\tau$ process can be important in the favored parameter region by a_μ. After the discovery of the Higgs boson at the LHC [25, 26], the muon $g-2$ has been reanalyzed by taking into account the Higgs boson search data in addition to the previous experimental constraints [20–22]. Furthermore, the recent observation of $\mathrm{Br}(B_s \to \mu^+\mu^-)$ at the LHC [27] gives a new constraint on the parameter space of 2HDMs [21].

The difference between the Type-II and Type-X 2HDMs is the quark couplings to the extra Higgs bosons. In the Type-II 2HDM, both the lepton and down-type quark couplings are enhanced simultaneously, and thus the model is severely constrained by flavor physics and direct searches of the extra Higgs bosons. On the other hand, in the Type-X 2HDM, the quark couplings to the extra Higgs bosons are suppressed when the lepton couplings are enhanced. Thus, the constraints are weaker than those in the Type-II 2HDM. In fact, it was clarified in refs. [20, 21] that only the Type-X 2HDM can solve the muon $g-2$ anomaly with satisfying the current experimental data.[1]

[1] In addition to the muon $g-2$ anomaly, there are several other motivations for this model. For example, see refs. [28, 29].

Table 1. Assignment of the Z_2 parity and ξ_f factors in eq. (2.21) in each type of the Yukawa interactions.

Another important constraint comes from the lepton flavor physics. In the Type-X 2HDM, the constraint from the leptonic τ decay [11, 30–32] gives a severe constraint on the parameter space favored to explain the $g-2$ anomaly because of the lepton coupling enhancements. However, this important constraint has not been included in the previous analyses. Therefore, in this paper, we calculate the leptonic τ decay and the $Z\tau\tau$ vertex at the one-loop level in the Type-X 2HDM in order to compare the precise experimental measurements. We then investigate the favored parameter region by a_μ under these constraints in addition to those already known. Furthermore, we evaluate the running of the scalar quartic couplings by renormalization group equations (RGEs), and require that the couplings do not become too large up to a certain energy scale, for example 10 TeV. We find that extra Higgs boson loop contributions can reduce the discrepancy in a_μ to be 2σ level, but not less than 1σ level. We then study the collider phenomenology in the favored parameter region.

This paper is organized as follows. In section 2, we define the Lagrangian of the 2HDM, and derive the Higgs boson couplings with the gauge bosons and the fermions. In section 3, we discuss constraints from direct searches for the extra Higgs bosons at LEP II and the LHC Run-I, electroweak precision observables, the decay of $B_s \to \mu^+\mu^-$, the leptonic τ decay, and the triviality bound. In section 4, we show the favored parameter regions by the muon $g-2$ anomaly. In section 5, we discuss the collider phenomenology of the extra Higgs bosons at the LHC, the deviations in the SM-like Higgs boson h couplings, and the decay branching fractions of h. We also discuss the exotic decay mode: $h \to ZA$. Conclusion is given in section 6. In appendix, we present the expressions for the decay rates of extra Higgs bosons and those for the parton level cross sections for the production of extra Higgs bosons at the LHC.

2 The 2HDMs

In this section, we define the Lagrangian of the 2HDM, in which the Higgs sector is composed of two $\mathrm{SU}(2)_L$ doublet scalar fields H_1 and H_2. To avoid the tree level FCNC, we impose a Z_2 symmetry in the Higgs sector which can be softly-broken in general. Under the Z_2 parity, four types of Yukawa interactions are defined depending on the assignment of Z_2 charge as listed in table 1.

JHEP07(2015)064

The most general Higgs potential with the softly-broken Z_2 parity is given as

$$V = m_{11}^2|H_1|^2 + m_{22}^2|H_2|^2 - (m_{12}^2 H_1^\dagger H_2 + h.c.) + \frac{\lambda_1}{2}|H_1|^4 + \frac{\lambda_2}{2}|H_2|^4 + \lambda_3|H_1|^2|H_2|^2 + \lambda_4|H_1^\dagger H_2|^2 + \left[\frac{\lambda_5}{2}(H_1^\dagger H_2)^2 + h.c.\right]. \quad (2.1)$$

Throughout the paper, we consider the CP-conserving case of the Higgs sector for simplicity, so that the imaginary parts of m_{12}^2 and λ_5 are assumed to be zero. The Higgs fields are parametrized as

$$H_i = \begin{bmatrix} h_i^+ \\ \frac{1}{\sqrt{2}}(v_i + h_i - ia_i) \end{bmatrix}, \quad (i = 1, 2), \quad (2.2)$$

where v_1 and v_2 are the VEVs of the Higgs doublets which are related to the Fermi constant G_F by $v^2 \equiv v_1^2 + v_2^2 = 1/(\sqrt{2}G_F)$. The ratio of the two VEVs is parametrized by $\tan\beta = v_2/v_1$.

The mass eigenstates of the scalar bosons are expressed by introducing the mixing angles α and β as

$$\begin{pmatrix} h_1 \\ h_2 \end{pmatrix} = \begin{pmatrix} \cos\alpha & -\sin\alpha \\ \sin\alpha & \cos\alpha \end{pmatrix} \begin{pmatrix} H \\ h^0 \end{pmatrix}, \quad (2.3)$$

$$\begin{pmatrix} a_1 \\ a_2 \end{pmatrix} = \begin{pmatrix} \cos\beta & -\sin\beta \\ \sin\beta & \cos\beta \end{pmatrix} \begin{pmatrix} G^0 \\ A \end{pmatrix}, \quad (2.4)$$

$$\begin{pmatrix} h_1^\pm \\ h_2^\pm \end{pmatrix} = \begin{pmatrix} \cos\beta & -\sin\beta \\ \sin\beta & \cos\beta \end{pmatrix} \begin{pmatrix} G^\pm \\ H^\pm \end{pmatrix}, \quad (2.5)$$

where G^0 and $G^\pm$ are the Nambu-Goldstone bosons which are absorbed by the Z and W bosons as the longitudinal component, respectively.

The squared masses for the physical Higgs bosons are given by

$$\begin{aligned} m_{H^\pm}^2 &= M^2 - \frac{v^2}{2}(\lambda_4 + \lambda_5), \\ m_A^2 &= M^2 - v^2\lambda_5, \\ m_H^2 &= \cos^2(\alpha-\beta)M_{11}^2 + \sin^2(\alpha-\beta)M_{22}^2 + \sin 2(\alpha-\beta)M_{12}^2, \\ m_h^2 &= \sin^2(\alpha-\beta)M_{11}^2 + \cos^2(\alpha-\beta)M_{22}^2 - \sin 2(\alpha-\beta)M_{12}^2, \end{aligned} \quad (2.6)$$

where $M^2 = m_{12}^2/(\sin\beta\cos\beta)$ describes the breaking scale of the Z_2 symmetry, and M_{ij}^2 are given by

$$M_{11}^2 = v^2(\lambda_1\cos^4\beta + \lambda_2\sin^4\beta) + \frac{v^2}{2}\lambda_{345}\sin^2 2\beta, \quad (2.7)$$

$$M_{22}^2 = M^2 + v^2(\lambda_1 + \lambda_2 - 2\lambda_{345})\sin^2\beta\cos^2\beta, \quad (2.8)$$

$$M_{12}^2 = \frac{v^2}{2}(\lambda_2\sin^2\beta - \lambda_1\cos^2\beta + \lambda_{345}\cos 2\beta)\sin 2\beta, \quad (2.9)$$

JHEP07(2015)064

where $\lambda_{345} = \lambda_3 + \lambda_4 + \lambda_5$. The mixing angle α is also expressed in terms of M^2_{ij} as

$$\tan 2(\alpha - \beta) = \frac{2M^2_{12}}{M^2_{11} - M^2_{22}}. \tag{2.10}$$

All the quartic coupling constants in the Higgs potential can be rewritten in terms of the physical parameters as

$$\begin{aligned}
\lambda_1 v^2 &= -M^2 \tan^2\beta + (m^2_H \tan^2\beta + m^2_h) s^2_{\beta-\alpha} + (m^2_H + m^2_h \tan^2\beta) c^2_{\beta-\alpha} \\
&\quad + 2(m^2_H - m^2_h) \tan\beta s_{\beta-\alpha} c_{\beta-\alpha}, \\
\lambda_2 v^2 &= -M^2 \cot^2\beta + (m^2_H \cot^2\beta + m^2_h) s^2_{\beta-\alpha} + (m^2_H + m^2_h \cot^2\beta) c^2_{\beta-\alpha} \\
&\quad - 2(m^2_H - m^2_h) \cot\beta s_{\beta-\alpha} c_{\beta-\alpha}, \\
\lambda_3 v^2 &= 2m^2_{H^\pm} - M^2 + (m^2_h - m^2_H)[s^2_{\beta-\alpha} - c^2_{\beta-\alpha} - (\tan\beta - \cot\beta) s_{\beta-\alpha} c_{\beta-\alpha}], \\
\lambda_4 v^2 &= M^2 + m^2_A - 2m^2_{H^\pm}, \\
\lambda_5 v^2 &= M^2 - m^2_A,
\end{aligned} \tag{2.11}$$

where $s_{\beta-\alpha} = \sin(\beta - \alpha)$ and $c_{\beta-\alpha} = \cos(\beta - \alpha)$.

A size of some combinations of λ's in the Higgs potential is constrained by taking into account perturbative unitarity [33–37] and vacuum stability [38–41]. Through eq. (2.11), such a constraint can be translated into a bound on the physical parameters; e.g., the masses of the scalar bosons. First, the condition for vacuum stability; i.e., the requirement for bounded from below in any direction of the Higgs potential with large scalar fields, is given by [38–41]

$$\lambda_1 > 0, \quad \lambda_2 > 0, \quad \sqrt{\lambda_1 \lambda_2} + \lambda_3 + \mathrm{MIN}(0, \lambda_4 + \lambda_5, \lambda_4 - \lambda_5) > 0. \tag{2.12}$$

Second, the perturbative unitarity bound is obtained by requiring that all the eigenvalues of the s-wave amplitude matrix $a^0_{i,\pm}$ for the elastic scatterings of two body boson states are satisfied as

$$|a^0_{i,\pm}| \leq \frac{1}{2}. \tag{2.13}$$

All the independent eigenvalues $a^0_{i,\pm}$ were derived in refs. [35–37] as

$$a^0_{1,\pm} = \frac{1}{32\pi}\left[3(\lambda_1 + \lambda_2) \pm \sqrt{9(\lambda_1 - \lambda_2)^2 + 4(2\lambda_3 + \lambda_4)^2}\right], \tag{2.14}$$

$$a^0_{2,\pm} = \frac{1}{32\pi}\left[(\lambda_1 + \lambda_2) \pm \sqrt{(\lambda_1 - \lambda_2)^2 + 4\lambda^2_4}\right], \tag{2.15}$$

$$a^0_{3,\pm} = \frac{1}{32\pi}\left[(\lambda_1 + \lambda_2) \pm \sqrt{(\lambda_1 - \lambda_2)^2 + 4\lambda^2_5}\right], \tag{2.16}$$

$$a^0_{4,\pm} = \frac{1}{16\pi}(\lambda_3 + 2\lambda_4 \pm 3\lambda_5), \tag{2.17}$$

$$a^0_{5,\pm} = \frac{1}{16\pi}(\lambda_3 \pm \lambda_4), \tag{2.18}$$

$$a^0_{6,\pm} = \frac{1}{16\pi}(\lambda_3 \pm \lambda_5). \tag{2.19}$$

JHEP07(2015)064

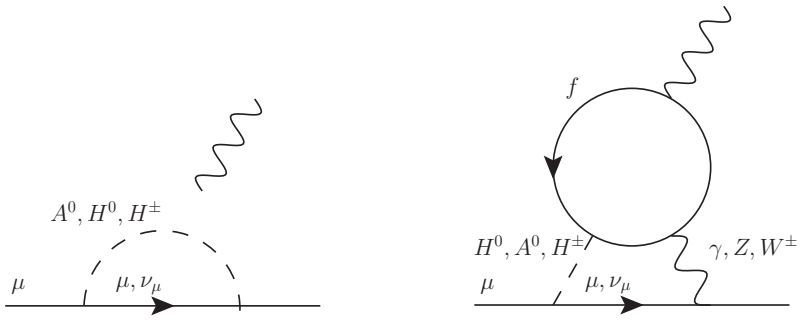

Figure 1. One-loop (left) and two-loop Barr-Zee (right) diagrams which give corrections to the muon $g-2$.

The Yukawa interaction terms are given by

$$\mathcal{L}_{\text{Yukawa}} = -y_u \tilde{H}_u^T Q_L u_R^c - y_d H_d^\dagger Q_L d_R^c - y_\ell H_\ell^\dagger L_L e_R^c + h.c., \tag{2.20}$$

where $\tilde{H}_u = i\tau^2 H_u$. In eq. (2.20), H_u, H_d and H_ℓ are either H_1 or H_2 depending on the type of Yukawa interaction. In the mass eigenstates of the scalar bosons, the interaction terms are expressed as

$$\begin{aligned}\mathcal{L}_{\text{Yukawa}} = &- \sum_{f=u,d,\ell} \frac{m_f}{v}\left(\xi_f^h\, h\bar{f}f + \xi_f^H\, H\bar{f}f - 2iT_f^3\xi_f\, A\bar{f}\gamma_5 f\right) \\ &+ \left[\sqrt{2}V_{ud}H^+\bar{u}\left(\frac{m_u\xi_u}{v}P_L - \frac{m_d\xi_d}{v}P_R\right)d - \frac{\sqrt{2}m_\ell\xi_\ell}{v}H^+\bar{\nu}P_R\ell + h.c.\right],\end{aligned} \tag{2.21}$$

where $T_f^3 = +1/2$ $(-1/2)$ for $f = u$ (d, ℓ), and $V_{ff'}$ is the Cabibbo-Kobayashi-Maskawa matrix element. The ξ_f^h and ξ_f^H factors are defined by

$$\xi_f^h = s_{\beta-\alpha} + \xi_f c_{\beta-\alpha}, \quad \xi_f^H = c_{\beta-\alpha} - \xi_f s_{\beta-\alpha}. \tag{2.22}$$

The ξ_f factors in eqs. (2.21) and (2.22) are given in table 1.

From the kinetic terms of the scalar fields, the ratios of the coupling constant among the CP-even scalars and gauge bosons are extracted as

$$\frac{g_{hVV}}{g_{hVV,\text{SM}}} = s_{\beta-\alpha}, \qquad \frac{g_{HVV}}{g_{hVV,\text{SM}}} = c_{\beta-\alpha}. \qquad (V = W, Z) \tag{2.23}$$

As it is seen in eqs. (2.21), (2.22) and (2.23), in the limit of $\sin(\beta-a) \to 1$, both $hf\bar{f}$ and hVV couplings become the same as those in the SM, so that we can call this limit as the SM-like limit.

3 Constraints on the Type-X 2HDM

In the 2HDMs, the one-loop diagrams and the two-loop Barr-Zee type diagrams shown in figure 1 give dominant contributions to the muon $g-2$. It has been known that the Barr-Zee type diagrams give a sizable positive contribution to a_μ in the case of a large

JHEP07(2015)064

$A\ell^+\ell^-$ coupling and a small m_A as pointed it out in refs. [13, 14]. In the Type-X 2HDMs, a large $A\ell^+\ell^-$ can be realized by taking $\tan\beta \gg 1$ since $\xi_\ell = -\tan\beta$ as shown in table 1. Typically, when $\tan\beta \gtrsim 40$ and $m_A = \mathcal{O}(10\text{-}100)\,\text{GeV}$, the muon $g-2$ anomaly can be explained in the Type-X 2HDM [20]. In this section, we focus on the Type-X 2HDM with the large $\tan\beta$ and small m_A scenario to explain the $g-2$ anomaly, and we discuss important experimental constraints in this situation.

3.1 Direct searches for the extra Higgs bosons

There has been no signal of the extra Higgs bosons at any collider experiments. This gives lower limits on the masses of the extra Higgs bosons depending on the magnitude of couplings with SM particles. We first summarize the current bounds from the LEP II experiment, and we also review those from the LHC Run-I.

3.1.1 LEP II

There are constraints on the masses of the extra Higgs bosons from the direct production at the LEP II experiment with the maximal collision energy to be about 200 GeV. From the $H^\pm$ pair production process $e^+e^- \to \gamma^*/Z^* \to H^+H^-$ the lower bound was obtained by $m_{H^\pm} > 93.5$ GeV at 95 % C.L. [42] under the assumption of $\text{Br}(H^+ \to \tau^+\nu_\tau) = 1$ which is realized by $\tan\beta \gtrsim 2$, $\sin(\beta-\alpha) \simeq 1$ in the Type-X 2HDM.

From the pair production of the neutral Higgs bosons $e^+e^- \to Z^* \to AH$, the lower bound for the sum of m_A and m_H is given to be about 190-195 GeV for $m_A > 40$ GeV [43] under the assumption of $\text{Br}(H \to \tau^+\tau^-) = \text{Br}(A \to \tau^+\tau^-) = 1$ which is realized by $\tan\beta \gtrsim 3$ and $\sin(\beta-\alpha) \simeq 1$ in the Type-X 2HDM.

The searches for A and H from the bremsstrahlung process $e^+e^- \to \tau\tau A/H$ have also been performed for the range of $m_{A/H} < 50$ GeV. This process gives an upper bound on $\tan\beta$ for a fixed value of $m_{A/H}$. For example, $\tan\beta > 128.1$ (120.1) and $\tan\beta > 44.8$ (40.0) are respectively excluded at 95% C.L. for m_A (m_H) to be 30 GeV and 15 GeV [44] with the case of $\text{Br}(A \to \tau\tau)$=$\text{Br}(H \to \tau\tau)$=1. We note that the branching fractions for the extra Higgs bosons into a fermion pair can be reduced when there is a non-zero mass splitting among them. For example, $H^\pm \to AW^{(*)}$ and $H \to AZ^{(*)}$ open in the case of $m_{H^\pm} > m_A$ and $m_H > m_A$, respectively. There also happen the inverse processes like $A \to H^\pm W^{\mp(*)}$ and $A \to HZ^{(*)}$ as long as they are kinematically allowed. In such decay modes associated with a gauge boson, the bounds on masses on the extra Higgs bosons can be weaker than those given in the above.

3.1.2 LHC run-I

At the LHC, extra Higgs boson searches have been performed in various channels. In the most of channels, an enhancement of the Yukawa couplings of the extra Higgs bosons becomes important to obtain a bound on their masses or coupling constants. However, in the Type-X 2HDM, the couplings of the neutral extra Higgs bosons to the quarks are suppressed by $\cot\beta$. Thus, the processes such as $gg \to A/H \to \tau\tau$ and $gg \to b\bar{b}A/b\bar{b}H \to b\bar{b}\tau\tau$ do not set a limit on the masses in a large $\tan\beta$ case.

JHEP07(2015)064

Similar to the neutral Higgs boson productions, the cross section of the $H^\pm$ production such as $gb \to H^\pm t$ is also suppressed by $\cot^2\beta$ in the Type-X 2HDM. If $m_{H^\pm}+m_b < m_t$, the top decay $t \to H^\pm b$ can be used to constrain $m_{H^\pm}$. From the process $pp \to t\bar{t} \to b\bar{b}H^\pm W^\mp$ with $H^\pm \to \tau^\pm\nu$, the upper limit on BR($t \to H^\pm b$)×BR($H^\pm \to \tau^\pm\nu$) has been driven to be between 0.23% and 1.3% at 95% C.L. for $m_{H^\pm}$ in the range of 80 GeV to 160 GeV [45]. This gives the bounds, for example, $\tan\beta \lesssim 6$ and 15 for $m_{H^\pm} = 100$ and 150 GeV at 95% C.L. in the Type-X 2HDM using 0.23% of the product of the branching fractions.

Apart from the production processes via Yukawa couplings, one must take care of the $h \to AA$ decay in the case of $m_A < m_h/2$. In the Type-X 2HDM, this typically gives the four τ final state, because the $A \to \tau\tau$ decay can be the main decay mode as explained in section 3.1.1. In ref. [46, 47], the upper bound on Br($h \to AA \to 4\tau$) is given to be about 0.2 for $m_A > 30$ GeV and 0.2-0.5 for $15 < m_A < 30$ GeV. In the 2HDMs, the branching fraction is determined by the dimensionless hAA coupling λ_{hAA} defined as the coefficient of the hAA vertex in the Lagrangian; i.e., $\mathcal{L} = v\lambda_{hAA}\, hAA + \cdots$ which is given by

$$\lambda_{hAA} = \frac{1}{2v^2}\left[(2M^2 - 2m_A^2 - m_h^2)s_{\beta-\alpha} + (M^2 - m_h^2)(\cot\beta - \tan\beta)c_{\beta-\alpha}\right]. \tag{3.1}$$

The partial decay width of $h \to AA$ is then expressed by

$$\Gamma_{h\to AA} = \frac{\lambda_{hAA}^2 v^2}{8\pi m_h}\sqrt{1-\frac{4m_A^2}{m_h^2}} \simeq \Gamma_{\rm SM} \times \left(\frac{\lambda_{hAA}}{0.015}\right)^2 \sqrt{1-\frac{4m_A^2}{m_h^2}}, \tag{3.2}$$

where $\Gamma_{\rm SM} = 4.41\,\text{MeV}$ is the total decay width of the SM Higgs boson for $m_h = 125$ GeV [48]. Therefore, to satisfy Br($h \to AA$)< 0.2, $\lambda_{hAA} \lesssim 6.7 \times 10^{-3}$ is required. We can simply take $\lambda_{hAA} = 0$ by setting an appropriate value of $\beta - \alpha$ from eq. (3.1) as

$$\tan(\beta-\alpha) = \frac{M^2 - m_h^2}{2M^2 - 2m_A^2 - m_h^2}(\tan\beta - \cot\beta). \tag{3.3}$$

In the case of $\tan\beta \gg 1$, $m_h^2/m_{H^\pm}^2 \ll 1$ and $m_A^2/m_{H^\pm}^2 \ll 1$, we obtain

$$\sin(\beta-\alpha) \simeq 1 - \frac{2}{\tan^2\beta}\left(1 + \frac{m_h^2}{m_{H^\pm}^2} - \frac{2m_A^2}{m_{H^\pm}^2}\right), \tag{3.4}$$

$$\cos(\beta-\alpha) \simeq \frac{2}{\tan\beta}\left(1 + \frac{m_h^2}{2m_{H^\pm}^2} - \frac{m_A^2}{m_{H^\pm}^2}\right). \tag{3.5}$$

From the above expressions, we find that the SM-like behavior of h is realized by taking $\tan\beta \gg 1$, because of $\sin(\beta-\alpha) \simeq 1$.

3.2 Electroweak precision observables

The extra Higgs bosons can modify the electroweak precision observables from the SM prediction via the loop effects. Such an effect can be used as an indirect search for the extra Higgs bosons and also used to constrain parameter space in the 2HDM. In this subsection, we discuss the constraints from the oblique parameters and the Z boson decay.

JHEP07(2015)064

3.2.1 Oblique parameters

The electroweak oblique S, T and U parameters are introduced by Peskin and Takeuchi [49] which parametrize new physics effects on the gauge boson two point functions. These parameters are calculated in 2HDMs in refs. [50–56]. In the SM-like limit $\sin(\beta-\alpha)\to 1$, these parameters are given to be the same formulae as those given in the inert doublet model [57]. For the case of $m_A \ll m_Z \ll m_{H^\pm} \simeq m_H$, the contribution from the additional scalar bosons is given by

$$\Delta S \simeq -\frac{5}{72\pi} \simeq 0.022, \tag{3.6}$$

$$\Delta T \simeq \frac{m_H(m_{H^\pm}-m_H)}{32\pi^2\alpha_{\rm em}v^2} \simeq 0.013\times\left(\frac{m_H}{200\ {\rm GeV}}\right)\times\left(\frac{m_{H^\pm}-m_H}{10\ {\rm GeV}}\right). \tag{3.7}$$

We also find that ΔU is the same order as ΔS in our setup for large ΔT regime. If we take $m_H = m_{H^\pm}$ and $\sin(\beta-\alpha)=1$, the Higgs potential respects the custodial SU(2)$_V$ symmetry [52, 54], which makes $\Delta T = 0$. The S and T parameters driven by the Gfitter group [58] are

$$\Delta S = 0.05 \pm 0.11, \qquad \Delta T = 0.09 \pm 0.13, \tag{3.8}$$

with the reference values of $m_h = 125\,{\rm GeV}$ and $m_t = 173\,{\rm GeV}$. The prediction of ΔS parameter is inside the 1σ error of the measured value, and the T parameter constrains on the mass splitting $|m_H - m_{H^\pm}| = \mathcal{O}(10)$ GeV. Hence we take $m_H = m_{H^\pm}$ to avoid the constraint on the oblique parameters in the following analysis.

3.2.2 Z boson decay

The property of the Z boson such as the mass, the total width, and the decay branching ratios were precisely measured at the LEP experiment. If new physics particles modify such a precisely measured quantity, their masses and/or couplings are severely constrained.

In our scenario, the $Z\tau^+\tau^-$ vertex can be significantly deviated from the SM prediction by loop effects of the extra Higgs bosons, because they strongly interact with charged leptons in the large $\tan\beta$ case. In order to discuss how the modified vertex affects the observables, we define the effective $Zf\bar{f}$ vertex as

$$\mathcal{L} = g_Z \bar{f}\gamma^\mu(\hat{v}_f - \hat{a}_f\gamma_5) f Z_\mu, \tag{3.9}$$

where $g_Z = g/\cos\theta_W$ and θ_W being the weak mixing angle. Although there are several definitions for $\sin^2\theta_W$, we here use the on-shell definition [59] of it which is determined by using W and Z boson masses, i.e., $\sin^2\theta_W = 1 - m_W^2/m_Z^2$. The effective vector coupling $\hat{v}_f$ and axial vector coupling $\hat{a}_f$ can be separately written by the contributions from the tree level and from the one-loop level as

$$\hat{v}_f = v_f + v_f^{\rm loop}, \quad \hat{a}_f = a_f + a_f^{\rm loop}, \tag{3.10}$$

where the tree level contributions are expressed as

$$v_f = \frac{1}{2}T_f^3 - \sin^2\theta_W Q_f, \quad a_f = \frac{1}{2}T_f^3, \tag{3.11}$$

JHEP07(2015)064

with Q_f being the electric charge of f. The loop contributions $v_f^{\rm loop}$ and $a_f^{\rm loop}$ are composed of the counter term and the one particle irreducible (1PI) $Zf\bar{f}$ vertex correction diagram:

$$v_f^{\rm loop} = \delta v_f + v_f^{\rm 1PI}, \quad a_f^{\rm loop} = \delta a_f + a_f^{\rm 1PI}. \tag{3.12}$$

After imposing the on-shell renormalization conditions, the counter term contribution is expressed by [60]

$$\delta v_f = -a_f \Pi^{\rm 1PI}_{ff,A}(m_f^2) - v_f \left[\Pi^{\rm 1PI}_{ff,V}(m_f^2) - 2m_f^2 \frac{d}{dp^2}[\Pi^{\rm 1PI}_{ff,V}(p^2) + \Pi^{\rm 1PI}_{ff,S}(p^2)]_{p^2=m_f^2}\right], \tag{3.13}$$

$$\delta a_f = -a_f \left[\Pi^{\rm 1PI}_{ff,V}(m_f^2) + 2m_f^2 \frac{d}{dp^2}[\Pi^{\rm 1PI}_{ff,V}(p^2) + \Pi^{\rm 1PI}_{ff,S}(p^2)]_{p^2=m_f^2}\right] - v_f \Pi^{\rm 1PI}_{ff,A}(m_f^2), \tag{3.14}$$

where $\Pi^{\rm 1PI}_{ff,X}$ are the 1PI diagram contributions to the fermion two point functions defined as

$$\Pi^{\rm 1PI}_{ff}(p^2) = \not{p}\Pi^{\rm 1PI}_{ff,V}(p^2) - \not{p}\gamma_5 \Pi^{\rm 1PI}_{ff,A}(p^2) + m_f \Pi^{\rm 1PI}_{ff,S}(p^2). \tag{3.15}$$

In the SM-like limit $\sin(\beta-\alpha)=1$, the deviation in $v_\tau^{\rm loop}$ and $a_\tau^{\rm loop}$ purely comes from the extra Higgs boson loop diagrams. In this case for $f=\tau$, we obtain

$$\begin{aligned}
&\Delta v_\tau^{\rm loop} = v_\tau^{\rm loop} - v_\tau^{\rm loop}({\rm SM}) \qquad (3.16)\\
&\simeq \frac{1}{16\pi^2}\left(\frac{m_\tau}{v}\xi_\ell\right)^2 \Big[v_\tau F_1(m_H) + v_\tau F_1(m_A) - 2a_\tau F_1(m_{H^\pm}) + (v_\tau + a_\tau) F_2(m_{H^\pm}, m_{H^\pm})\Big],\\
&\Delta a_\ell^{\rm loop} = a_\tau^{\rm loop} - a_\tau^{\rm loop}({\rm SM})\\
&\simeq -\frac{1}{16\pi^2}\left(\frac{m_\tau}{v}\xi_\ell\right)^2 \Big[a_\tau F_1(m_H) + a_\tau F_1(m_A) - 2a_\tau F_1(m_{H^\pm})\\
&\qquad + (v_\tau + a_\tau) F_2(m_{H^\pm}, m_{H^\pm}) - 4a_\tau F_2(m_H, m_A)\Big], \qquad (3.17)
\end{aligned}$$

where the loop functions are given as

$$F_1(m) = \ln\frac{m^2}{m_Z^2} + \frac{5}{4} - i\pi + \frac{1}{2}\int_0^1 dxdy \frac{m_Z^2 xy(2y-1) + m^2(2+y-yx)}{m_Z^2 x(1-y) - m^2(1-x)}, \tag{3.18}$$

$$F_2(m_1, m_2) = \frac{1}{4}\left(\ln\frac{m_2^2}{m_1^2} + 1\right) - \int_0^1 dxdy \frac{y^2}{2}\frac{m_2^2 - x[m_1^2 - m_Z^2(1-2y)]}{m_2^2(1-y) + xy[m_1^2 - m_Z^2(1-y)]}. \tag{3.19}$$

In the above expressions, we neglect the mass of the tau lepton in the loop functions. We note that the $F_2(m_1, m_2)$ function is invariant under the interchange of $m_1 \leftrightarrow m_2$, so that $\Delta v_\tau^{\rm loop}$ and $\Delta a_\tau^{\rm loop}$ does not change the value under $m_H \leftrightarrow m_A$.

Let us apply the modified $Z\tau^+\tau^-$ vertex to the leptonic partial decay width of the Z boson $Z \to \ell\ell$:

$$\Gamma(Z \to \ell\ell) = g_Z^2 \frac{m_Z}{12\pi}(\hat{v}_\ell^2 + \hat{a}_\ell^2). \tag{3.20}$$

We define the ratio of the partial width of $Z \to \tau\tau$ to that of $Z \to ee$ as

$$R_{\tau/e} \equiv \Gamma(Z \to \tau\tau)/\Gamma(Z \to ee). \tag{3.21}$$

The deviation in the ratio from the SM predictions are then given by

$$\Delta R_{\tau/e} \equiv R_{\tau/e} - R_{\tau/e}^{\rm SM} \simeq \frac{1}{\Gamma(Z \to \ell\ell)_{\rm SM}} \frac{g_Z^2}{6\pi} m_Z \left[v_\ell {\rm Re}\Delta v_\ell^{\rm loop} + a_\ell {\rm Re}\Delta a_\ell^{\rm loop}\right]. \tag{3.22}$$

JHEP07(2015)064

The SM prediction is given by

$$\Gamma(Z \to \ell\ell)_{\rm SM} = 83.995 \pm 0.010 \text{ MeV}. \tag{3.23}$$

The measured values of the leptonic decay width and $R_{\tau/e}$ are given by [64]

$$\Gamma(Z \to \ell\ell)_{\rm exp} = 83.984 \pm 0.086 \text{ MeV}, \quad R^{\rm exp}_{\tau/e} = 1.0019 \pm 0.0032. \tag{3.24}$$

We find that $\tan\beta > 50$ (70) is excluded for $m_A = 10$ (50) GeV when $m_H = m_{H^\pm} = 300\,\text{GeV}$. The bound becomes weaker for the larger $m_{H^\pm}$. We will combine the constraint from the $Z \to \ell\ell$ decay with the muon $g-2$ result in section 4.

3.3 Flavor experiments

Effects of the extra Higgs bosons can appear in various observables measured at flavor experiments. Therefore, similar to the electroweak precision measurements, flavor measurements can be used to constrain the parameter space in the 2HDM. In this subsection, we discuss $B_s \to \mu^+\mu^-$ and the leptonic decay of τ.

3.3.1 $B_s \to \mu^+\mu^-$

It was pointed out in ref. [61] that the branching fraction of the $B_s \to \ell\ell$ process in the Type-II 2HDM is enhanced by the factor $\tan^4\beta$ which comes from the box type and the penguin type diagrams with extra Higgs boson mediation. The origin of the $\tan^4\beta$ dependence is that both the charged lepton and down-type quark couplings to the extra Higgs bosons are proportional to $\tan\beta$ in the Type-II 2HDM. On the other hand, in the Type-X 2HDM, the lepton couplings are enhanced by $\tan\beta$, while the quark couplings are suppressed by $\cot\beta$. Thus, the $\tan^4\beta$ dependence does not appear in the branching fraction of $B_s \to \ell\ell$, and the additional leading contribution is almost independent on $\tan\beta$ for large $\tan\beta$. Although the deviation from the SM becomes mild as compared to the case of Type-II, we check $\text{Br}(B_s \to \mu^+\mu^-)$ because the light CP-odd Higgs boson A could give a sizable contribution, which is required to explain muon $g-2$ anomaly.

For the calculation of $B_s \to \mu^+\mu^-$ in the 2HDM, we use the formulae given in ref. [62]. The observed branching fraction at the LHC is $\text{Br}(B_s \to \mu^+\mu^-) = (2.9 \pm 0.7) \times 10^{-9}$ [27]. We show the constraint from $B_s \to \mu^+\mu^-$ on the parameter space of 2HDM in section 4.

3.3.2 Leptonic τ decay at the tree level

In the SM, the leptonic τ decay is caused by the W boson exchange diagram at tree level. In the 2HDM, the $H^\pm$ mediated diagram also contributes to the leptonic τ decay. The effect of $H^\pm$ contribution on the partial decay width of τ was calculated in refs. [11, 31], and that on the Michel parameters, which is defined just below, in ref. [32].

The differential decay rate of $\tau \to \mu\nu_\mu\nu_\tau$ is given in terms of the Michel parameters (ρ, η, δ and ξ) and $\hat{G}_{\mu\tau}$ defined in eqs. (3.28) and (3.29) as [63]

$$\frac{d^2\Gamma}{dx\,d\cos\theta} = \frac{m_\mu \omega^4}{2\pi^3}\hat{G}^2_{\mu\tau}\sqrt{x^2-x_0^2}\left(F(x) - \frac{\xi}{3}\mathcal{P}_\tau\cos\theta\sqrt{x^2-x_0^2}A(x)\right), \tag{3.25}$$

JHEP07(2015)064

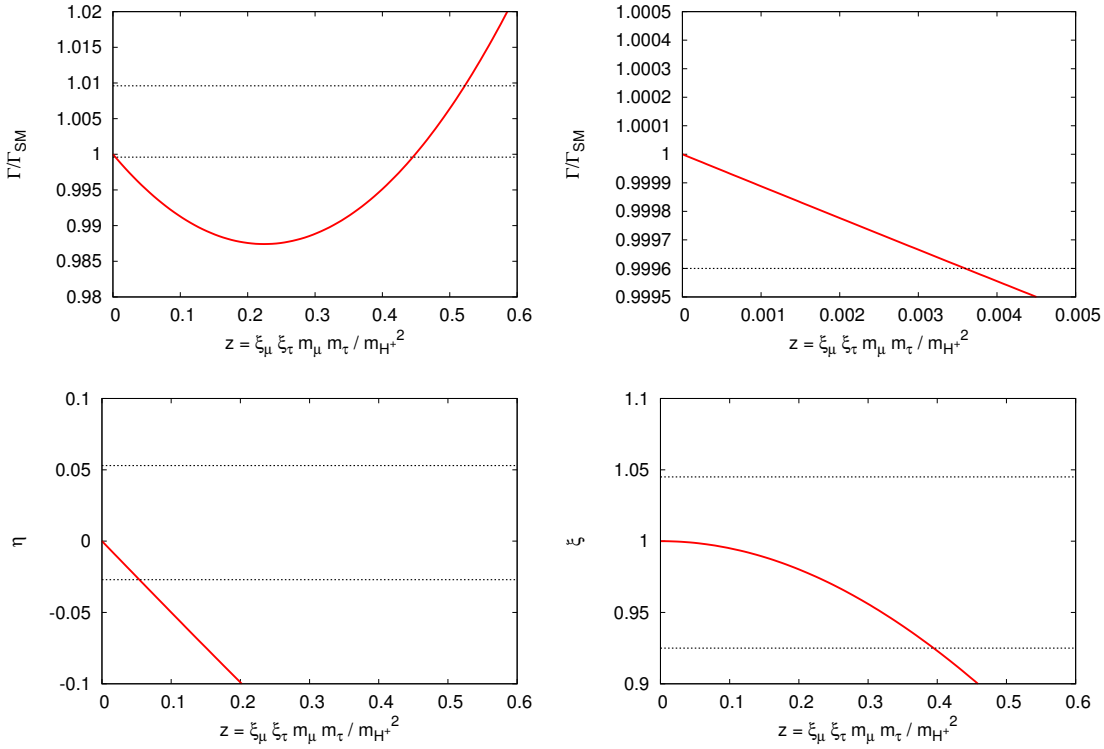

Figure 2. The ratio of the decay rate (upper left and upper right) and the Michel parameters η (lower left) and ξ (lower right) as a function of z in the leptonic tau decay. In each panel, outside regions from the dotted lines are excluded at the 95 % C.L.

where $\omega \equiv (m_\tau^2 + m_\mu^2)/2m_\tau$, $x \equiv E_\mu/\omega$ and $x_0 \equiv m_\mu/\omega$ with E_μ being the muon energy. $\mathcal{P}_\tau$ is the polarization of the tau, and θ is the angle between the polarization and the momentum direction of the muon. The functions $F(x)$ and $A(x)$ are defined as

$$F(x) = x(1-x) + \frac{2}{9}\rho(4x^2 - 3x - x_0^2) + \eta x_0(1-x), \tag{3.26}$$

$$A(x) = 1 - x + \frac{2}{3}\delta(4x - 4 + \sqrt{1-x_0^2}). \tag{3.27}$$

By using $z \equiv m_\mu m_\tau \tan^2\beta/m_{H^+}^2$, we find[2]

$$\hat{G}_{\mu\tau} = G_F\left(1 + \frac{z^2}{4}\right)^{1/2}, \tag{3.28}$$

$$\rho = \frac{3}{4}, \qquad \eta = -\frac{2z}{4+z^2}, \qquad \delta = \frac{3}{4}, \qquad \xi = \frac{4-z^2}{4+z^2}. \tag{3.29}$$

We see that ρ and δ are equal to the SM values at the tree level. The observed Michel parameters of the τ decay are $\eta = 0.013 \pm 0.020$ and $\xi = 0.985 \pm 0.030$ [64]. The ratio of the decay rate in the 2HDM to that in the SM prediction is given as [11, 31]

$$\left(\frac{G_{\mu\tau}}{G_F}\right)^2 \equiv \frac{\Gamma(\tau \to \mu\nu\nu)_{\rm 2HDM}}{\Gamma(\tau \to \mu\nu\nu)_{\rm SM}} = 1 - 2z\frac{m_\mu}{m_\tau}\frac{g(m_\mu^2/m_\tau^2)}{f(m_\mu^2/m_\tau^2)} + \frac{z^2}{4}, \tag{3.30}$$

[2]We find these expressions are inconsistent with ref. [32].

JHEP07(2015)064

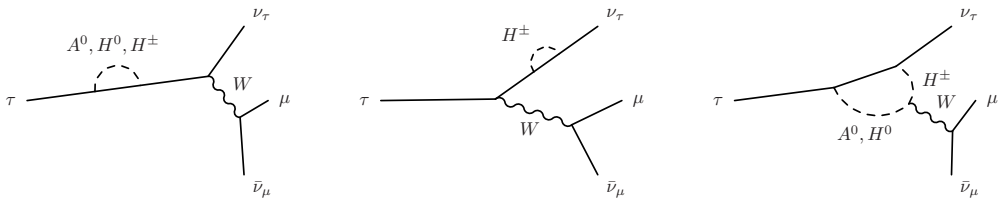

Figure 3. The leading one-loop diagrams for the leptonic tau decay process.

where the phase functions $f(x)$ and $g(x)$ are given by $f(x) = 1 - 8x - 12x^2 \log x + 8x^3 - x^4$ and $g(x) = 1 + 9x - 9x^2 - x^3 + 6x(1+x)\log x$. To find a constraint on eq. (3.30), we can use the constraint on the flavor universality. In the similar manner to eq. (3.30), we introduce $G_{e\mu}$ and $G_{e\tau}$. Since $m_e, m_\mu \ll m_\tau$, the corresponding terms to the rightest term in eq. (3.30) for $G_{e\mu}$ and $G_{e\tau}$ are 1, and thus $G_{e\mu} = G_{e\tau} = G_F$ in 2HDM. There are constraints on the lepton universality given by HFAG group [65][3]

$$\frac{G_{\mu\tau}}{G_{e\mu}} = 1.0029 \pm 0.0015, \quad \frac{G_{\mu\tau}}{G_{e\tau}} = 1.0018 \pm 0.0014, \tag{3.31}$$

and their correlation coefficient is 0.48. Since $G_{e\mu} = G_{e\tau} = G_F$ in the present scenario, by combining the above two values, we find

$$\frac{G_{\mu\tau}}{G_F} = 1.0023 \pm 0.0012, \tag{3.32}$$

and thus we find

$$\left(\frac{G_{\mu\tau}}{G_F}\right)^2 = 1.0046 \pm 0.0025. \tag{3.33}$$

We use this bound and eq. (3.30) to make constraint on 2HDM.

In figure 2, we show the z dependence of the ratio of the decay rate given in eq. (3.30) (upper two panels) and the Michel parameters η (lower left) and ξ (lower right). First, from the upper panels we can see that the allowed ranges of z are found to be $z \lesssim 0.003$ and $0.50 \lesssim z \lesssim 0.57$. Second, from the lower left panel, $z \gtrsim 0.05$ is excluded by the measurement of η. The constraints from the ξ parameter is weaker than that from η. Therefore, by combining the first and the second statements, the allowed region of z is restricted to be $z \lesssim 0.003$ By using $z \simeq 1.88 \times 10^{-3} \times (\tan\beta/30)^2 \times (300\ \text{GeV}/m_{H^\pm})^2$, we find that $\tan\beta \gtrsim 38$ is excluded for $m_{H^\pm} = 300\,\text{GeV}$.

3.3.3 Lepton universality at the one-loop level

As we discussed in section 3.3.2, the typical size of the $H^\pm$ contribution to the ratio of the tau decay is $\mathcal{O}(10^{-2})$ at the tree level as it is seen in figure 2. However, the SM prediction is given at almost the lower edge of the experimental bound (see eq. (3.33)), so that the negative contribution to $G_{\mu\tau}/G_F$ of order 10^{-4} is constrained. Thus, we focus on the quantum corrections to the process via W exchange diagram.

[3]The ratio of the effective Fermi constant $G_{\mu\tau}/G_{e\tau}$, $G_{\mu\tau}/G_{e\mu}$ and $G_{e\tau}/G_{e\mu}$ are corresponds to g_μ/g_e, g_τ/g_e and g_τ/g_μ in ref. [65], respectively.

JHEP07(2015)064

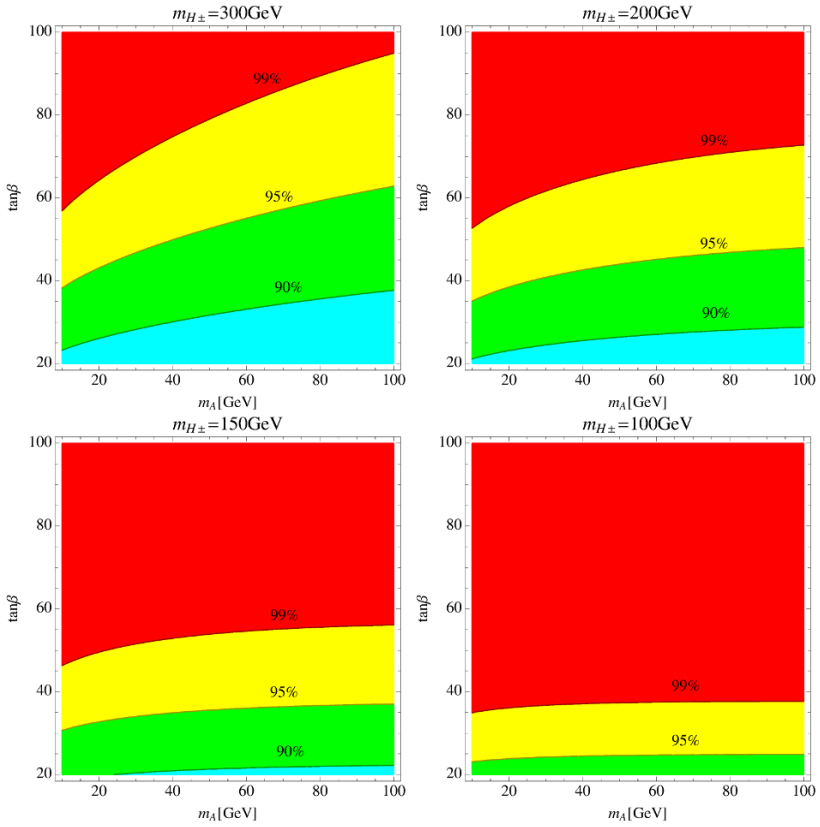

Figure 4. Constraints on the $(m_A, \tan\beta)$-plane by the leptonic tau decay at the one-loop level for $m_{H^\pm}$ =300 (upper left), 200 (upper right), 150 (lower left), and 100 GeV (lower right) in the case with $m_H = m_{H^\pm}$. The green, yellow, and red regions are excluded at 90%, 95%, and 99% C.L., respectively.

The dominant contribution arises from the diagrams with picking up two tau Yukawa couplings which are proportional to $(m_\tau^2/v^2)\tan^2\beta$. We show the diagrams which give the dominant contributions to the process at the one-loop level in figure 3. Other diagrams, such as box diagrams, are smaller than these contributions and we ignore them in this analysis. The quantum correction is flavor dependent, and there is no flavor dependent counter terms in this model, so the correction is finite. We find the contributions from figure 3 modifies the W-τ-ν_τ couplings

$$g_{W\tau\nu} \to g_{W\tau\nu}\,(1+\delta g)\,, \tag{3.34}$$

where

$$\delta g = \frac{1}{(4\pi)^2}\frac{m_\tau^2}{v^2}\tan^2\beta\left[1+\frac{m_{H^\pm}^2+m_A^2}{4(m_{H^\pm}^2-m_A^2)}\ln\frac{m_A^2}{m_{H^\pm}^2}+\frac{m_{H^\pm}^2+m_H^2}{4(m_{H^\pm}^2-m_H^2)}\ln\frac{m_H^2}{m_{H^\pm}^2}\right]. \tag{3.35}$$

In $m_A \ll m_{H^\pm} \sim m_{H^0}$ case

$$\delta g = \frac{1}{(4\pi)^2}\frac{m_\tau^2}{v^2}\tan^2\beta\left[\frac{1}{2}+\frac{1}{4}\ln\frac{m_A^2}{m_{H^\pm}^2}+\mathcal{O}\left(\frac{m_A^2}{m_{H^\pm}^2}\ln\frac{m_A^2}{m_{H^\pm}^2}\right)\right]. \tag{3.36}$$

JHEP07(2015)064

Finally, we find

$$\Gamma = \frac{1}{96\pi^3} m_\tau \omega^4 G_F^2 \left[\sqrt{1-x_0^2} \Big(2(4(1+\delta g)^2 + z^2) - 8x_0 z(1+\delta g) \right.$$
$$\left. - 5x_0^2(4(1+\delta g)^2 + z^2) - 16x_0^3 z(1+\delta g) \Big) \right.$$
$$\left. + 3x_0^3 \left(8z(1+\delta g) + x_0(4(1+\delta g)^2 + z^2) \right) \ln \frac{1+\sqrt{1-x_0^2}}{x_0} \right], \qquad (3.37)$$

where ω and x_0 are defined in section 3.3.2. Using eqs. (3.30), (3.33) and (3.37), we find that the large $\tan\beta$ region and light charged Higgs region are disfavored, see figure 4. This constraint is the most severe for the explanation of the muon $g-2$ anomaly, as we will see in section 4

3.4 Triviality bound

In order to avoid the constraints from the various observables, we need to take large mass differences between A and $H^\pm$, and A and H. As a result, the Higgs quartic couplings are as large as $\mathcal{O}(1)$. Such a large coupling can be grown up in a certain energy scale, and it becomes too strong to rely on the perturbative calculation. We thus take into account the triviality bound in which we require that all the Higgs quartic couplings do not exceed a certain value until a given energy scale.

We calculate the β-functions up to the two loop level for the RGE by using `SARAH` [66], and run the couplings to higher energies. We treat the coupling values at the tree level as the input parameters at $\mu = m_t$. We define $\lambda_{\rm max} = \max\{|\lambda_1|, |\lambda_2|, |\lambda_3|, |\lambda_4|, |\lambda_5|\}$ and the cutoff scale of the model, Λ, as $\lambda_{\rm max}(\Lambda) = 4\pi$ or $\sqrt{4\pi}$.

The result for $\Lambda = 10\,\text{TeV}$ with requiring $\lambda_{\rm max} < 4\pi$ is shown in the left panel in figure 5. We find that $m_{H^\pm} \lesssim 370\,\text{GeV}$ for $m_A \simeq 20\,\text{GeV}$ is required for Λ 10 TeV. This constraint on $m_{H^\pm}$ is stronger than the one from the perturbative unitarity bound using eqs. (2.13)–(2.19), i.e., $m_{H^\pm} \lesssim 700\,\text{GeV}$. We check that this result is consistent with that given in [67, 68]. If we require $\lambda_{\rm max} < \sqrt{4\pi}$ instead of $\lambda_{\rm max} < 4\pi$, then the bound becomes stronger. In such a case, we find $m_{H^\pm} \simeq 260\,\text{GeV}$ is required. Here we take $\tan\beta = 30$ at $\mu = m_t$ as the input value, but the result is insensitive for $\tan\beta$. We also plot the case for $\Lambda = 100\,\text{TeV}$ in the right panel in figure 5. The bound is stronger than $\Lambda = 10\,\text{TeV}$ case. We find $m_{H^\pm} \lesssim 310\,\text{GeV}$ (240 GeV) for $\lambda_{\rm max} = 4\pi$ ($\sqrt{4\pi}$). Our parameter choice here is the same as in section 4.

4 Muon $g-2$

We show the numerical results for the muon $g-2$ under all the constraints discussed in the previous section. We calculate the muon $g-2$ by using `2HDMC 1.6.4` [69, 70] which contains the one-loop diagrams [12] and the two-loop Barr-Zee diagrams [13] as shown in figure 1. In the Type-X 2HDM, the contributions from the one-loop diagrams and the Barr-Zee diagrams are comparable and have opposite sign. Thus, we have to take into

JHEP07(2015)064

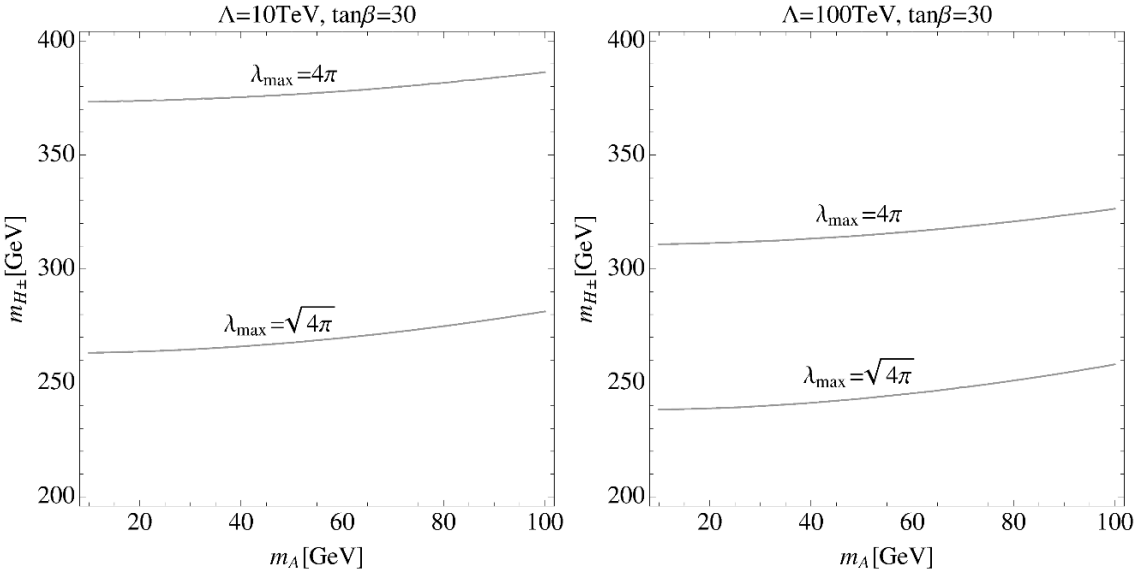

Figure 5. The triviality bound with $\Lambda = 10\,\text{TeV}$ (left) and $\Lambda = 100\,\text{TeV}$ (right). The numbers shown in the panel are $\lambda_{\text{max}} = 4\pi$ and $\sqrt{4\pi}$.

account both contributions. The contributions from the beyond the SM part should be sizable to solve the muon $g-2$ anomaly, and thus at least one of the new particles has to be light. The lower mass bound on $H^\pm$ is order of 100 GeV, so that it can not be arbitrary small. The effect from H gives a destructive contribution to the SM one, so that it makes the situation becomes even worse if H is light. On the other hand, the effect from A gives the constructive contribution, and it makes the discrepancy small. Therefore, A is required to be lighter than H and $H^\pm$ in order to solve the muon $g-2$ anomaly.

The Higgs sector in the 2HDM has eight parameters. Two of them are fixed to reproduce the SM parameters, i.e., $G_F = 2^{-1/2}v^{-2} = 1.166379\times10^{-5}\,\text{GeV}^{-2}$ and $m_h = 125\,\text{GeV}$. To suppress $\text{Br}(h \to AA)$, we set $\lambda_{hAA} = 0$. In addition, we take $m_H = m_{H^\pm}$ to avoid a large contribution to ΔT. Furthermore, we fix $\lambda_1 = 0.1$. This λ_1 value is realized by taking $M^2 \simeq m_H^2$ in the large $\tan\beta$ case, and the fixing the value of λ_1 is not significant to the result in the following. Therefore, we have three remaining parameters which can be expressed as $\tan\beta$, m_A and $m_{H^\pm}$. We note that in this parametrization, $\sin(\beta-\alpha)$ is given as the output parameter, which is determined via eq. (3.1). As it is seen in eq. (3.4), $1-\sin(\beta-\alpha)$ is suppressed by $1/\tan^2\beta$ in the large $\tan\beta$ case, so that h behaves as the SM-like Higgs boson.

In figure 6, we show the prediction of a_μ on the m_A-$\tan\beta$ plane in each fixed value of $m_{H^\pm}$, e.g., $m_{H^\pm} = 200$ (upper-left), 250 (upper-right), 300 (lower-left) and 350 GeV (lower right). In the dark and light shaded regions, a_μ can be explained at the 1σ and 2σ levels, respectively. We find that the measurement of $\tau \to \mu\nu_\mu\nu_\tau$ gives the stringent constraint on the parameter space in the m_A-$\tan\beta$ plane. This constraint is getting stronger in the cases of smaller $m_{H^\pm}$ or m_A and larger $\tan\beta$. For example, in the case of $m_{H^\pm} = 200\,\text{GeV}$, $\tan\beta \gtrsim 35$ is excluded at the 95% C.L. in the case of $m_A = 20$ GeV. For $m_A \simeq 10\,\text{GeV}$, $\text{Br}(B_s \to \mu^+\mu^-)$ gives additional excluded regions which are not excluded by the measurement of

JHEP07(2015)064

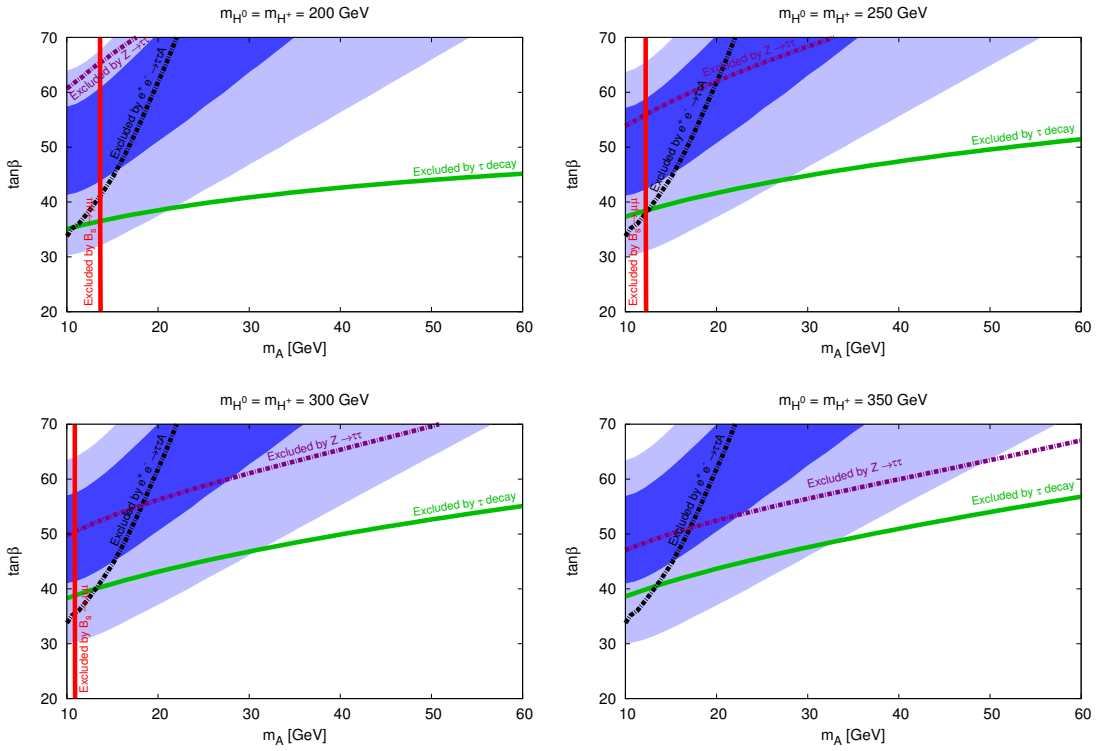

Figure 6. Results in the Type-X 2HDM in the case of $\lambda_{hAA} = 0$ and $\lambda_1 = 0.1$. Dark and light blue shaded regions can explain the muon $g-2$ anomaly [3] at the 1σ and 2σ levels, respectively. We take $m_{H^\pm}(= m_H)$ =200, 250, 300 and 350 GeV in the upper-left, upper-right, lower-left and lower-right panels, respectively. The left region from the red line is excluded by the measurement of $B_s \to \mu\mu$. The above regions of green, black, purple line are excluded by the τ decay, the direct search at the LEP and the $Z \to \tau\tau$ decay, respectively. All of the exclusions are given at the 95% C.L.

the tau decay. The $\tan\beta$ dependence in $\mathrm{Br}(B_s \to \mu^+\mu^-)$ is negligible as we expected in the discussion in section 3.3.1. In most of the parameter region shown in this figure, the deviation of $\mathrm{Br}(B_s \to \mu^+\mu^-)$ from the SM value is $\mathcal{O}(1)$ %. The constrained from $Z \to \tau\tau$ is weaker than that from the tau decay in all the parameter regions shown in this figure.

Consequently, the parameter region which can explain the $g-2$ anomaly at the 1σ level is excluded by the measurement of the tau decay at the 95% C.L., and at best we can explain the anomaly at the 2σ level. The typical parameters to explain muon $g-2$ anomaly at the 2σ level is $10 \lesssim m_A \lesssim 30$ GeV, $200 \lesssim m_{H^\pm} \lesssim 350$ GeV and $30 \lesssim \tan\beta \lesssim 50$. In this parameter space, however, the region with $m_{H^\pm} \lesssim 270$ GeV has tension with the signal strength for the $h \to \tau\tau$ mode measured at the LHC as we will see in the next section.

5 Impact on the Higgs phenomenology at collider experiments

In the previous section, we have seen that the relatively light extra Higgs bosons and large $\tan\beta$ are favored to explain the muon $g-2$ anomaly. Such a light particle can be directly discovered at the LHC Run-II and the International Linear Collider (ILC). Furthermore, the

JHEP07(2015)064

precise measurement of the property of the SM-like Higgs boson h will give an indirect probe of this scenario. In this section, we first discuss the decay and production of the extra Higgs bosons at the LHC, and then we investigate how the property of the SM-like Higgs boson is modified in the favored parameter set indicated by the muon $g-2$ in the Type-X 2HDM.

Throughout this section, we consider the case of

$$\begin{aligned} &200\ \text{GeV} \le m_{H^\pm} \le 400\ \text{GeV}, \qquad m_H = M = m_{H^\pm},\ \ 10\ \text{GeV} \le m_A \le 30\ \text{GeV}, \\ &30 \le \tan\beta \le 50, \qquad \tan(\beta-\alpha) = \frac{M^2 - m_h^2}{2M^2 - 2m_A^2 - m_h^2}(\tan\beta - \cot\beta). \end{aligned} \tag{5.1}$$

In addition, the following values of the SM parameters are used [64, 71]:

$$\begin{aligned} &m_Z = 91.1876\ \text{GeV}, \quad m_W = 80.385\ \text{GeV}, \quad G_F = 1.1663787 \times 10^{-5}\ \text{GeV}^{-2}, \\ &m_t = 173.07\ \text{GeV}, \quad m_b = 3.0\ \text{GeV}, \quad m_c = 0.677\ \text{GeV},\ m_\tau = 1.77684\ \text{GeV}. \end{aligned} \tag{5.2}$$

m_c and m_b are evaluated at the m_Z scale in $\overline{\text{MS}}$ scheme, which are taken from ref. [71]. Other parameters are taken from ref. [64]. The mass observed Higgs boson is taken to be 125 GeV.

5.1 Phenomenology of the extra Higgs bosons

First, we discuss the branching fraction of the extra Higgs bosons in the parameter set given in eq. (5.1). For the CP-odd Higgs boson A, only the $A \to \tau\tau$ and $A \to b\bar{b}$ modes are allowed at the tree level. Since the decay rate of the former (latter) channel is enhanced (suppressed) by $\tan^2\beta$ ($\cot^2\beta$) in the Type-X 2HDM, the branching fraction of $A \to \tau\tau$ becomes almost 100% in our scenario. Similar enhancement happens in the decay rates of $H \to \tau\tau$ and $H^\pm \to \tau^\pm\nu$. At the same time, the other modes $H \to AZ$ and $H^\pm \to AW^\pm$ are also important because of the large mass difference between $H/H^\pm$ and A. Therefore, the following decay modes should be taken into account:

$$H^\pm \to \tau^\pm\nu, \quad H^\pm \to AW^\pm, \quad H \to \tau\tau, \quad H \to AZ, \quad A \to \tau\tau. \tag{5.3}$$

The formulae for the decay rates are given in appendix A. We here note that the $H \to AA$ and $H \to hh$ decays also open whose decay rates are determined by the trilinear HAA and Hhh couplings, respectively. However, these couplings are proportional to $\cos(\beta-\alpha)$, and its magnitude is suppressed by $\cot\beta$ in the large $\tan\beta$ case. Thus, these decay modes are not important in our scenario.

In figure 7, we show the contour plots for the branching fractions of $H \to AZ$ (left panel) and $H^+ \to AW^+$ on the $m_{H^\pm}$-$\tan\beta$ plane. The $H \to \tau\tau$ and $H^+ \to \tau^+\nu$ modes fulfill almost the remaining branching ratios for H and $H^\pm$, respectively. In the large $m_{H^\pm}$ and small $\tan\beta$ region, the branching fractions of $H \to AZ$ and $H^+ \to AW^+$ are getting larger. For example, we obtain $\text{Br}(H \to AZ) > 70\ (90)\%$ in the case of $\tan\beta \lesssim 35$ with $m_H = 200\,\text{GeV}$ ($\tan\beta \lesssim 33$ with $m_H = 300\,\text{GeV}$), and $\text{Br}(H^+ \to AW^+) > 70\ (90)\%$ in the case of $\tan\beta \lesssim 38$ with $m_H = 200\,\text{GeV}$ ($\tan\beta \lesssim 35$ with $m_{H^\pm} = 300\,\text{GeV}$).

Next, we discuss the production process of the extra Higgs bosons at the LHC. As we mentioned in section 3.1.2, the production processes via the Yukawa interaction cannot be

JHEP07(2015)064

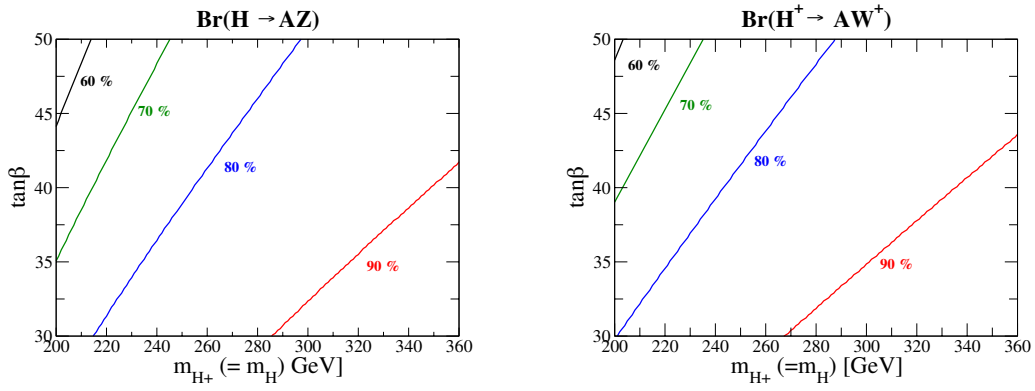

Figure 7. Contour plots for the branching fractions of $H \to AZ$ (left panel) and $H^+ \to AW^+$ (right panel) on the $m_{H^\pm}$-$\tan\beta$ plane. We take $m_H = m_{H^\pm}$ and $m_A = 20\,\text{GeV}$. $\text{Br}(H \to AZ)$+$\text{Br}(H \to \tau\tau) \simeq 1$ and $\text{Br}(H^+ \to AW^+)$+$\text{Br}(H^+ \to \tau^+\nu) \simeq 1$ are satisfied.

used in the large $\tan\beta$ case in the Type-X 2HDM. Therefore, the following electroweak processes give the dominant production mode:

$$\begin{aligned} &pp \to Z^*/\gamma^* \to H^+H^-, && pp \to Z^* \to HA, \\ &pp \to W^* \to H^\pm H, && pp \to W^* \to H^\pm A. \end{aligned} \tag{5.4}$$

The analytic expressions for the parton level cross section are given in appendix B. We find that the cross sections are determined by the masses of the extra Higgs bosons and $\sin(\beta-\alpha)$, and they do not depend on the type of Yukawa interactions. By using `CalcHEP` [72] with `CTEQ6L` [73] parton distribution functions, the cross sections are calculated in table 2. In this calculation, we neglect the small deviation in $\sin(\beta-\alpha)$ from unity. Because of the small m_A, the cross sections of $pp \to H^\pm A$ and $pp \to HA$ are relatively large as compared to those of $pp \to H^+H^-$ and $pp \to H^\pm H$. We note that the cross section for H^+H/H^+A is about twice larger than that for H^-H/H^-A, because the parton luminosity of $u\bar{d}$ in the initial proton is larger than that of $\bar{u}d$.

Combining the discussions of the decay and the production of the extra Higgs bosons, we can consider the following processes:

$$\begin{aligned} &pp \to H^\pm A/H^\pm H \to \tau^\pm\nu\tau^+\tau^-, && pp \to H^\pm A/H^\pm H \to 4\tau + W^\pm, \\ &pp \to HA \to 4\tau, && pp \to HA \to 4\tau + Z. \end{aligned} \tag{5.5}$$

The H^+H^- production may not be so useful for the feasibility study of the extra Higgs bosons as compared to the above processes because of the small cross section as seen in table 2. The cross sections of 4τ ($\sigma_{4\tau}$), 3τ ($\sigma_{3\tau}$), 4τ plus W ($\sigma_{4\tau W}$) and 4τ plus Z ($\sigma_{2\tau Z}$) can be estimated as follows:

$$\sigma_{4\tau} \simeq \sigma_{HA} \times \text{Br}(H \to \tau\tau), \tag{5.6}$$

$$\begin{aligned} \sigma_{3\tau} \simeq\ & (\sigma_{H^+A} + \sigma_{H^-A}) \times \text{Br}(H^\pm \to \tau^\pm\nu) \\ & + (\sigma_{H^+H} + \sigma_{H^-H}) \times \text{Br}(H^\pm \to \tau^\pm\nu) \times \text{Br}(H \to \tau\tau), \end{aligned} \tag{5.7}$$

JHEP07(2015)064

$m_{H^\pm}$ [GeV]	$\sigma_{H^+H^-}$	σ_{H^+H}	σ_{H^-H}	σ_{H^+A}	σ_{H^-A}	σ_{AH}	$\sigma_{4\tau}$	$\sigma_{3\tau}$	$\sigma_{4\tau W}$	$\sigma_{4\tau Z}$
200	18.6	22.0	11.3	116	67.0	101	29.3	50.1	143	70.7

350	2.1	2.6	1.1	16.2	8.2	13.0	0.9	1.7	22.9	12.0

Table 2. Cross sections of the electroweak production processes expressed in eq. (5.4), and those of the multi-tau processes expressed in eqs. (5.6)–(5.9) at $\sqrt{s} = 14\,\text{TeV}$ in the unit of fb. We take $m_A = 20\,\text{GeV}$, $m_H = m_{H^\pm}$, $\sin(\beta-\alpha) = 1$ and $\tan\beta = 35$.

$$\sigma_{4\tau W} \simeq (\sigma_{H^+A} + \sigma_{H^-A}) \times \text{Br}(H^\pm \to AW^\pm) + (\sigma_{H^+H} + \sigma_{H^-H}) \times \text{Br}(H^\pm \to AW^\pm) \times \text{Br}(H \to \tau\tau), \tag{5.8}$$

$$\sigma_{4\tau Z} \simeq \sigma_{HA} \times \text{Br}(H \to AZ), \tag{5.9}$$

where we used $\text{Br}(A \to \tau\tau) \simeq 100\%$. The cross sections of the above processes are also shown in table 2 in the case of $\tan\beta = 35$.

The signal and background for the four and three tau final states (without a gauge boson) were studied in ref. [74, 75] in the Type-X 2HDM. It was clarified that the main background for these processes can be significantly reduced by requiring the high multiplicity of charged leptons and tau-jets with appropriate kinematical cuts in the final state. In this paper, we only show the signal cross sections of the above mentioned processes as given in table 2. Although the detailed background simulation must be necessary to clarify the feasibility to detect the signal events, such a study is beyond the scope of this paper.

5.2 Phenomenology of the SM-like Higgs boson

Another important impact on the Higgs phenomenology in our scenario is found in the property of the SM-like Higgs boson h. Because the properties of h; e.g., the width, the branching fractions, and the couplings will be precisely measured at future collider experiments such as the LHC Run-II, the high luminosity LHC, and the ILC [76], it must be quite important to study the deviation in the property of h from the SM prediction. In particular, studying the pattern of the deviation in the various h couplings can be a powerful tool to determine the structure of the Higgs sector.[4]

As we discussed in section 2, the value of $\sin(\beta-\alpha)$ describes "*SM-like ness*" of h, namely, all the h couplings to the SM particles become the same as those in the SM prediction in the limit of $\sin(\beta-\alpha) \to 1$. In other words, once $\sin(\beta-\alpha) \neq 1$ is given, both the hVV and $hf\bar{f}$ couplings deviate from those of the SM values. In our scenario, the value of $\sin(\beta-\alpha)$ is determined from eq. (5.1). Thus, a small but non-zero deviation from the SM-like limit is given.

[4]In ref. [77], the pattern of the deviation was investigated in various extended Higgs sectors; e.g., models with isospin singlets, doublets and triplets at the tree level. For example, it was shown that the four types of Yukawa interactions in the 2HDM can be well discriminated by measuring the correlation between the deviation in $hd\bar{d}$ and $h\ell\ell$ couplings [77]. In addition, it was clarified in ref. [78, 79] that even if we take into account the one-loop corrections to the $hf\bar{f}$ couplings, discrimination of the 2HDMs is still valid.

JHEP07(2015)064

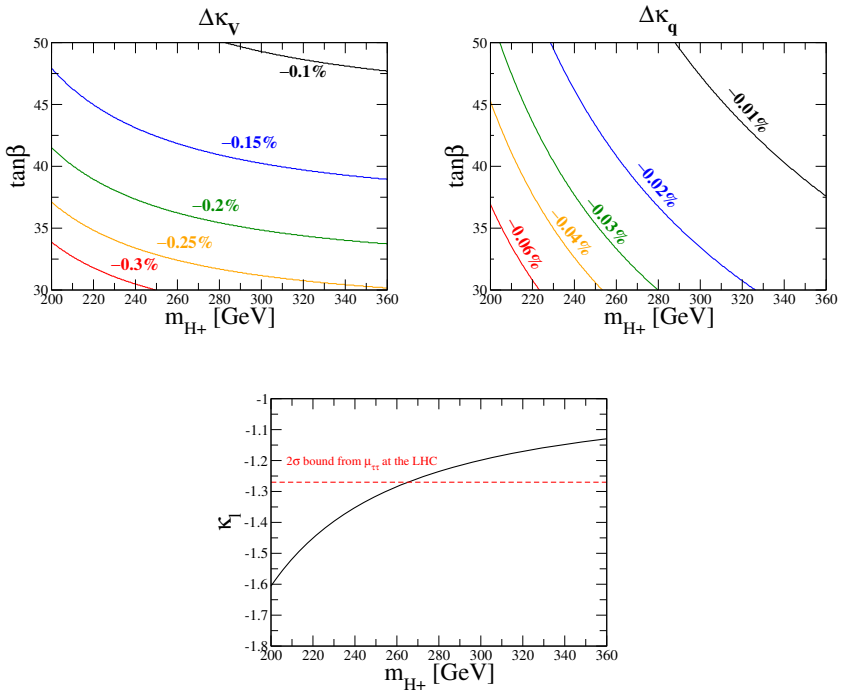

Figure 8. Contour plots for $\Delta\kappa_V$ (upper left) and $\Delta\kappa_q$ (upper right) on the $m_{H^\pm}$-$\tan\beta$ plane, where $\Delta\kappa_X = \kappa_X - 1$. The $m_{H^\pm}$ dependence of $\Delta\kappa_\ell$ is shown in the lower panel with $\tan\beta = 35$. We take $m_H = M = m_{H^\pm}$ and $m_A = 20\,\text{GeV}$ in all the panels. The horizontal dashed line represents the bound from the signal strength using eq. (5.14).

In order to describe the deviation in the h couplings, we introduce the so-called scaling factors defined as $\kappa_X = g_{hXX}/g_{hXX}^{\text{SM}}$ and its deviation from unity; i.e, $\Delta\kappa_X = \kappa_X - 1$. From eqs. (2.22) and (2.23) and the approximate formulae given in eqs. (3.4) and (3.5), we obtain

$$\Delta\kappa_V \simeq -\frac{2}{\tan^2\beta}\left(1 + \frac{m_h^2}{m_{H^\pm}^2} - \frac{2m_A^2}{m_{H^\pm}^2}\right), \tag{5.10}$$

$$\Delta\kappa_q \simeq -\frac{2}{\tan^2\beta}\left(\frac{m_h^2}{2m_{H^\pm}^2} - \frac{m_A^2}{m_{H^\pm}^2}\right), \tag{5.11}$$

$$\kappa_\ell \simeq -1 - \frac{m_h^2}{m_{H^\pm}^2} + \frac{2m_A^2}{m_{H^\pm}^2}. \tag{5.12}$$

In the upper panels of figure 8, we show the contour plots for $\Delta\kappa_V$ and $\Delta\kappa_q$, where $\Delta\kappa_X = \kappa_X - 1$, on the $m_{H^\pm}$-$\tan\beta$ plane. In the lower panel, we show the $m_{H^\pm}$ dependence of κ_ℓ instead of showing contour plots, because the $\tan\beta$ dependence of κ_ℓ can be neglected as seen in eq. (5.12). For definiteness, we take $\tan\beta = 35$ in the plot for $m_{H^\pm}$-κ_ℓ. We find that the deviations in the hVV and $hq\bar{q}$ couplings are respectively $-\mathcal{O}(0.1)\%$ and $-\mathcal{O}(0.01)\%$ which can also be estimated from eqs. (5.10), (5.11). For the $h\ell\ell$ coupling, we find that its magnitude is maximally about 1.6 times larger than the SM prediction, and its sign is opposite to the SM one [21]. From the measurement of the signal strength of the $h \to \tau\tau$ channel, i.e., $\mu_{\tau\tau}$ at the LHC, the magnitude of κ_ℓ is constrained. The definition

JHEP07(2015)064

of the signal strength is given as

$$\mu_{XY} \equiv \frac{\sigma_h \times \mathrm{Br}(h \to XY)}{[\sigma_h \times \mathrm{Br}(h \to XY)]_{\mathrm{SM}}}, \tag{5.13}$$

where σ_h and $\mathrm{Br}(h \to XY)$ are respectively the production cross section of the SM-like Higgs boson h and the decay branching fraction of the $h \to XY$ mode. In our parameter set, σ_h is almost the same as that in the SM, because of the small $\Delta\kappa_q$ and $\Delta\kappa_V$, so that the signal strength is simply given as the ratio of the branching fraction as $\mu_{XY} \simeq \mathrm{Br}(h \to XY)/\mathrm{Br}(h \to XY)_{\mathrm{SM}}$.

The ATLAS and CMS collaborations report the signal strength as $\mu_{\tau\tau} = 1.43^{+0.43}_{-0.37}$ [80] and $\mu_{\tau\tau} = 0.91 \pm 0.28$ [81], respectively. By taking a naive combination of them,[5] we obtain

$$\mu_{\tau\tau} = 1.08 \pm 0.23. \tag{5.14}$$

Thus, the region with $|\kappa_\ell| > 1.27$ is excluded at 2σ level, which corresponds to the constraint of $m_{H^\pm} \lesssim 270$ GeV as seen in figure 8.

The deviation in the h couplings makes a difference in the branching fraction of h from the SM prediction. In figure 9, we show the branching fraction of h as a function of $m_{H^\pm}$. Because only the magnitude of the $h\ell\ell$ coupling can be larger than the SM prediction, only the branching fraction of the $h \to \tau\tau$ mode is enhanced. On the other hand, that of all the other modes shown in this figure are reduced. The size of deviations becomes smaller as $m_{H^\pm}$ increases. We note that the branching fraction of the $h \to \mu\mu$ decay is also enhanced similar to the $h \to \tau\tau$ mode. When $m_{H^\pm} = 300\,\mathrm{GeV}$, and all the other parameters are taken to be the same as in figure 9, $\mathrm{Br}(h \to \mu\mu)$ is about 3.4 (2.5) $\times 10^{-4}$ in the Type-X 2HDM (SM).

It is important to mention here that there appears the exotic decay mode $h \to AZ$ in our parameter set as seen in figure 9. Although the coupling constant of the hZA interaction is proportional to $\cos(\beta - \alpha)$ which is suppressed by $\cot\beta$ as seen in eq. (3.5), its branching fraction is not so small, especially for the case with small m_A. For example, we obtain $\mathrm{Br}(h \to AZ) \simeq 7\%$ with $m_A = 10\,\mathrm{GeV}$ and $m_{H^\pm} = 200\,\mathrm{GeV}$. This new decay mode of h gives the additional contribution to the four-lepton channel in the SM Higgs boson search if A decays into a pair of muon. In the present scenario, $\mathrm{Br}(A \to \mu\mu) \simeq \mathrm{Br}(A \to \tau\tau) \times (m_\mu/m_\tau)^2 \simeq 0.0036$ is obtained. On the other hand, from Higgs boson searches at the LHC, the upper bound on $\mathrm{Br}(h \to ZA) \times \mathrm{Br}(A \to \ell\ell)$ with $\ell = e$ or μ is given as 5-10 $\times 10^{-4}$ for $12 < m_A < 34$ GeV [46, 47]. This limit is translated into the bound $\mathrm{Br}(h \to AZ) \lesssim$ 14-28% in the Type-X 2HDM. The typical size of $\mathrm{Br}(h \to AZ)$ is below the upper bound as explained in the above. In addition to this channel, e and μ are produced from the leptonic decay of τ. Thus, the $ZA \to \ell\ell\tau\tau \to 4\ell + \not{E}_T$ channel can also contribute to the four lepton channel even though the invariant mass distribution of the four lepton system is different from that by $ZZ^* \to 4\ell$. This will be a subject of a future work.

Next, we discuss the one-loop induced $h \to \gamma\gamma$ decay mode. Because of the $H^\pm$ contribution, the decay rate can be significantly modified even if the h couplings are not

[5] To obtain the naive combination, we treat the signal strength from ATLAS as 1.43 ± 0.40 by taking the average of errors.

JHEP07(2015)064

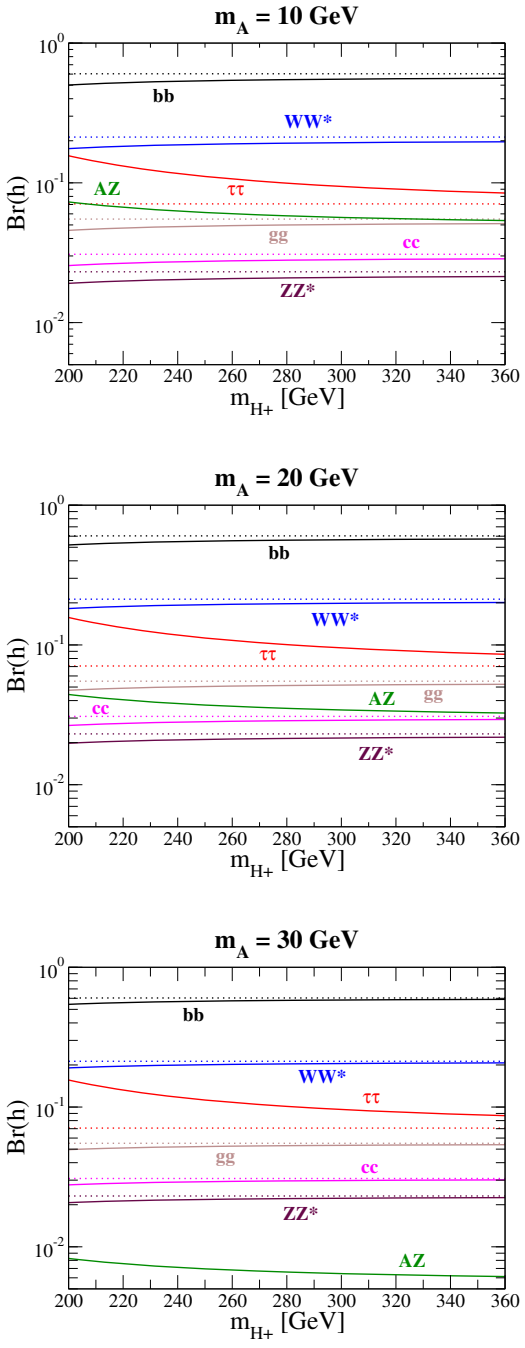

Figure 9. The branching fraction of h as a function of $m_{H^\pm}$ in the case of $m_H = M = m_{H^\pm}$ and $\tan\beta = 35$. The top, middle and bottom panels show the cases with $m_A = 10$, 20 and 30 GeV, respectively. The solid (dotted) curves shows the prediction in the Type-X 2HDM (SM).

JHEP07(2015)064

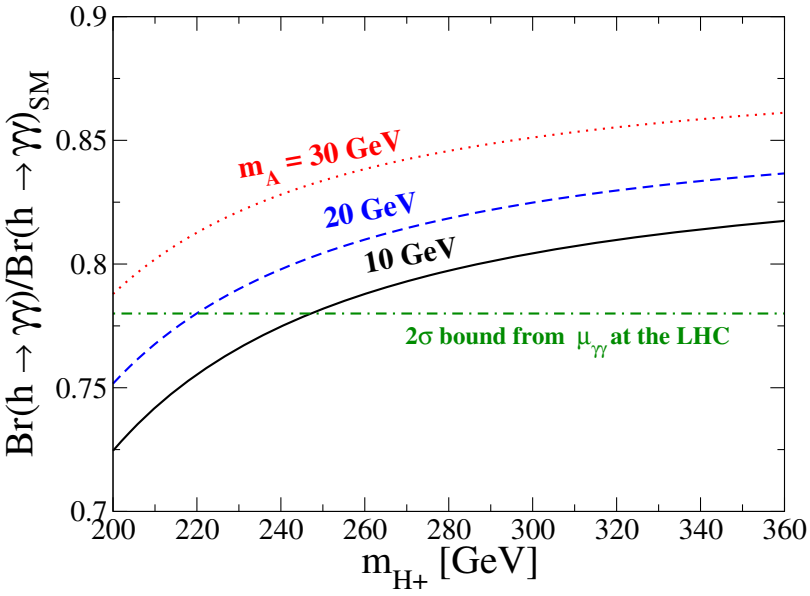

Figure 10. Ratio of the branching fraction $\mathrm{Br}(h \to \gamma\gamma)/\mathrm{Br}(h \to \gamma\gamma)_{\mathrm{SM}}$ in our scenario with $\tan\beta = 35$. The solid, dashed and dotted curves show the cases with m_A=10, 20 and 30 GeV, respectively. The horizontal dashed line shows the bound from $\mu_{\gamma\gamma}$ given in eq. (5.21) at 2σ level.

changed so much from the SM prediction. We note that the deviation in the $h\ell\ell$ coupling can be neglected in the decay rate of the $h \to \gamma\gamma$ mode, because its effect appears in the tau loop contribution, but the tau Yukawa coupling is too small as compared to the top Yukawa coupling. The decay rate of the diphoton mode is given as

$$\Gamma(h \to \gamma\gamma) = \frac{G_F \alpha_{\mathrm{em}}^2 m_h^3}{128\sqrt{2}\pi^3} \left| s_{\beta-\alpha} A_1(\tau_W) + \sum_f \xi_f^h A_{1/2}^f(\tau_f) + \frac{\lambda_3 v^2}{2m_{H^\pm}^2} A_0(\tau_{H^\pm}) \right|^2 ,$$
$$\text{with} \quad \tau_X = \frac{m_h^2}{4m_X^2}, \tag{5.15}$$

where the A_1, $A_{1/2}^f$ and A_0 terms correspond to the W boson, fermion and $H^\pm$ loop contributions, respectively. Each of the loop functions are given by

$$A_1(\tau) = -\tau^{-2}[2\tau^2 + 3\tau + 3(2\tau - 1)f(\tau)], \tag{5.16}$$
$$A_{1/2}^f(\tau) = 2N_c^f Q_f^2 \tau^{-2}[\tau + (\tau - 1)f(\tau)], \tag{5.17}$$
$$A_0(\tau) = -\tau^{-2}[\tau - f(\tau)], \tag{5.18}$$

JHEP07(2015)064

where $f(\tau)$ is defined as

$$f(\tau) = \begin{cases} \arcsin^2 \sqrt{\tau}. & (\tau \leq 1) \\ -\frac{1}{4}\left(\log \frac{1+\sqrt{1-\tau^{-1}}}{1-\sqrt{1-\tau^{-1}}} - i\pi\right)^2 . & (\tau > 1) \end{cases} \tag{5.19}$$

We note that in the SM-like limit, which gives a good approximation for the numerical study in our scenario, we obtain the numerical value of the SM W and top loop contributions; i.e., $A_1(\tau_W) + A_{1/2}^t(\tau_t) \simeq -6.45$.

We here discuss the impact of the $H^\pm$ loop contribution to the $h \to \gamma\gamma$ decay. In our scenario, since the light CP-odd Higgs boson is required to explain the muon $g-2$ anomaly, the relatively large mass difference between A and $H^\pm$ is needed to avoid the current experimental constraints, which is generated by the Higgs quartic couplings. This can be clearly seen by rewriting the λ_3 coupling appearing in eq. (5.15) as follows

$$\lambda_3 v^2 = 2(m_{H^\pm}^2 - m_A^2) + \lambda_{hAA} v^2, \tag{5.20}$$

where the second term is now zero according to our benchmark scenario shown in eq. (5.1). In addition, the loop function A_0 is expanded as $A_0(x) = 1/3 + 8x/45 + \mathcal{O}(x^2)$ under $x \ll 1$ or equivalently $m_{H^\pm} \gg m_h$. Thus, even if $H^\pm$ is relatively heavy, its contribution is not decoupled as we can see the asymptotic behavior $\lambda_3 v^2/(2m_{H^\pm}^2) A_0(\tau_{H^\pm}) \to 1/3$ $(m_{H^\pm} \to \infty)$.

The ATLAS and CMS collaborations report the signal strength as $\mu_{\gamma\gamma} = 1.17 \pm 0.27$ [82] and and $\mu_{\gamma\gamma} = 1.12 \pm 0.24$ [81], respectively. By taking naive combination of them, we obtain

$$\mu_{\gamma\gamma} = 1.14 \pm 0.18. \tag{5.21}$$

In figure 10, we show the ratio of the branching fraction of the $h \to \gamma\gamma$ mode as a function of $m_{H^\pm}$ with $\tan\beta = 35$. We find that the deviation in the branching fraction from the SM prediction is obtained in the range of -30% to -15%. The expected accuracy for the measurement of the decay rate of the diphoton mode is around -10% at the LHC 14 TeV 300 fb^{-1} and 5% at the ILC [83]. Therefore, our scenario is also probed by detecting the deviation in the $h \to \gamma\gamma$ decay rate in addition to the extra Higgs boson searches discussed in section 5.1 and the measurement of κ_ℓ. By looking at the horizontal line representing the bound from $\mu_{\gamma\gamma}$, we see that $m_{H^\pm} \lesssim 220$ GeV is excluded in the case of $m_A = 20$ GeV, which weaker than the constraint of κ_ℓ.

6 Conclusion

In this paper, we have explored the possibility to explain the muon $g-2$ anomaly in the Type-X 2HDM. We have shown in figure 6 that the measurement of the leptonic tau decay gives an important constraint on the parameter space. As a result, the region which can explain the discrepancy in the muon $g-2$ at the 1σ level is excluded by the constraint from the tau decay, and that at the 2σ level is allowed. We have found that the parameter space with $10 \lesssim m_A \lesssim 30$ GeV, $200 \lesssim m_{H,H^\pm} \lesssim 350$ GeV and $30 \lesssim \tan\beta \lesssim 50$ is favored by the explanation of the anomaly at the 2σ level.

JHEP07(2015)064

After finding the viable parameter region for the muon $g-2$, we have discussed the implication of the favored parameter region to the collider phenomenology. In our scenario, the 4τ, 3τ, $4\tau+Z$ and $4\tau+W$ signatures are expected from the electroweak productions of the extra Higgs bosons at the LHC. The cross sections of these signals are shown in table 2.

Finally, we have investigated the possible deviation in the property of the SM-like Higgs boson h. We have found that the value of the $h\ell\ell$ coupling is predicted to be the SM prediction times about -1.6 to -1.0, and the current data of the signal strength $\mu_{\tau\tau}$ at the LHC excludes $m_{H^\pm} \lesssim 270$ GeV in the case of $m_{H^\pm} = m_H$ and $m_A = 20$ GeV. We also have evaluated the branching fraction of the $h \to \gamma\gamma$ mode which is modified by the non-decoupling charged Higgs boson loop effect. We have shown that the deviation in the branching fraction of the $h \to \gamma\gamma$ mode is about -30% to -15% which can be detected at the future collider experiments such as the high-luminosity LHC and the ILC. Therefore, the precise measurements of the branching fractions of $h \to \gamma\gamma$ and $h \to \tau\tau$ gives an important indirect test to probe our scenario. Furthermore, we have found that the branching fraction of $h \to ZA$ becomes a few percent, and it also would provide another important signature to test our scenario. Therefore, in the Type-X 2HDM motivated by the explanation of the muon $g-2$ anomaly, there are various characteristic deviations in the 125 GeV Higgs boson property, which will be tested at collider experiments in the near future.

A Decay rates for the extra Higgs bosons

The decay rates of the extra Higgs bosons into the fermion pair are calculated at the tree level as

$$\Gamma(H^\pm \to f\bar{f}') = \sqrt{2}G_F \frac{m_{H^\pm}^3}{8\pi} N_c^f |V_{ff'}|^2 \lambda^{1/2}(x_{fH^\pm}, x_{f'H^\pm}) \times \left[(x_{fH^\pm}\xi_f^2 + x_{f'H^\pm}\xi_{f'}^2)(1 - x_{fH^\pm} - x_{f'H^\pm}) + 4x_{fH^\pm}x_{f'H^\pm}\xi_f\xi_{f'} \right], \tag{A.1}$$

$$\Gamma(H \to f\bar{f}) = \sqrt{2}G_F \frac{m_H m_f^2}{8\pi} (\xi_f^H)^2 N_c^f \lambda^{3/2}\left(x_{fH}, x_{fH}\right), \tag{A.2}$$

$$\Gamma(A \to f\bar{f}) = \sqrt{2}G_F \frac{m_A m_f^2}{8\pi} \xi_f^2 N_c^f \lambda^{1/2}\left(x_{fA}, x_{fA}\right), \tag{A.3}$$

where $x_{ab} = m_a^2/m_b^2$, N_c^f is the color factor, and the two body phase space function $\lambda(x,y)$ is given by

$$\lambda(x,y) = 1 + x^2 + y^2 - 2x - 2y - 2xy. \tag{A.4}$$

JHEP07(2015)064

We note that the above formulae are applied to all the types of Yukawa interactions. The decay rates into the gauge boson associated modes are calculated at the tree level as

$$\Gamma(H \to AZ) = s^2_{\beta-\alpha} \frac{\sqrt{2} G_F}{16\pi} m_H^3 \lambda^{3/2}\left(x_{ZH}, x_{AH}\right), \tag{A.5}$$

$$\Gamma(H^\pm \to AW^\pm) = \frac{\sqrt{2} G_F}{16\pi} m_{H^\pm}^3 \lambda^{3/2}\left(x_{WH^\pm}, x_{AH^\pm}\right). \tag{A.6}$$

B Electroweak production of a pair of Higgs bosons

Spin and color-averaged parton level cross sections are given as [85][6]

$$\hat{\sigma}(\hat{s}; u\bar{d} \to H^+ A) = \frac{G_F^2 m_W^4}{72\pi} \frac{s^2_{\beta-\alpha}}{\hat{s}} \left(\frac{\hat{s}}{\hat{s} - m_W^2}\right)^2 \lambda^{3/2}\left(\frac{m^2_{H^\pm}}{\hat{s}}, \frac{m_A^2}{\hat{s}}\right), \tag{B.1}$$

$$\hat{\sigma}(\hat{s}; u\bar{d} \to H^+ H) = \frac{G_F^2 m_W^4}{72\pi} \frac{s^2_{\beta-\alpha}}{\hat{s}} \left(\frac{\hat{s}}{\hat{s} - m_W^2}\right)^2 \lambda^{3/2}\left(\frac{m^2_{H^\pm}}{\hat{s}}, \frac{m_H^2}{\hat{s}}\right), \tag{B.2}$$

$$\hat{\sigma}(\hat{s}; q\bar{q} \to HA) = \frac{G_F^2 m_Z^4}{18\pi} (v_q^2 + a_q^2) \frac{s^2_{\beta-\alpha}}{\hat{s}} \left(\frac{\hat{s}}{\hat{s} - m_Z^2}\right)^2 \lambda^{3/2}\left(\frac{m_H^2}{\hat{s}}, \frac{m_A^2}{\hat{s}}\right), \tag{B.3}$$

$$\begin{aligned}\hat{\sigma}(\hat{s}; q\bar{q} \to H^+ H^-) = \frac{\pi \alpha_{\rm em}^2}{9\hat{s}} &\left[\left(Q_q - \frac{v_q v_H}{s_W^2 c_W^2} \frac{\hat{s}}{\hat{s} - m_Z^2}\right)^2 + \frac{a_q^2 v_H^2}{s_W^4 c_W^4} \left(\frac{\hat{s}}{\hat{s} - m_Z^2}\right)^2\right] \\ &\times \lambda^{3/2}\left(\frac{m^2_{H^\pm}}{\hat{s}}, \frac{m^2_{H^\pm}}{\hat{s}}\right),\end{aligned} \tag{B.4}$$

where $v_H = -1/2 + s_W^2$, and v_q and a_q are defined in eq. (3.11). Production cross section at the hadron collider is calculated as

$$\sigma(pp \to AB) = 2 \int_0^1 d\tau \sum_{q_1, \bar{q}_2} \frac{d\mathcal{L}_{q_1\bar{q}_2}}{d\tau} \hat{\sigma}(q_1\bar{q}_2 \to AB; \hat{s} = \tau s). \tag{B.5}$$

where $\mathcal{L}$ is the parton luminosity which is defined as

$$\frac{d\mathcal{L}_{q_1\bar{q}_2}}{d\tau} = \int_\tau^1 \frac{dx}{x} q_1(x) \bar{q}_2(\tau/x). \tag{B.6}$$

We note that the parton level cross sections of $\bar{u}d \to H^- A$ and $\bar{u}d \to H^- H$ processes are the same as those given in eqs. (B.1) and (B.2), respectively. However, because of the difference of parton luminosity of the initial proton, the cross section of H^+H/A and H^-H/A are different in the stage after the convolution of the luminosity function shown in eqs. (B.5) and (B.6).

Abstract: We show that in studies of light quark- and gluon-initiated jet discrimination, it is important to include the information on softer reconstructed jets (associated jets) around a primary hard jet. This is particularly relevant while adopting a small radius parameter for reconstructing hadronic jets. The probability of having an associated jet as a function of the primary jet transverse momentum (p_T) and radius, the minimum associated jet p_T and the association radius is computed up to next-to-double logarithmic accuracy (NDLA), and the predictions are compared with results from `Herwig++`, `Pythia6` and `Pythia8` Monte Carlos (MC). We demonstrate the improvement in quark-gluon discrimination on using the associated jet rate variable with the help of a multivariate analysis. The associated jet rates are found to be only mildly sensitive to the choice of parton shower and hadronization algorithms, as well as to the effects of initial state radiation and underlying event. In addition, the number of k_t subjets of an anti-k_t jet is found to be an observable that leads to a rather uniform prediction across different MC's, broadly being in agreement with predictions in NDLA, as compared to the often used number of charged tracks observable.

A Distributions of discrimination variables 17

1 Introduction

Hadronic jets are the most abundant objects at a proton-proton collider like the LHC, and it is a major challenge to separate the signals being looked for from standard model (SM) backgrounds in multijet final states. One promising direction that has recently received attention in both theoretical and experimental studies is that the separation of light quark-initiated jets from gluon-initiated ones can be viable in these search channels. Quarks are often encountered in the decays of new particles predicted by scenarios beyond the standard model, as well as in the decay of the weak bosons, Higgs and top quark in the SM itself. On the other hand, in the corresponding SM backgrounds involving multiple hard jets, there is a larger fraction of gluon-initiated jets from QCD radiation. Here, quark- or gluon-initiated jets (henceforth simply referred to as quark and gluon jets) refer to the parton in the hard process at leading order in perturbation theory that initiates the parton shower. Based on the difference in the radiation pattern of quarks and gluons, a likelihood based discriminant can be built to separate decay jets from QCD radiation jets with a certain efficiency [1].

Several variables have been proposed to separate quark and gluon jets, mostly relying on the fact that a gluon of similar energy leads to more soft emissions compared to a quark. This includes both discrete variables like the number of charged tracks inside the jet cone, as well as continuous ones like the width of a jet and energy-energy-correlation (EEC) angularity [1–5]. ATLAS and CMS collaborations have also studied the discrimination of light quarks from gluons along these lines with the 7 and 8 TeV LHC data respectively [6, 7].

JHEP04(2015)131

Using data samples with "enriched quark and gluon content", data-based taggers were also developed, and compared to the predictions from Monte Carlo (MC) simulations. While there are differences between the predictions of different MC's, as well as between the data-based tagger and the MC results, they are consistent with each other within the large systematic uncertainties at present.

An important question in this regard is the proper choice of a jet algorithm and radius parameter. In the LHC environment, in order to keep the contribution of the underlying event and multiple proton-proton collisions at a minimum, for multijet processes the standard choice is an anti-k_t algorithm with radius parameter $R = 0.4$. In addition, in the ATLAS study mentioned above, jets are required to satisfy an isolation criterion: a jet is considered isolated if there is no other reconstructed jet within a cone of size $\Delta R < 0.7$ (where $\Delta R = \sqrt{(\Delta\eta)^2 + (\Delta\phi)^2}$ is the standard distance measure in the pseudorapidity-azimuthal angle plane). An optimum choice for the jet radius parameter was discussed in refs. [8, 9] for quark and gluon jets as a function of their transverse momenta (p_T), and it was observed that one usually requires a larger radius for a gluon jet in order for the parton p_T to be close to the jet p_T. However, for experimental purposes it is advantageous to use a fixed and small radius parameter for the jets, for reasons mentioned above. Therefore, we propose to recover the missed information on radiation from the parent parton outside the chosen jet radius by including softer reconstructed jets that can be present (with a calculable probability) around a certain radius of a primary hard jet. These softer jets are referred to as "associated jets" in this study. It is important to note here that imposing an isolation criterion as above while studying quark and gluon jet properties might not be appropriate, since it leads to rejecting a fraction of the jet candidates beforehand, and thus biasing the sample to ones where the initial quark or gluon has not radiated outside the adopted jet radius.

We first compute the associated jet rates in QCD to next-to-double logarithmic accuracy in section 2, and then compare the analytical results with those from different parton shower MC's in section 3. Using the information on the presence (or absence) of associated jets can improve the discrimination of quarks and gluons. We demonstrate this through a multivariate analysis in section 4. Several combinations of jet discrimination variables are tried out, and an attempt is made to determine an optimum choice. Even though we include standard discrimination variables like the number of charged tracks as inputs to our multivariate analysis, it should be emphasized that they are subject to MC ambiguities stemming from parton shower algorithms and their associated parameters, and tunings of hadronization and underlying event (UE) models. However, in order to judge the improvement in tagger performance on using the associated jet rates, we compare the performance of different sets of variables within the same MC.

In sections 5 and 6 we study the use of the number of subjets of a jet (defined with an exclusive k_t algorithm) in place of the number of charged tracks, since the different MC prediction tend to be similar for the former observable. We compute the subjet rates upto NDLA as well, and compare the NDLA results with predictions from different MC's. Our results on both associated jets and subjets are summarized in section 7. We discuss the 2-dimensional joint distributions of the three discrimination variables used as inputs in the

JHEP04(2015)131

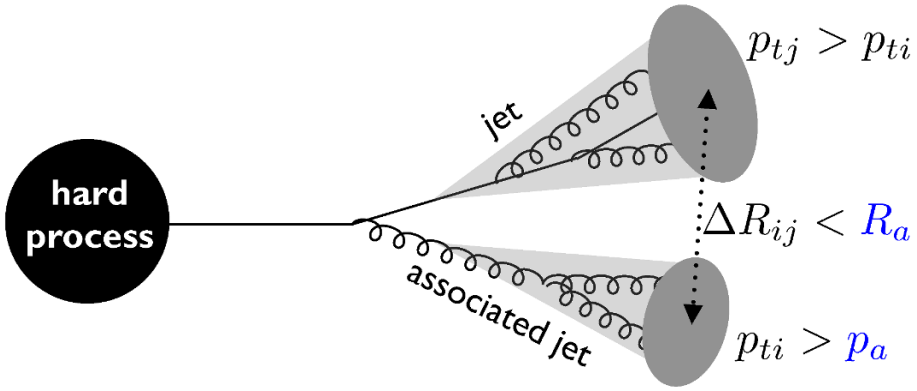

Figure 1. A schematic illustration of associated jets, and the relevant variables which determine the associated jet rate (see text for details).

multivariate analysis in an appendix.

2 Associated jet rates: analytical calculations

To begin with, let us define the longitudinally invariant jet algorithms [10–13] adopted in this study. The distance measures between each pair of objects i and j (d_{ij}), and between an object and the beam (d_{iB}) are given by

$$\begin{aligned} d_{ij} &= \min\{p_{ti}^{2p}, p_{tj}^{2p}\}\frac{\Delta R_{ij}^2}{R^2}\,, \\ d_{iB} &= p_{ti}^{2p}\,, \end{aligned} \tag{2.1}$$

where p_{ti}, y_i and ϕ_i are the transverse momentum, rapidity and azimuth of object i, respectively, $\Delta R_{ij}^2 \equiv (y_i - y_j)^2 + (\phi_i - \phi_j)^2$, and R is the jet radius parameter. The jet algorithm in use is fixed by the parameter p, with $p = 1, 0, -1$ for the k_t [11], Cambridge/Aachen [14–16] and anti-k_t [13] algorithms, respectively. At any stage of clustering, if a d_{ij} is the smallest measure we combine objects i and j. If d_{iB} is the smallest we call i a jet and remove it from the clustering list. This procedure is continued until there are no more objects left to cluster.

Once a primary jet j has been defined, say using the anti-k_t algorithm with radius parameter R, we define a nearby jet i with $p_{tj} > p_{ti} > p_a$ and $R < \Delta R_{ij} < R_a$ as an *associated jet*. Thus the associated jet rates are functions of the primary jet $p_t = p_j$, its radius R, the association radius R_a and the minimum associated jet $p_t = p_a$. In figure 1 we illustrate the idea of an associated jet schematically, and show the relevant variables that determine the associated jet rate.

In perturbative QCD, the rate of n-jet production from a primary object of type i ($i = q, g$ in this case), R_n^i, can be obtained from the associated generating function [17–21]

$$\Phi_i(u) = \sum_n R_n^i u^n\,. \tag{2.2}$$

JHEP04(2015)131

We can recover the jet rates by differentiating at $u = 0$,

$$R_n^i = \frac{1}{n!} \left. \frac{d^n \Phi_i}{du^n} \right|_{u=0} . \tag{2.3}$$

The jet rates $R_n^i = R_n^i(p_j, \xi)$ are functions of the trigger jet transverse momentum p_j, and the evolution scale for parton showering, which, for hadron-hadron collisions is taken as $\xi = \Delta R^2/2$. This is equivalent to the evolution scale for coherent parton showering, $\xi \equiv 1 - \cos\theta$, with θ being the emission angle ($\Delta R^2/2 \approx \theta^2/2 \approx 1 - \cos\theta$). To be resolved, an emission must have $\xi > \xi_j = R^2/2$ and $p_t > p_a$. Since the jet rates R_n^i include the trigger jet j, the probability of n *associated jets* for a jet of type i with transverse momentum p_j is

$$P_n^i = R_{n+1}^i(p_j, \xi_a) . \tag{2.4}$$

Here, $\xi_a = R_a^2/2$, with R_a being the association radius defined above.

The generating functions $\Phi_i(u)$ were computed in the context of e^+e^- collisions in ref. [17], upto next-to-double logarithmic accuracy (NDLA). Here, leading double and next-to-double logarithms refer to $\alpha_{\rm S}^n \log^{2n}$ and $\alpha_{\rm S}^n \log^{2n-1}$, where the logarithms are those of R_a/R and/or p_j/p_a. For p_a sufficiently large, these terms are determined by the timelike showering of final-state partons, while contributions from initial-state showers and the underlying event can be avoided. Following the same methods as in ref. [17] for hadron hadron collisions, for $\xi > \xi_j$ and $p_j > p_a$, we have the quark and gluon generating functions to NDLA

$$\begin{aligned}
\Phi_q(u, p_j, \xi) &= u + \int_{\xi_j}^{\xi} \frac{d\xi'}{\xi'} \int_{p_a/p_j}^{1} dz \frac{\alpha_{\rm S}(k_t^2)}{2\pi} P_{gq}(z) \Phi_q(u, p_j, \xi') \left[\Phi_g(u, zp_j, \xi') - 1\right] , \\
\Phi_g(u, p_j, \xi) &= u + \int_{\xi_j}^{\xi} \frac{d\xi'}{\xi'} \int_{p_a/p_j}^{1} dz \frac{\alpha_{\rm S}(k_t^2)}{2\pi} \Big\{ P_{gg}(z) \Phi_g(u, p_j, \xi') \left[\Phi_g(u, zp_j, \xi') - 1\right] \\
&\quad + P_{qg}(z) \left[\{\Phi_q(u, p_j, \xi')\}^2 - \Phi_g(u, p_j, \xi')\right] \Big\} .
\end{aligned} \tag{2.5}$$

Here, the running coupling is evaluated at the transverse momentum scale of the emission, $k_t^2 = z^2 p_j^2 \xi'$. Defining $\overline{\alpha}_{\rm S} = \alpha_{\rm S}(p_j^2 \xi)/\pi$, i.e. in terms of the coupling at the hard scale, we have to NDLA

$$\frac{\alpha_{\rm S}(k_t^2)}{\pi} = \overline{\alpha}_{\rm S} - b_0 \overline{\alpha}_{\rm S}^2 \left[2 \ln z + \ln\left(\frac{\xi'}{\xi}\right) \right] , \tag{2.6}$$

with $b_0 = (11 C_A - 2 n_f)/12$.

The solution for the quark generating function is easily seen to be

$$\Phi_q(u, p_j, \xi) = u \exp\left\{ \int_{\xi_j}^{\xi} \frac{d\xi'}{\xi'} \int_{p_a/p_j}^{1} dz \frac{\alpha_{\rm S}(k_t^2)}{2\pi} P_{gq}(z) \left[\Phi_g(u, zp_j, \xi') - 1\right] \right\} . \tag{2.7}$$

We can solve for the gluon generating function by iteration, and then substitute in this equation to get the complete solution. For brevity we define the following logarithms:

$$\begin{aligned}
\kappa &= \ln(p_j/p_a) , & \kappa' &= \ln(zp_j/p_a) , \\
\lambda &= \ln(\xi_a/\xi_j) = 2\ln(R_a/R) , & \lambda' &= \ln(\xi'/\xi_j) .
\end{aligned} \tag{2.8}$$

JHEP04(2015)131

In terms of these variables the NDLA quark generating function is

$$\Phi_q(u,\kappa,\lambda) = u\exp\left\{\int_0^\lambda d\lambda' \int_0^\kappa d\kappa'\,\Gamma_q\left(\kappa',\lambda',\kappa,\lambda\right)\left[\Phi_g(u,\kappa',\lambda')-1\right]\right\} \tag{2.9}$$

where, including the full P_{gq} splitting function,[1]

$$\Gamma_q\left(\kappa',\lambda',\kappa,\lambda\right) = C_F\overline{\alpha}_{\rm S}\left[1-\mathrm{e}^{\kappa'-\kappa}+\frac{1}{2}\mathrm{e}^{2(\kappa'-\kappa)}\right] - C_F b_0\overline{\alpha}_{\rm S}^2\left[2(\kappa'-\kappa)+\lambda'-\lambda\right]. \tag{2.10}$$

Defining similarly[2]

$$\begin{aligned}\Gamma_g(\kappa',\lambda',\kappa,\lambda) &= C_A\overline{\alpha}_{\rm S}\left[1-\mathrm{e}^{\kappa'-\kappa}+\frac{1}{2}\mathrm{e}^{2(\kappa'-\kappa)}-\frac{1}{2}\mathrm{e}^{3(\kappa'-\kappa)}\right] - C_A b_0\overline{\alpha}_{\rm S}^2\left[2(\kappa'-\kappa)+\lambda'-\lambda\right],\\ \Gamma_f(\kappa',\kappa) &= \frac{n_f}{4}\overline{\alpha}_{\rm S}\left[\mathrm{e}^{\kappa'-\kappa}-2\mathrm{e}^{2(\kappa'-\kappa)}+2\mathrm{e}^{3(\kappa'-\kappa)}\right],\end{aligned} \tag{2.11}$$

we solve the gluon generating function by iteration to second order in u, which gives the probabilities for 0 or 1 associated jets:

$$\begin{aligned}\Phi_g(u,\kappa,\lambda) = u\Delta_g(\kappa,\lambda)\Bigg\{1+u\int_0^\lambda d\lambda'\int_0^\kappa d\kappa'\,\big[&\Gamma_g(\kappa',\lambda',\kappa,\lambda)\,\Delta_g(\kappa',\lambda')\\ &+\Gamma_f(\kappa',\kappa)\Delta_f(\kappa,\lambda')\big]+\mathcal{O}(u^2)\Bigg\},\end{aligned} \tag{2.12}$$

where $\Delta_q(\kappa,\lambda)$ and $\Delta_g(\kappa,\lambda)$ are the quark and gluon Sudakov factors (the probabilities for no associated jets) and we have defined $\Delta_f(\kappa,\lambda)=\Delta_q^2(\kappa,\lambda)/\Delta_g(\kappa,\lambda)$. Hence

$$\begin{aligned}P_0^q &= \Delta_q(\kappa,\lambda) = \exp\left\{-\int_0^\lambda d\lambda'\int_0^\kappa d\kappa'\,\Gamma_q(\kappa',\lambda',\kappa,\lambda)\right\}\\ &= \exp\Bigg\{-C_F\overline{\alpha}_{\rm S}\lambda\left[\kappa-\frac{3}{4}+\mathrm{e}^{-\kappa}-\frac{1}{4}\mathrm{e}^{-2\kappa}\right]-C_F b_0\overline{\alpha}_{\rm S}^2\kappa\lambda\left[\kappa+\frac{1}{2}\lambda\right]\Bigg\},\end{aligned} \tag{2.13}$$

$$\begin{aligned}P_0^g &= \Delta_g(\kappa,\lambda) = \exp\left\{-\int_0^\lambda d\lambda'\int_0^\kappa d\kappa'\,\left[\Gamma_g(\kappa',\lambda',\kappa,\lambda)+\Gamma_f(\kappa',\kappa)\right]\right\}\\ &= \exp\Bigg\{-C_A\overline{\alpha}_{\rm S}\lambda\left[\kappa-\frac{11}{12}+\mathrm{e}^{-\kappa}-\frac{1}{4}\mathrm{e}^{-2\kappa}+\frac{1}{6}\mathrm{e}^{-3\kappa}\right]\\ &\quad -\frac{n_f}{4}\overline{\alpha}_{\rm S}\lambda\left[\frac{2}{3}-\mathrm{e}^{-\kappa}+\mathrm{e}^{-2\kappa}-\frac{2}{3}\mathrm{e}^{-3\kappa}\right]-C_A b_0\overline{\alpha}_{\rm S}^2\kappa\lambda\left[\kappa+\frac{1}{2}\lambda\right]\Bigg\},\end{aligned} \tag{2.14}$$

$$P_1^q = \Delta_q(\kappa,\lambda)\int_0^\lambda d\lambda'\int_0^\kappa d\kappa'\,\Gamma_q(\kappa',\lambda',\kappa,\lambda)\,\Delta_g(\kappa',\lambda') \tag{2.15}$$

$$P_1^g = \Delta_g(\kappa,\lambda)\int_0^\lambda d\lambda'\int_0^\kappa d\kappa'\big[\Gamma_g(\kappa',\lambda',\kappa,\lambda)\Delta_g(\kappa',\lambda')+\Gamma_f(\kappa',\kappa)\Delta_f(\kappa,\lambda')\big]. \tag{2.16}$$

[1] We keep terms that are formally power-suppressed in order to satisfy the boundary condition $P_0=1$ when $p_a=p_j$.

[2] We drop the $\overline{\alpha}_{\rm S}^2$ term in Γ_f as it is beyond NDLA and does not affect the boundary condition.

JHEP04(2015)131

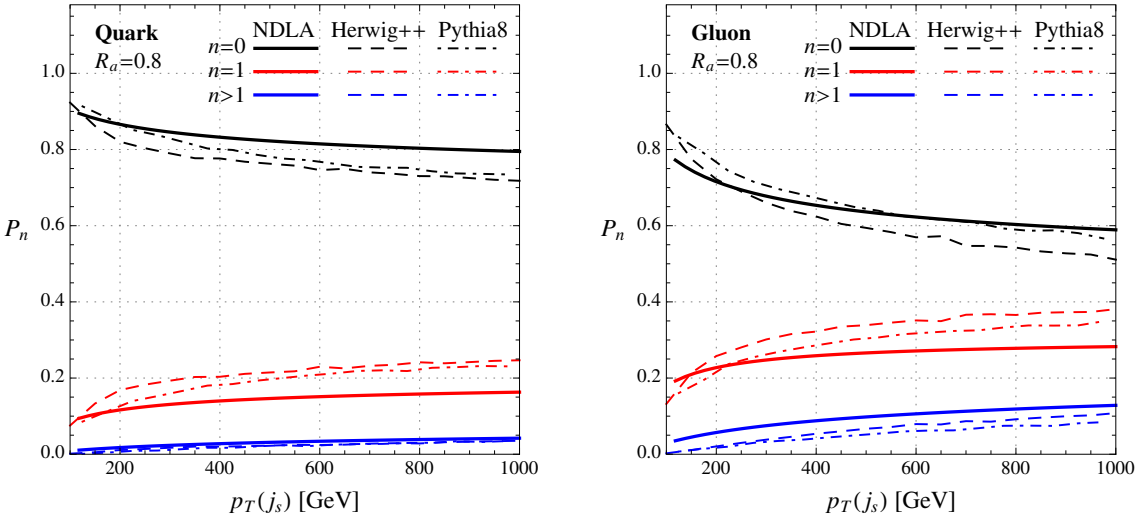

Figure 2. Comparison of the `Herwig++` and `Pythia8` MC predictions for associated jet rates with the NDLA results, as a function of $p_T(j_s)$: for quark jets (left), and gluon jets (right), with $R_a = 0.8$ and $p_a = 20\,\text{GeV}$. Here, $p_T(j_s)$ is the vector sum of the leading jet and associated jet p_T's.

3 Associated jet rates: comparison with Monte Carlo

We are now in a position to compare the NDLA predictions for associated jet rates discussed in the previous section with the results obtained using the `Herwig++` [22] and `Pythia8` [23, 24] event generators,[3] where the quark- and gluon-initiated jets are simulated using the $Z+q$ and $Z+g$ processes at leading order in QCD (with the Z boson subsequently decayed to $\nu\bar{\nu}$). The event samples were generated for proton-proton collisions at the 13 TeV LHC, using the `CTEQ6L1` [25] parton distribution functions (PDF) for the `Pythia` generators and the default `MRST LO**` [26] PDF and UE model for `Herwig++`. Subsequently, we used a modified version of `DELPHES2` [27] for including detector effects. For observables based on charged tracks to be discussed in the following, we use a minimum p_T threshold of 1 GeV for each track. All jets are reconstructed with an anti-k_t algorithm [13, 28, 29] with radius parameter $R = 0.4$, and are required to have $p_T > 20\,\text{GeV}$. In addition, the leading jet is required to be central with $|\eta| < 2$.

In figure 2 we show the probability of obtaining n associated jets P_n as a function of the jet p_T for $n = 0, 1$ and $n > 1$, for quark- and gluon-initiated jets, in the left and right columns respectively. The association radius is set to be $R_a = 0.8$ and the minimum associated jet transverse momentum is $p_a = 20\,\text{GeV}$. In the MC simulations, P_n has been computed as a function of $p_T(j_s)$, which is the vector sum of the leading jet and associated jet p_T's. The jet rates are studied as a function of $p_T(j_s)$, as it is closer to the transverse momentum of the parton that initiates the final state shower.

We see that the functional behaviour with respect to the jet p_T in the MC computation[4]

[3] To be specific, we use `Herwig++ 2.7.0` and `Pythia 8.201` (tune `4C`) for all our calculations.

[4] For the associated jet rate calculations, we generated MC event samples with a statistics of 20,000 events each fixing the threshold for the minimum leading jet p_T at $50 \times (i+1)\,\text{GeV}$, for $i \in [0, 19]$. Only

JHEP04(2015)131

and the NDLA calculation are similar, although there are some differences in the values of P_n. In particular, the MC prediction of P_1 for quark and gluon jets is higher than the NDLA result, especially at higher $p_T(j_s)$, with `Herwig++` giving rise to a slightly larger P_1 compared to `Pythia8`. For a quark jet, the probability of having at least one associated jet ranges from around 15% to 25% as we go from $p_T(j_s) = 200\,\text{GeV}$ to $p_T(j_s) = 500\,\text{GeV}$ and at higher $p_T(j_s)$ the probability essentially remains the same. For gluon jets, the corresponding probability ranges from around 30% to 40% as we go from $p_T(j_s) = 200\,\text{GeV}$ to $p_T(j_s) = 500\,\text{GeV}$. The larger probability to have an associated jet around a gluon can thus be utilized to better discriminate it from quarks, as we shall see in the next section.

The NDLA computation includes only the time-like showering of the final state partons, and ignores some power-suppressed effects due to momentum conservation and hadronization. On the other hand, the MC results shown above include momentum conservation and hadronization as well as the effects of initial state radiation (ISR) and multiple interaction (MPI). In order to quantify the effect of ISR and MPI, we compare the predictions for P_n with and without ISR and MPI in `Herwig++`, `Pythia8` as well as in `Pythia6` [30] (we use the version `Pythia 6.4.28` with the `AUET2B-CT6L` tune) in figure 3. It is clear from this figure that the impact of ISR and MPI is rather small for our choice of the association radius $R_a = 0.8$, thereby making the predictions stable against such effects. For this choice of R_a, we can see that `Pythia8` shows the highest variation against such effects, followed by `Pythia6`, while the effects are indeed negligible for the case of `Herwig++`.[5] Furthermore, the MC results become closer to the NDLA ones when ISR and MPI effects are switched off.

We also investigated the effects of momentum conservation, by changing the recombination scheme in the anti-k_t jet algorithm from the default E-scheme to the "winner-take-all" scheme introduced in [31], which is less sensitive to recoils in the parton shower [32]. Such a change increases the MC associated jet rates very slightly. We believe this is because the axis of the leading jet is moved away from the overall momentum vector of the system. The effects are roughly proportional for quark and gluon jets, so they would not affect discrimination significantly.

4 Quark-gluon separation: multivariate analysis

4.1 Variables for quark-gluon separation

A large number of variables have been surveyed in the context of quark-gluon discrimination, constructed out of either track based observables or calorimeter based ones [1–5]. While the former category has the practical advantage of being more accurate due to better track momentum resolution as well as being less prone to pile-up contamination, the latter category can be used for jets with larger rapidities outside the tracker coverage. The most widely studied variables include the number of charged tracks inside the jet cone

events with the leading jet $p_T(j_s)$ above the generation threshold are used in the analysis. This ensures uniform MC statistics in the whole range of $p_T(j_s)$.

[5] However, we have checked that if we take a larger association radius, $R_a > 1.2$, the ISR effects become appreciable in `Herwig++`.

JHEP04(2015)131

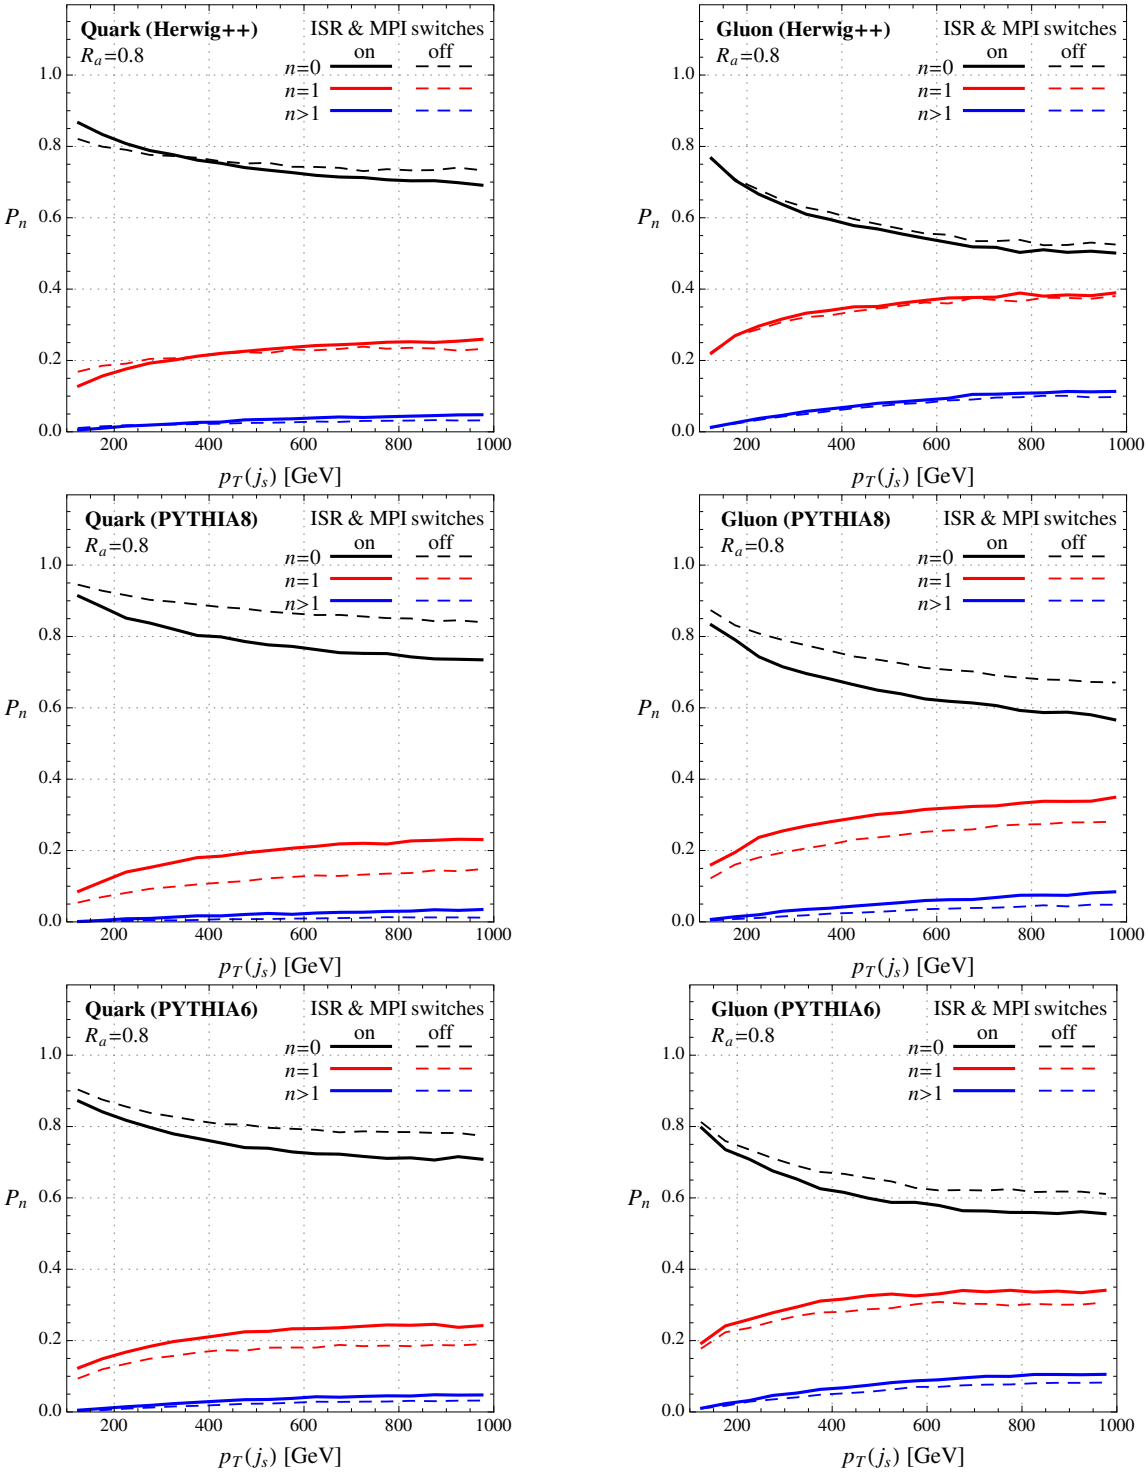

Figure 3. Comparison of the `Herwig++`, `Pythia8` and `Pythia6` predictions for associated jet rates with and without ISR and MPI, as a function of $p_T(j_s)$: for quark jets (left), and gluon jets (right). Here, $p_T(j_s)$ is the vector sum of the leading jet and associated jet p_T's.

JHEP04(2015)131

($n_{\rm ch}$), the jet width [1] and energy-energy-correlation (EEC) angularity [4]. The jet width is defined as

$$w = \frac{\sum_i p_{T,i} \times \Delta R(i,\ \text{jet})}{\sum_i p_{T,i}} \tag{4.1}$$

where the sum goes over all the tracks associated to the jet. A similar track-based EEC variable, denoted by $C_1^{(\beta)}$ can be defined as

$$C_1^{(\beta)} = \frac{\sum_i \sum_j p_{T,i} \times p_{T,j} \times (\Delta R(i,j))^{\beta}}{(\sum_i p_{T,i})^2}. \tag{4.2}$$

Here again the sum over i and j run over all the tracks associated to the jet with $j > i$, while β is a tunable parameter. It has been demonstrated in ref. [3, 4] that smaller values of the exponent β leads to a better quark-gluon separation, and $\beta = 0.2$ is found to be optimal from perturbative calculations and MC studies based on `Herwig++` and `Pythia8` generators. We have compared the performance of the jet width variable w and the EEC variable $C_1^{(\beta=0.2)}$ in the multivariate analyses (MVA) to be discussed below, and find that in all cases $C_1^{(\beta=0.2)}$ leads to a better separation of gluons from quarks. Therefore, in the following, we only show results based on $n_{\rm ch}$ (with each charged track having $p_T > 1\,\text{GeV}$) and $C_1^{(\beta=0.2)}$. In addition, we shall include the associated jet information as well as the jet mass variable and compare the performance of the different MVA methods. As seen in the previous section, for $n = 1$ or $n > 1$, the probability of finding n associated jets, P_n, is significantly larger for gluon jets compared to quark-initiated ones across the whole p_T range of interest. Therefore, the presence (or absence) of an associated jet within a certain distance R_a of a high-p_T jet can be used to further improve the separation.

As the boundary between the signal and background regions in the hyper-surface spanned by the variables is non-linear, it is beneficial to adopt a multivariate analysis strategy as compared to a cut-based one. For this purpose, we employed a Boosted Decision Tree (BDT) algorithm with the help of the `TMVA-Toolkit` [33–35] in the `ROOT` framework. The training of the classifier was performed with $Z + q-$jet and $Z + g-$jet samples, and we generated the above MC samples uniformly distributed in jet-p_T.[6] The input variables for the two variable training are taken to be $n_{\rm ch}$ and $C_1^{(\beta=0.2)}$, while for three-variable trainings we further include the variable $m_J/p_{T,J}$, where m_J is the jet mass and $p_{T,J}$ is the transverse momentum of the leading jet. The information on the number of associated jets is included in the form of two categories ($n = 0$ or $n \geq 1$) in the MVA.

It should be emphasized that the MC prediction of the discrimination variables, especially the number of charged tracks $n_{\rm ch}$ is quite sensitive not only to the parton shower (PS) algorithm adopted and the related parameters, but also to the tuning of the hadronization and underlying event models. This is expected, since $n_{\rm ch}$ is not an infrared safe quantity, and only the ratio $n_{\rm ch}^{\rm gluon}/n_{\rm ch}^{\rm quark}$ converges rather slowly to the ratio of the colour factors C_A/C_F for high jet p_T [36, 37]. The disagreement between different MC's can therefore be reduced only by appropriate tuning at the LHC energies. With this limitation of the MC

[6] The MC event samples for the training of the classifier were generated in the same manner as for the associated jet rate computation in the previous section, but with a smaller step size of 10 GeV for the minimum $p_T(j_s)$ thresholds.

JHEP04(2015)131

predictions in view, in this study, we compare the performance of different MVA methods within the same MC generator to estimate the improvement in adding associated jet related observables. We also show the quark-gluon separation as predicted by the different MC's for comparison. In appendix A we present details of the distributions of the discrimination variables and the differences between the MC predictions for them.

4.2 Performance in MVA

Based on the BDT analysis, we obtain the efficiencies of tagging quark (ϵ_q) and gluon jets (ϵ_g) as a function of the cut on the BDT score. It is more useful to compare the ratio of the tagging efficiencies as a function of ϵ_q, in order to judge the separation power of a "quark-rich signal" from a "gluon-rich" background. In figures 4–6 (left column) we show the ratio of the quark and gluon tagging efficiencies, ϵ_q/ϵ_g as a function of ϵ_q, for $400 < p_T(j_s) < 500\,\text{GeV}$, with the event samples generated with all the three MC codes. Four different MVA methods are shown corresponding to different choices for the discrimination variables:

- **Method-1:** Two variables, n_{ch} and C_1 with $\beta = 0.2$.
- **Method-2:** Two variables, n_{ch} and C_1 with $\beta = 0.2$, with two categories determined in terms the number of associated jets ($n = 0$ or $n \geq 1$).
- **Method-3:** Three variables, n_{ch}, C_1 with $\beta = 0.2$ and $m_J/p_{T,J}$.
- **Method-4:** Three variables, n_{ch}, C_1 with $\beta = 0.2$ and $m_J/p_{T,J}$, with two categories determined in terms the number of associated jets ($n = 0$ or $n \geq 1$).

We can quantify the improvement in quark-gluon separation using ϵ_g(Method-1)/ϵ_g(Method-{2,3,4}) as a function of ϵ_q, as shown in figures 4–6 (right). For example, for an operating point of $\epsilon_q = 0.4$, we can obtain an improvement of around 10%, 15% and 20% using Methods-2,3 and 4 respectively, when compared to Method-1. The differences between the improvement factors obtained using the three MC's are found to be small.

In order to estimate the change in tagger performance as we consider lower p_T jets, we show in figure 7 the same results as in figure 4, but now with $150 < p_T(j_s) < 200\,\text{GeV}$. The improvement on adding associated jet rates is still appreciable, although it is somewhat reduced compared to the higher p_T range. The fluctuations in the ϵ_g ratio for lower values of ϵ_q in figure 7 are due to low MC statistics.

We can see in figures 4–6 that there is an improvement in going from a two variable analysis to a three variable one by including the variable $m_J/p_{T,J}$. This can be understood as follows. The jet mass variable is related to $C_1^{(\beta=2)}$, as can be seen by writing both of them in terms of the z, θ variables for the hardest emission inside the jet cone: $m_J^2 \simeq z(1-z)\theta^2 p_{TJ}^2$. Furthermore, $C_1^{(\beta=2)}$ and $C_1^{(\beta=0.2)}$ are two independent variables belonging to the C_1 class which carry all the information on this hardest emission, and including both of them improves the tagger performance. For this reason, further addition of a third variable in the C_1 class does not change the performance appreciably, a fact that we explicitly checked by a separate MVA analysis. There is a further improvement in the

JHEP04(2015)131

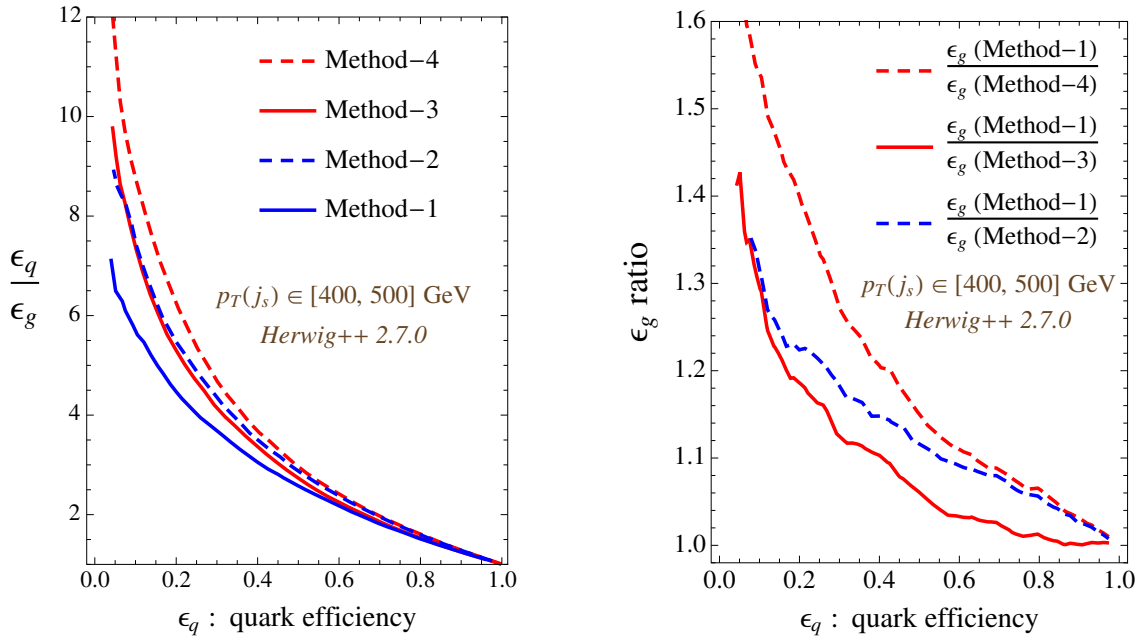

Figure 4. The ratio of the quark and gluon tagging efficiencies, ϵ_q/ϵ_g as a function of ϵ_q, for $400 < p_T(j_s) < 500\,\text{GeV}$, as determined by MC simulations with `Herwig++` (left column). The different MVA methods, determined in terms of the input variables are explained in the text. To quantify the improvement in quark gluon separation as we go to Methods 2,3 and 4, we show ϵ_g(Method-1)/ϵ_g(Method-{2,3,4}) as a function of ϵ_q as well (right column).

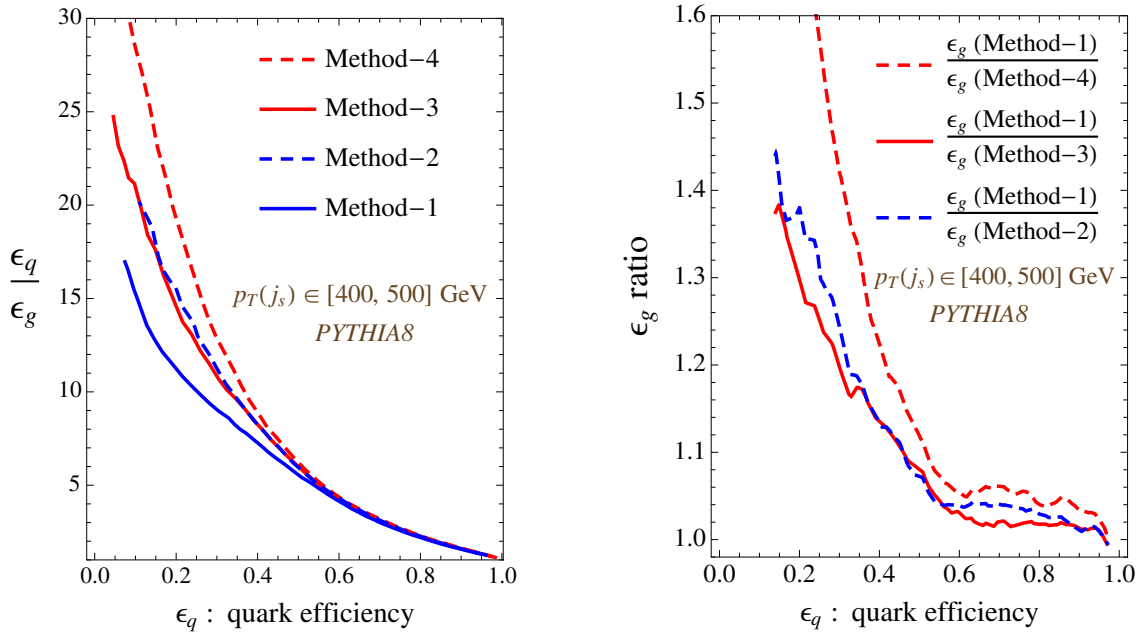

Figure 5. Same as figure 4, with MC simulations using `Pythia8`.

JHEP04(2015)131

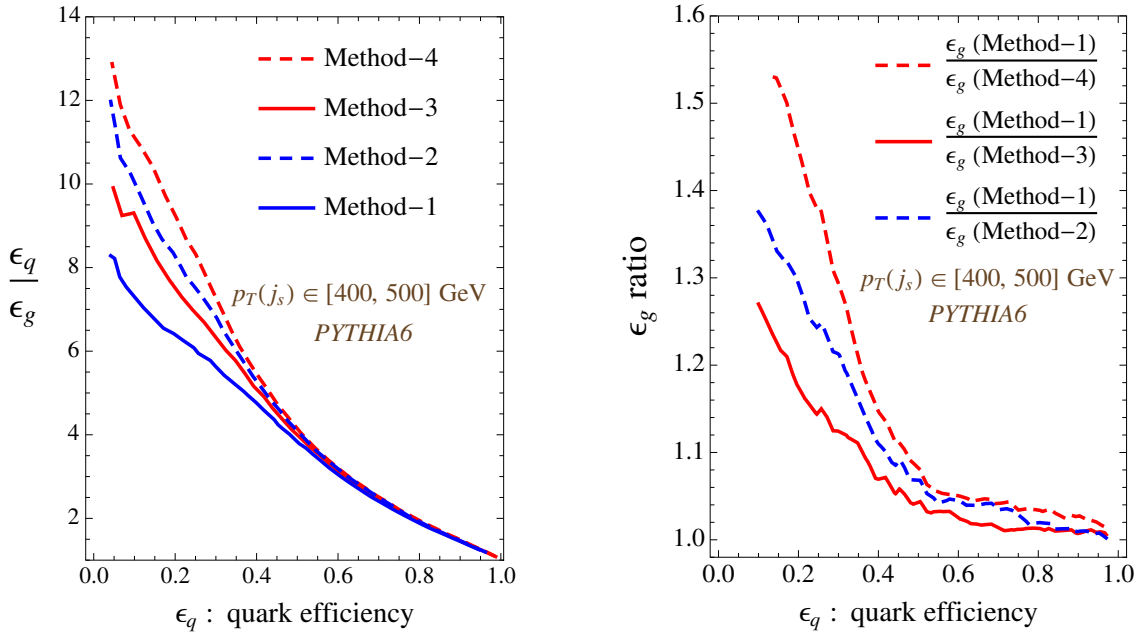

Figure 6. Same as figure 4, with MC simulations using `Pythia6`.

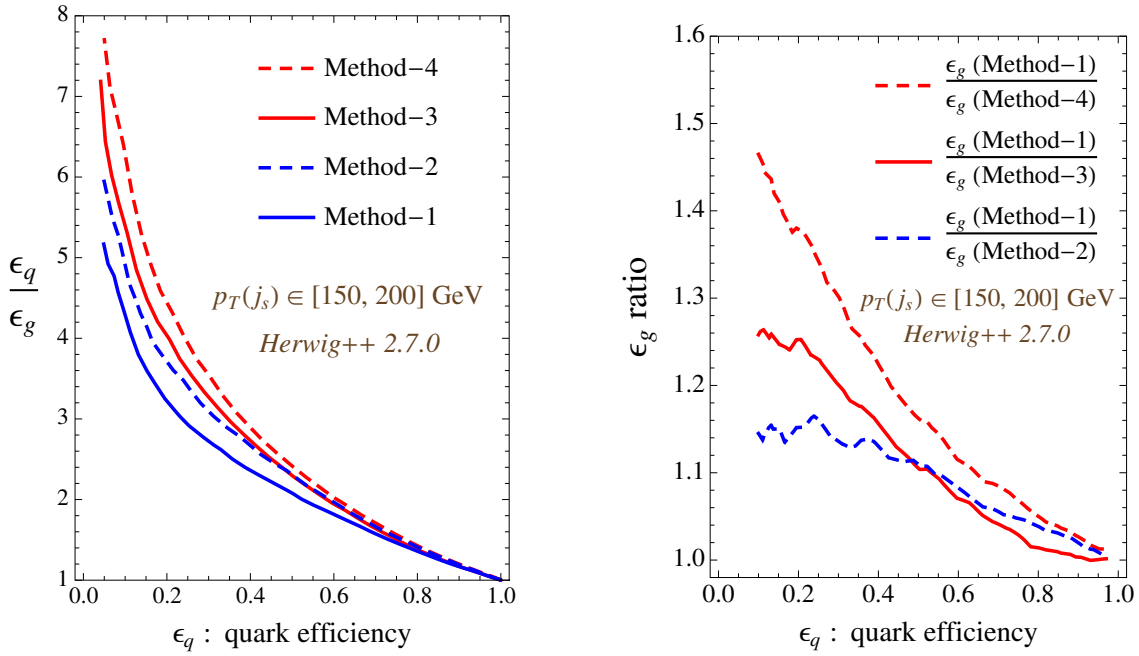

Figure 7. Same as figure 4, for a lower range of jet p_T, $150 < p_T(j_s) < 200\,\text{GeV}$. Results using only `Herwig++` are shown.

quark-gluon separation when the number of associated jets information is included at the level of categories in both the two and three variable MVA analyses. Since the associated jet rates carry the additional information of radiation outside the jet cone, Methods 2 and 4 lead to further improvements as compared to Methods 1 and 3, respectively.

JHEP04(2015)131

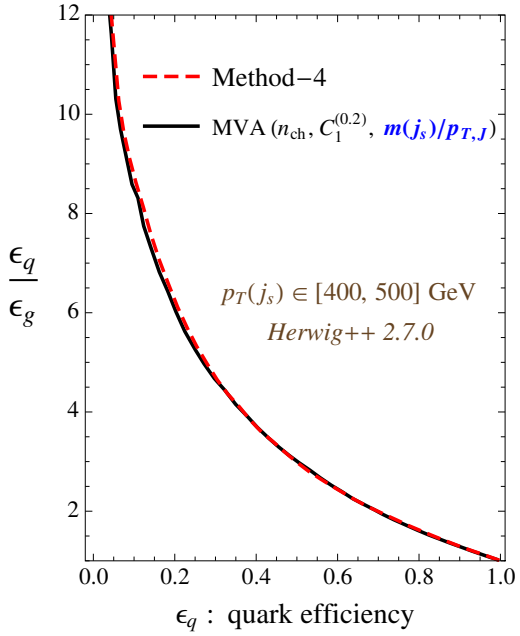

Figure 8. Comparison of Method 4 which includes $m_J/p_{T,J}$ and the associated jet rates as categories in the MVA, and the alternative method of including the associated jet rate information by using the modified jet mass variable $m(j_s)/p_{T,J}$. Both methods lead to the same MVA performance.

Method 4 leads to the best performance out of the four different MVA's considered. In fact, we find that there is an alternative way to include the associated jet rates information in Method 4 by using the modified jet mass variable $m(j_s)/p_{T,J}$ in Method 3. Here, $m(j_s)$ is the jet mass computed by adding the leading jet and associated jet four momenta. Because of a larger associated jet rate, for the same $p_T(j_s)$, $m(j_s)$ is higher for a gluon jet compared to a quark, while $p_{T,J}$ is lower. Therefore, using either associated jet rate categories and $m_J/p_{T,J}$, or using only the variable $m(j_s)/p_{T,J}$ leads to the same MVA performance, as shown in figure 8.

5 Subjet rates in jets: analytical calculations

The number of charged tracks inside a jet cone, $n_{\rm ch}$ (with each track having transverse momentum above a threshold, usually taken to be around 1 GeV) is often used as a good discriminating variable. However, as mentioned earlier, the MC predictions for this observable are quite sensitive not only to the parton shower (PS) algorithm and the related parameters, but also to the tuning of the hadronization and underlying event models. On the other hand, we find that the number of subjets of a primary jet leads to a more uniform prediction across the MC's, and thus can be better suited in quark gluon separation studies. The number of subjets as a quark-gluon separation variable was considered earlier in ref. [1]. In this study, we compute the subjet rates to NDLA accuracy, and show a detailed comparison with different MC's.

JHEP04(2015)131

We find the *subjets* of jet j with the *exclusive k_t algorithm*, which applies the dimensionless distance measure

$$y_{ik} = \min\{p_{ti}^2, p_{tk}^2\} \frac{\Delta R_{ik}^2}{R^2 p_j^2} \,, \tag{5.1}$$

to its constituent objects and clusters them as discussed for a generalized k_t algorithm in section 2, until the smallest y_{ik} is above $y_{\rm cut}$. Thus the subjet rates are functions of the jet $p_t = p_j$, the jet radius R, and $y_{\rm cut}$.

In this section, we compute the subjet rates to NDLA, i.e. considering double and next-to-double logarithms, $\alpha_{\rm S}^n L^{2n}$ and $\alpha_{\rm S}^n L^{2n-1}$, where now $L = \ln(1/y_{\rm cut})$. The relevant generating functions in this case are those given in refs. [10, 21]:

$$\phi_q(u,Q) = u\,\Delta_q(Q) \exp\left(\int_{Q_0}^{Q} dq\,\Gamma_q(Q,q)\phi_g(u,q)\right) \,, \tag{5.2}$$

$$\phi_g(u,Q) = u\,\Delta_g(Q) \exp\left(\int_{Q_0}^{Q} dq \left[\Gamma_g(Q,q)\phi_g(u,q) + \Gamma_f(q)\frac{\phi_q(u,q)^2}{\phi_g(u,q)}\right]\right) \tag{5.3}$$

where $Q = R\,p_j$ is the jet scale, $Q_0 = R\,p_j\sqrt{y}_{\rm cut}$ is the resolution scale,[7]

$$\Gamma_q(Q,q) = \frac{2C_F}{\pi}\frac{\alpha_{\rm S}(q^2)}{q}\left(\ln\frac{Q}{q} - \frac{3}{4} + \frac{q}{Q} - \frac{1}{4}\frac{q^2}{Q^2}\right) \,, \tag{5.4}$$

$$\Gamma_g(Q,q) = \frac{2C_A}{\pi}\frac{\alpha_{\rm S}(q^2)}{q}\left(\ln\frac{Q}{q} - \frac{11}{12} + \frac{q}{Q} - \frac{1}{4}\frac{q^2}{Q^2} + \frac{1}{6}\frac{q^3}{Q^3}\right) \,, \tag{5.5}$$

$$\Gamma_f(q) = \frac{n_f}{3\pi}\frac{\alpha_{\rm S}(q^2)}{q}\left(1 - \frac{3}{2}\frac{Q_0}{q} + \frac{3}{2}\frac{Q_0^2}{q^2} - \frac{Q_0^3}{q^3}\right) \,. \tag{5.6}$$

The Sudakov factors for no resolvable emission are now

$$\Delta_q(Q) = \exp\left(-\int_{Q_0}^{Q} dq\,\Gamma_q(Q,q)\right) \,, \tag{5.7}$$

$$\Delta_q(Q) = \exp\left(-\int_{Q_0}^{Q} dq\,[\Gamma_g(Q,q) + \Gamma_f(q)]\right) \,. \tag{5.8}$$

Hence the rates for 1, 2 or 3 subjets in a quark jet are:

$$\begin{aligned}
R_1^q &= \Delta_q(Q)\,, \\
R_2^q &= \Delta_q(Q)\int_{Q_0}^{Q} dq\,\Gamma_q(Q,q)\Delta_g(q)\,, \\
R_3^q &= \Delta_q(Q)\int_{Q_0}^{Q} dq \int_{Q_0}^{q} dq'\,\Gamma_q(Q,q)\Delta_g(q) \times \\
&\quad \left\{\left[\Gamma_q(Q,q') + \Gamma_g(q,q')\right]\Delta_g(q') + \Gamma_f(q')\Delta_f(q')\right\} \,,
\end{aligned} \tag{5.9}$$

[7] Here again we keep power-suppressed corrections in order to satisfy boundary conditions.

JHEP04(2015)131

where $\Delta_f = \Delta_q^2/\Delta_g$, and for a gluon jet we have

$$
\begin{aligned}
R_1^g &= \Delta_g(Q)\,, \\
R_2^g &= \Delta_g(Q) \int_{Q_0}^{Q} dq \left[\Gamma_g(Q,q)\Delta_g(q) + \Gamma_f(q)\Delta_f(q)\right]\,, \\
R_3^g &= \Delta_g(Q) \int_{Q_0}^{Q} dq \int_{Q_0}^{q} dq' \Big[\Gamma_g(Q,q)\Delta_g(q) \times \\
&\quad \left\{\left[\Gamma_g(Q,q') + \Gamma_g(q,q')\right]\Delta_g(q') + \Gamma_f(q')\Delta_f(q')\right\} + \Gamma_f(q)\Delta_f(q) \times \\
&\quad \left\{\left[\Gamma_g(Q,q') - \Gamma_g(q,q')\right]\Delta_g(q') + 2\Gamma_q(q,q')\Delta_q(q')\right\}\Big]\,.
\end{aligned}
\tag{5.10}
$$

6 Subjet rates in jets: comparison with Monte Carlo

We now compare the above results with Monte Carlo predictions. MC samples of quark and gluon jets were prepared for the subjet analysis using the same setup as in the associated jet study in section 2, however, detector effects and minimum p_T cuts for the charged and neutral hadrons were not included for this analysis. In this sense, our study of the subjet rates should be taken as illustrative, and we do not include the subjet rates in an MVA analysis in this paper. As we shall see in the following, one needs to go down to at least $L = 4$ to have some discrimination power. This corresponds to going down to 0.1 for ΔR resolution, which is the typical size of calorimeter cells, although the ΔR separation of subjets would be larger when the subjet p_T is smaller compared to the primary jet p_T. Therefore, in a proper analysis, combining track and calorimeter information is essential, and a detailed experimental study is necessary, which is beyond the scope of this paper.

Figure 9 shows comparisons between the resummed results of eqs. (5.9), (5.10) and the MC results for jets with $p_{T,J} \in [500, 600]\,\text{GeV}$ and $R = 0.4$. For quark jets the different MC's agree quite well with each other and with the resummed calculations, the MC predictions being somewhat below the resummed 1-subjet rate for $L > 4$, and vice-versa for 2 subjets. Hadronization effects are small for $L < 7$, after which the 1- and 2-subjet rates are suppressed and the higher subjet rates are therefore enhanced. At this value of $R\,p_{Tj}$, $L = 7$ corresponds to resolving subjets with $\min\{p_{ti}, p_{tj}\}\Delta R_{ij} \sim 6\,\text{GeV}$.

For gluon jets the agreement between the resummed results and the Monte Carlos is still quite close for 1 subjet. For 2 and 3 subjets the peak rates are in roughly the same place but have higher values than the resummed ones, with the effect that the rate for 4 or more subjets is substantially suppressed. Once again the hadronization effects are small for $L < 7$, after which the 1- and 2-subjet rates are suppressed and the higher subjet rates are enhanced, actually bringing the latter into close agreement with the analytical calculations.

In conclusion, the fairly good agreement between the Monte Carlos and the resummed 1-, 2- and 3-subjet rates for $R = 0.4$ and L not too large ($L < 5$, subjet resolution above about 15 GeV) suggests that in this range those subjet rates can be used for quark-gluon discrimination. At larger jet radii, the agreement remains similar, as we have checked using $R = 0.8$.

JHEP04(2015)131

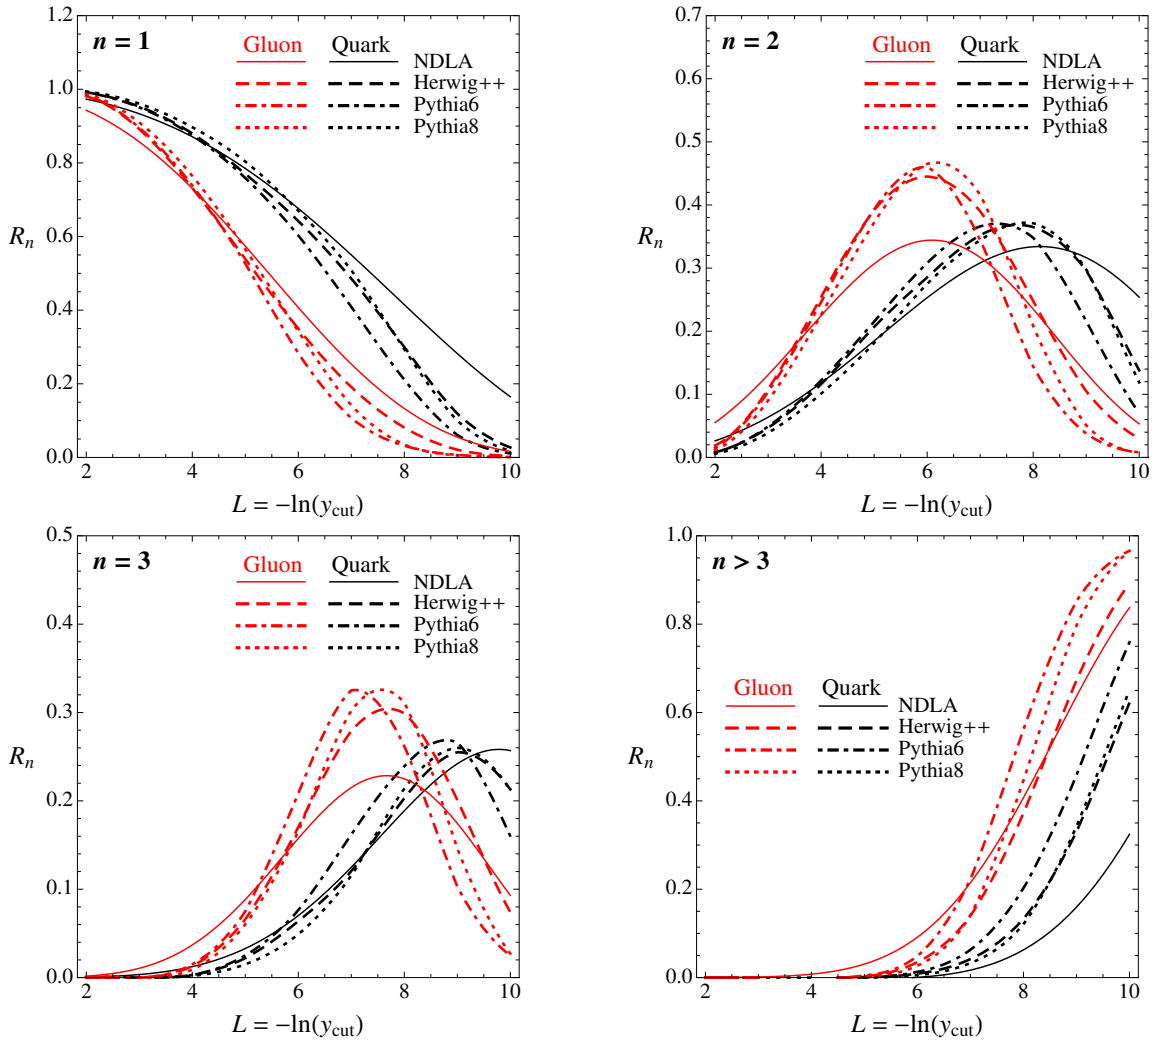

Figure 9. Subjet rates R_n with $n = 1, 2, 3$ and $n > 3$ as a function of $L = -\ln(y_{\rm cut})$, for quark jets (black) and gluon jets (red), with $p_{T,J} \in [500, 600]\,\text{GeV}$, $R = 0.4$. Curves are `Herwig++` (dashed), `Pythia6` (dot-dashed), `Pythia8` (dotted) and NDLA resummed (solid).

7 Summary

To summarize our findings, we show that in studies of light quark and gluon jet separation at the LHC, it is important to include the information on associated jet rates around a primary hard jet. Associated jet rates are defined as the probability of finding at least one softer reconstructed jet around the primary hard jet under consideration. This probability is found to be substantially higher for a gluon-initiated jet compared to a quark-initiated one. Since commonly a small jet radius parameter is adopted in LHC studies of hadronic jets, the associated jet rates carry the information on the radiation outside the chosen jet radius.

We compute the associated jet rates up to NDLA accuracy in perturbative QCD, as a function of the primary jet and minimum associated jet p_T's, as well as the jet radius and

JHEP04(2015)131

association radius parameters. The NDLA results are thereafter compared with predictions from different parton shower MC's. Since the NDLA predictions include only the time-like showering of the final state partons, we demonstrate the effects of ISR and MPI in the MC predictions as well, and it is observed that the NDLA predictions are closer to the MC's when ISR and MPI are switched off. Overall, the associated jet rates are not very sensitive to these effects as long as the association radius is not too large.

The probability of having at least one associated jet for a primary gluon jet is roughly a factor of two larger than for a quark jet, with a small variation in this number as a function of the jet p_T. This fact makes the presence or absence of associated jets a good variable for quark-gluon discrimination studies. We demonstrate the impact of including the associated jet rate information by including this variable in an MVA analysis, along with the well-studied variables of number of charged tracks, energy-energy-correlation angularities and jet mass. Comparing different two and three variable MVA's with and without the associated jet information, we find that including the associated jets leads to an improvement of around 10% in rejecting gluons, for a fixed quark selection efficiency of 0.4. We also show that using a three variable MVA with associated jet categories leads to the best performance, with an improvement of 20% in rejecting gluons, for the same quark efficiency as above.

Since for the number of charged tracks variable the MC predictions tend to differ, and are dependent on the parton shower and underlying event parameter tunes, we explore the number of k_t subjets of an anti-k_t jet as a quark-gluon separation variable. We compute the number of subjets to NDLA accuracy, and compare the resummed predictions with different MC's. The different MC predictions are found to be rather uniform, with the resummed predictions being broadly in agreement with them. However, for gluon jets the peak rates for 2 and 3 subjets are found to be lower in the resummed computation, which might arise due to higher-order effects that are in general bigger for gluons.

A Distributions of discrimination variables

In figures 10–12 we show 2-dimensional plots of the joint distributions of the three discrimination variables used in the MVA presented in section 4, for the two Monte Carlo event generators `Herwig++` and `Pythia8`. The following features may be observed:

JHEP04(2015)131

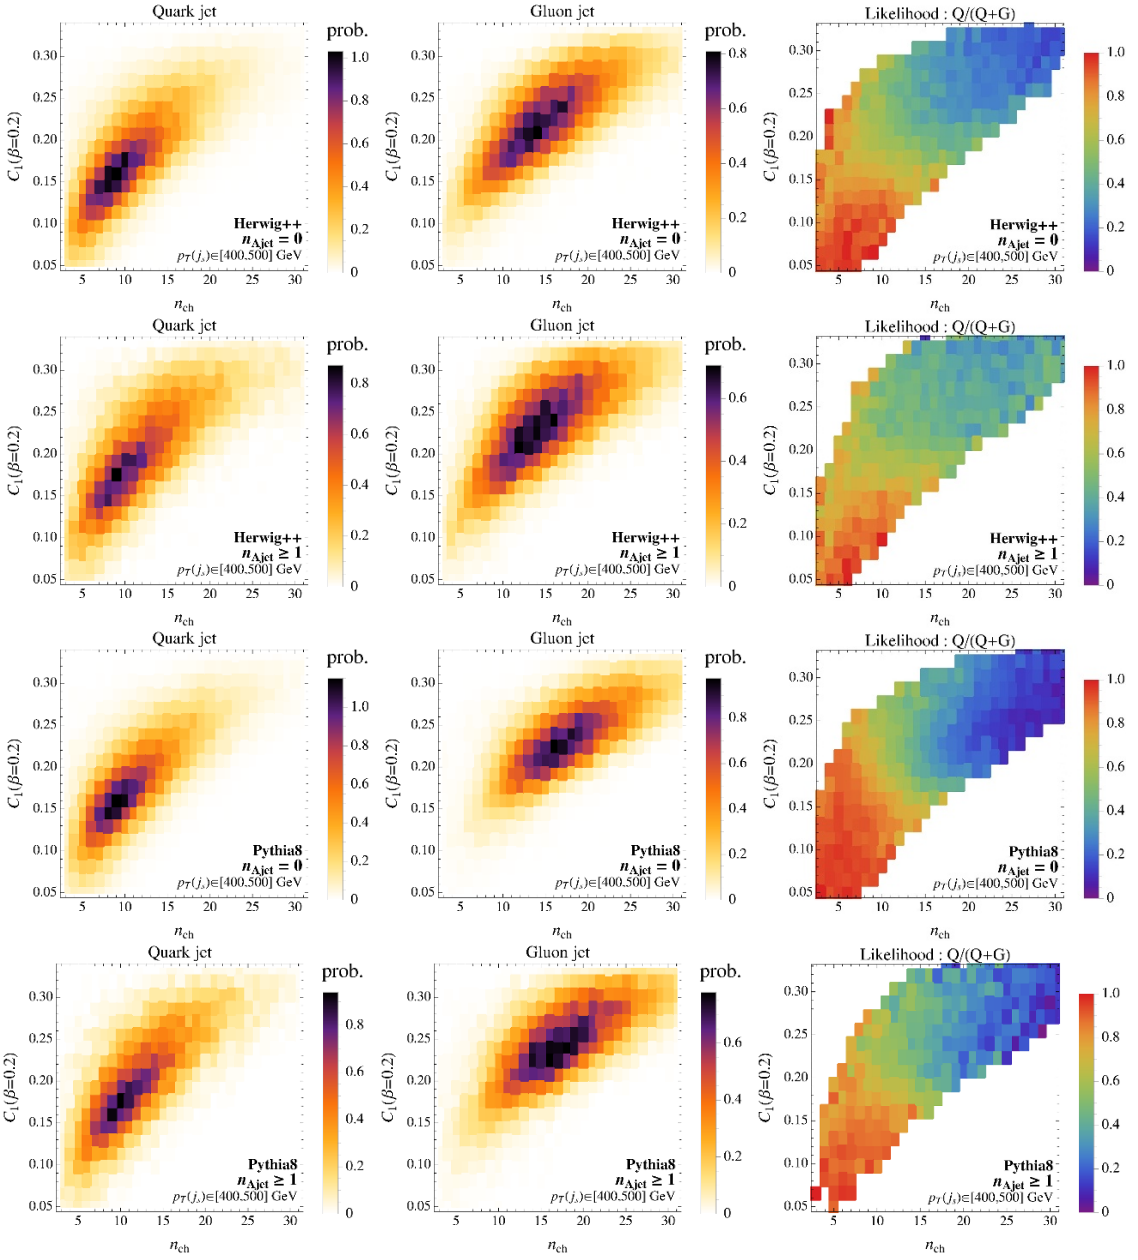

Figure 10. Joint distributions of n_{ch} and $C_1^{(\beta=0.2)}$ in `Herwig++` and `Pythia8`, for quark and gluon jets with $p_T(j_s) \in [400, 500]$ GeV having $n_{\text{Ajet}} = 0$ and ≥ 1 associated jets.

- There are differences between the distributions predicted by the two Monte Carlos, those of `Pythia8` being somewhat narrower for quark jets and substantially narrower for gluon jets.

- The distributions of the infrared-unsafe variable n_{ch} show the greatest differences, with those of `Pythia8` being larger at high n_{ch}. This could be due to differences in tuning of the non-perturbative parameters of the generators.

JHEP04(2015)131

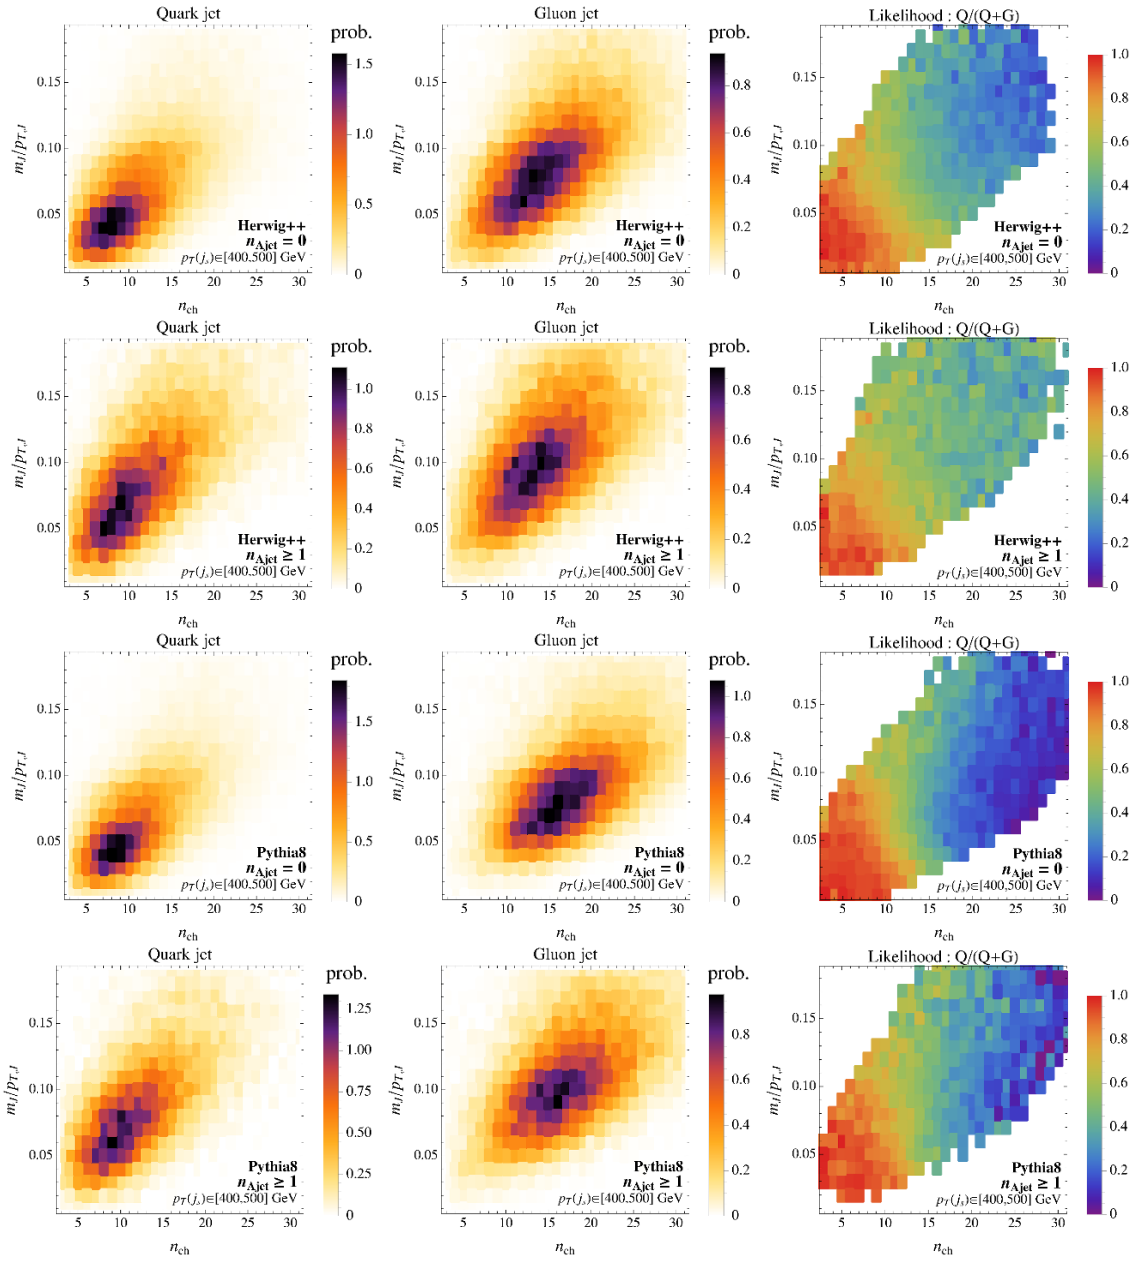

Figure 11. Joint distributions of $n_{\rm ch}$ and $m_J/p_{T,J}$ in `Herwig++` and `Pythia8`, for quark and gluon jets with $p_T(j_s) \in [400, 500]$ GeV having $n_{\rm Ajet} = 0$ and ≥ 1 associated jets.

- The above features are reflected in the likelihood plots, showing the probability ratio $P_q/(P_q + P_g)$, and account for the higher discrimination efficiency predicted by `Pythia8` (figure 5 vs figure 4).

- The quark-gluon discrimination in the events with associated jets is weaker than that for $n_{\rm Ajet} = 0$. This is expected because the events are selected according to $p_T(j_s)$, the sum of leading and associated jet p_T's. Therefore those with associated jets have leading jets with lower p_T's, which have lower discriminating power.

JHEP04(2015)131

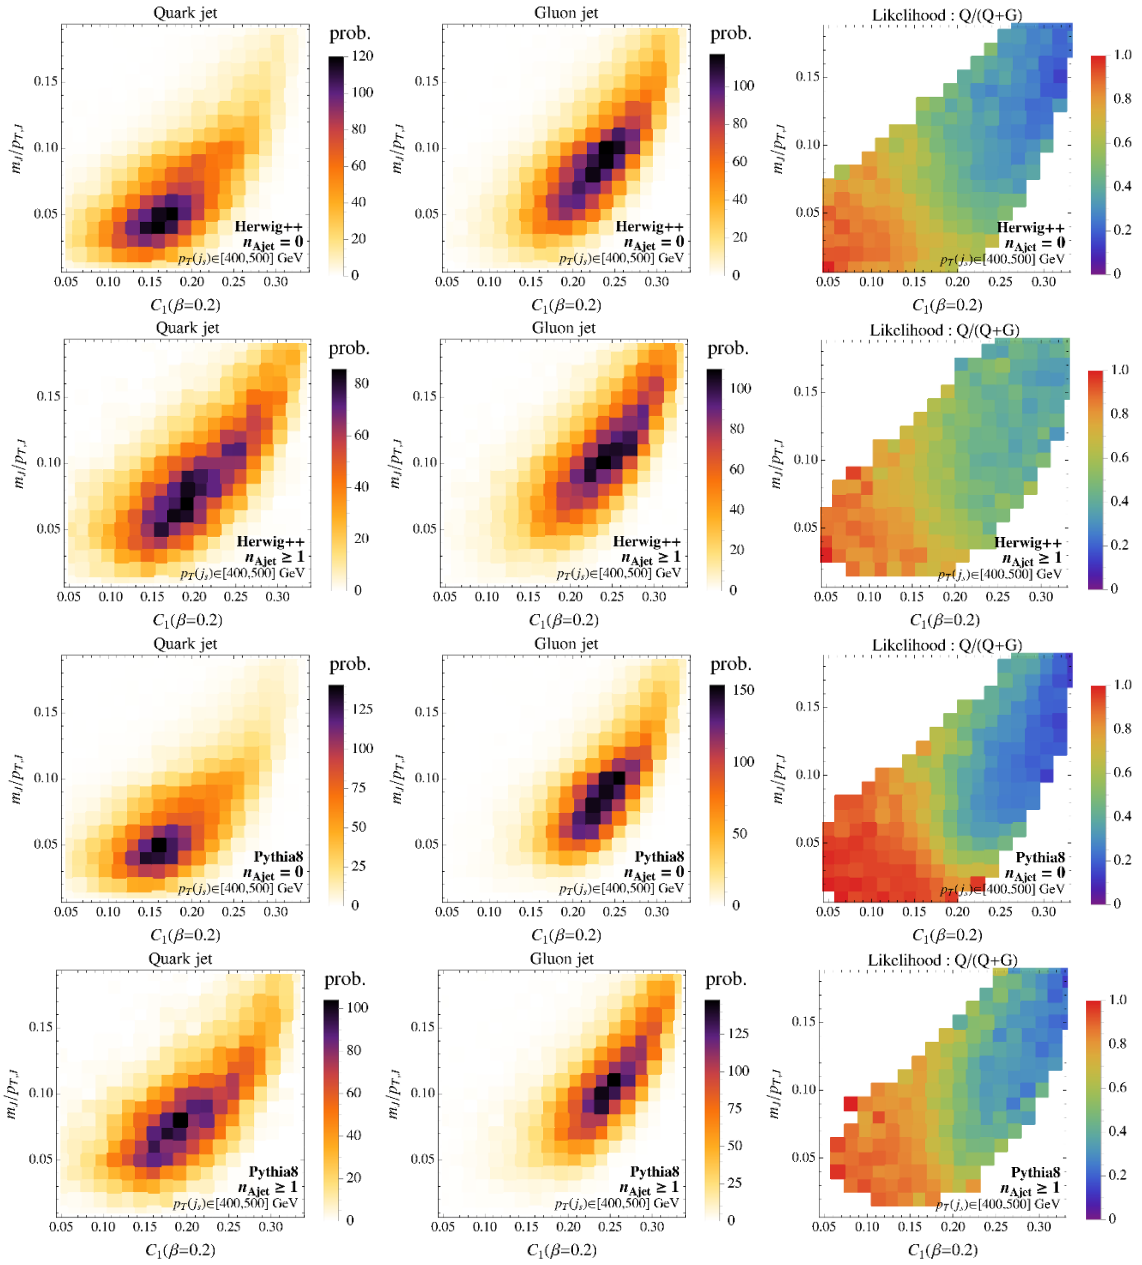

Figure 12. Joint distributions of $C_1^{(\beta=0.2)}$ and $m_J/p_{T,J}$ in `Herwig++` and `Pythia8`, for quark and gluon jets with $p_T(j_s) \in [400, 500]$ GeV having $n_{\text{Ajet}} = 0$ and ≥ 1 associated jets.

- Nevertheless the inclusion of the associated jet category improves the MVA performance, because the probability of an associated jet is lower for quark jets.

Fingerprinting nonminimal Higgs sectors

(Received 12 June 2014; published 1 October 2014)

After the discovery of the standard model-like Higgs boson at the LHC, the structure of the Higgs sector remains unknown. We discuss how it can be determined by the combination of direct and indirect searches for additional Higgs bosons at future collider experiments. First of all, we evaluate expected excluded regions for the mass of additional neutral Higgs bosons from direct searches at the LHC with the 14 TeV collision energy in the two Higgs doublet models with a softly broken Z_2 symmetry. Second, precision measurements of the Higgs boson couplings at future experiments can be used for the indirect search of extended Higgs sectors if the measured coupling constant with the gauge boson slightly deviates from the standard model value. In particular, in the two Higgs doublet model with the softly broken discrete symmetry, there are four types of Yukawa interactions, so that they can be discriminated by measuring the pattern of deviations in Yukawa coupling constants. Furthermore, we can fingerprint various extended Higgs sectors with future precision data by detecting the pattern of deviations in the coupling constants of the standard model-like Higgs boson. We demonstrate how the pattern of deviations can be different among various Higgs sectors that predict the electroweak rho parameter to be unity, such as models with additional an isospin singlet, a doublet, triplets, or a septet. We conclude that, as long as the gauge coupling constant of the Higgs boson slightly differs from the standard model prediction but is enough to be detected at the LHC and its high-luminosity run or at the International Linear Collider, we can identify the nonminimal Higgs sector even without direct discovery of additional Higgs bosons at the LHC.

DOI: 10.1103/PhysRevD.90.075001 PACS numbers: 12.60.Fr

I. INTRODUCTION

The new particle discovered at the LHC in 2012 was identified as a Higgs boson [1]. With the current LHC data, its measured properties are consistent with those of the Higgs boson in the standard model (SM) [2–4]. On the other hand, so far, no evidence for new physics beyond the SM has been found directly at the LHC. Therefore, our standard picture for high-energy particle phenomena, which is based on the gauge theory with spontaneous symmetry breaking, seems successful.

However, it has been well known that the Higgs sector in the SM is problematic from the theoretical viewpoint. First of all, the existence of the scalar boson causes the hierarchy problem [5–7] so that many physicists try to understand the essence of the Higgs boson, e.g., elementary or composite particle. To solve the hierarchy problem, several scenarios for the new paradigm have been introduced such as supersymmetry, dynamical symmetry breaking, and extra dimensions. Each of them gives a different answer for the question of the essence of the Higgs boson. Second, there is no principle for the structure of the Higgs sector so that the minimal Higgs sector adopted in the SM is just an assumption. There are many possibilities of nonminimal Higgs sectors with additional scalar fields such as singlets, doublets, and triplets. A model based on the above-discussed paradigms can predict the specific structure and property of the Higgs sector. For example, the minimal supersymmetric SM (MSSM) predicts the Higgs sector with two isospin doublet scalar fields [8,9]. In addition, nonminimal Higgs sectors can also be introduced in new physics models to explain the origin of neutrino masses, the existence of dark matter and baryon asymmetry of the Universe, etc., which cannot be explained in the SM. Each new physics model predicts a characteristic structure for the Higgs sector. Therefore, if the Higgs sector is determined by experiments in the future, the new physics scenario can be selected from many candidates.

To probe the extended Higgs sectors, the simplest way is to directly search for additional Higgs bosons such as the second scalar boson. By measuring its properties, e.g., the mass, the electric charge, the spin, and the parity, important information to reconstruct the Higgs sector can be extracted. Nonobservation of the second Higgs boson gives the experimental constraint on the parameter space

in the Higgs sector. Current bounds from searches for additional Higgs bosons at the LHC with the collision energy of 7 and 8 TeV can be found in Refs. [4,10–19].

In addition to the direct search results, precision measurements of various low-energy observables can be an indirect search for extended Higgs sectors, since the existence of additional Higgs multiplets can affect them. The electroweak rho parameter defined in terms of the masses of the W boson m_W and the Z boson m_Z, and the weak mixing angle θ_W by

$$\rho = \frac{m_W^2}{m_Z^2 \cos^2\theta_W}, \tag{1}$$

is one of the most important tools to constrain the structure of the Higgs sector, for which the experimental value is very close to unity; i.e., $\rho_{\rm exp} = 1.0004^{+0.0003}_{-0.0004}$ [20]. In the SM, the rho parameter is predicted to be unity at the tree level. In general, in extended Higgs sectors, predicted values for the rho parameter can deviate from unity. In the Higgs sector with an arbitrary number of scalar fields ϕ_i (a hypercharge Y_i and an isospin T_i) with vacuum expectation values (VEVs) v_i, the rho parameter is calculated at the tree level by [9]

$$\rho_{\rm tree} = \frac{\sum_i [T_i(T_i+1) - Y_i^2] v_i^2}{2\sum_i Y_i^2 v_i^2}. \tag{2}$$

From Eq. (2), an additional VEV of a Higgs field satisfying $T_i(T_i+1) - 3Y_i^2 = 0$ does not change the value of the rho parameter from the SM.[1] A VEV of a Higgs multiplet without satisfying the above equation, e.g., a triplet Higgs field, deviates $\rho_{\rm tree}$ from unity so that we need fine-tuning for such a VEV to avoid the constraint from $\rho_{\rm exp}$. However, even if the above equation is not satisfied, by allowing an alignment among VEVs, we can keep $\rho_{\rm tree} = 1$. The simplest realization is known as the Georgi-Machacek (GM) model [22] for which the Higgs sector is composed of additional real and complex triplet fields with $Y_i = 0$ and $Y_i = 1$, respectively.

The above discussion is very useful to discriminate extended Higgs sectors. However, the rho parameter has been measured quite precisely so that we need to take into account quantum effects to the rho parameter. Let us discuss how the rho parameter is modified at the one-loop level. The deviation of the rho parameter from unity measures the violation of the custodial $SU(2)_V$ symmetry [5,7,23] in the sector of particles in the loop.[2] For example, in the Yukawa Lagrangian, the custodial symmetry is broken by the mass splitting between the top and bottom quarks. As a result, the deviation of the rho parameter from unity $\Delta\rho \equiv \rho - 1$ due to the loop contribution of the top and bottom quarks takes a form of $\Delta\rho \propto (m_t - m_b)^2$. In fact, since $m_t \gg m_b$, there remains m_t^2 dependence in $\Delta\rho$. On the other hand, the Higgs potential in the SM respects the custodial symmetry so that the Higgs boson loop contribution is at most the logarithmic dependence of the Higgs boson mass through the hypercharge gauge interaction. However, in general, the custodial symmetry is broken in extended Higgs sectors. For example, in two Higgs doublet models (THDMs), the mass splitting between singly charged Higgs bosons and a CP-odd Higgs boson gives a quadratic mass dependence similarly to the top and bottom quark contributions in $\Delta\rho$ [29–33]. Therefore, a sizable amount of the mass difference has already been excluded [34,35]. In the above way, we can take bounds on various physical parameters by comparing precisely measured observables with theory predictions with radiative corrections.

Experimental data for flavor changing neutral current (FCNC) processes such as $K_L^0 \to \mu^+\mu^-$ and the B^0-$\bar{B}^0$ mixing strongly constrain extended Higgs sectors with multidoublet structures. The way to avoid such dangerous FCNC processes at the tree level is to assign a different quantum number for each Higgs doublet. Consequently, each quark or lepton can obtain its mass from only one Higgs doublet just like in the SM, and therefore the model escapes FCNC processes at the tree level. In the THDM, for example, this can be achieved by imposing a discrete Z_2 symmetry, which can be softly broken in the potential, to the model [36] as the simplest way. There are four independent types of Yukawa interactions under the Z_2 symmetry [37–39], which are called type-I, type-II, type-X, and type-Y [40].[3,4]

[1] Although there is an infinite number of solutions for the above equation, larger isospin representation fields cause violation of perturbative unitarity [21]. Therefore, only the three possibilities can be substantially considered, i.e., isospin singlets with $Y_i = 0$, doublets with $Y_i = 1/2$, and septets with $Y_i = 2$. The next possibility to the septet representation is isospin 26-plet with $Y_i = 15/2$.

[2] In models with $\rho_{\rm tree} \neq 1$, we need a different prescription for the calculation of the radiative corrections to the rho parameter from that in models with $\rho_{\rm tree} = 1$, because of an additional input parameter in the electroweak sector. In the Higgs sector with a real triplet Higgs field with $Y = 0$, one-loop corrections to the rho parameter have been calculated in Refs. [24,25]. That has been applied to the Higgs sector with a complex triplet Higgs field with $Y = 1$ in Refs. [26,27]. In the GM model, although $\rho_{\rm tree} = 1$ can be satisfied, a similar prescription in models with $\rho_{\rm tree} \neq 1$ is necessary due to the VEV alignment [28].

[3] The type-X (type-Y) THDM is referred to as the type-IV (type-III) THDM in Ref. [37], type-I' (type-II') THDM in Refs. [38,39], and the lepton-specific (flipped) THDM in Refs. [41–43]. Because the term "type-III" is sometimes used for the THDM with tree-level FCNCs [44], we adopt the terms "type-X" and "type-Y" to avoid confusion.

[4] If we introduce right-handed neutrinos, four more types of Yukawa interactions can be defined. In particular, if one of the two doublets gives Dirac neutrino masses, and another one gives masses of all the other fermions, it is known as the neutrinophilic THDM [45].

How can we explore extended Higgs sectors? It is important to understand that, in general, a new scale M is introduced in extended Higgs sectors, which is irrelevant to the VEV of the Higgs boson. When M is much larger than the TeV scale, the mass of the second Higgs boson is approximately given by M. In this case, the second Higgs boson is too heavy to be discovered directly at the LHC. In addition, the indirect effect of new particles decouples from the low-energy observables [46] such as the coupling constants of the discovered Higgs boson. However, if M is as high as the TeV scale, there can be two possibilities in searches for additional Higgs bosons. The first possibility is that the second Higgs boson can be discovered directly at the LHC. In this case, the properties can be directly measured at the LHC, and the useful information to determine the structure of the Higgs sector can also be obtained at the High Luminosity (HL)-LHC [47–49]. The second possibility is that it cannot be discovered directly, but its indirect effect on the Higgs couplings can be significant and thus detectable by precision measurements at the HL-LHC and at the International Linear Collider (ILC) [50]. It goes without saying that, in order to realize the second possibility, a small but detectable mixing between the SM-like Higgs boson and an additional Higgs boson is required. In this case, in addition to obtaining information on the mass of the second Higgs boson, the structure of the Higgs sector could be determined without the direct discovery by finding the pattern in deviations in various Higgs boson couplings [51,52]. On the other hand, if M stays at the electroweak scale, a large mixing between the SM-like Higgs boson and an additional Higgs boson can occur, and the Higgs boson couplings can deviate significantly from the SM values. If the last scenario is realized, both the direct search and the indirect search are possible to determine the Higgs sector. The direct search for additional Higgs bosons in THDMs at the LHC was discussed in Refs. [53–58] after the discovery of the Higgs boson. The complementarity of additional Higgs boson searches at the LHC and at the ILC was recently discussed in Ref. [59].

In this paper, we discuss how the structure of the Higgs sector can be determined at the LHC and at the ILC. In particular, we shed light on complementarity of direct searches of additional Higgs bosons at the upcoming 13 TeV or 14 TeV run of the LHC and precision measurements of the coupling constants of the discovered Higgs boson at future collider experiments. We consider extended Higgs sectors that satisfy $\rho_{\text{tree}} = 1$ without predicting FCNCs at the tree level, i.e., the THDM with the softly broken Z_2 symmetry, the doublet-singlet model [60], the GM model [22], and the doublet-septet model [61–63]. For the THDM, we discuss the four types of Yukawa interaction. We at first give a detailed explanation for properties in the THDMs such as the decay branching ratio, perturbative unitarity, and vacuum stability. We then analyze the direct search for additional neutral Higgs bosons at the LHC. The expected excluded regions on the mass of extra neutral Higgs bosons are shown assuming the 14 TeV energy at the LHC.[5] Next, as the indirect search, we show various patterns of deviations in the gauge interaction hVV and the Yukawa interactions $hf\bar{f}$ of the SM-like Higgs boson h from the SM predictions. We show the deviation in the $hf\bar{f}$ couplings in the THDMs. For the rest models, we also show those in the $hf\bar{f}$ and hVV couplings, where these models predict universal modifications for the $hf\bar{f}$ couplings. We use the latest results of allowed values of the Higgs boson couplings that have been obtained from the global fit to all Higgs data [64] in order to compare the various prediction of deviations in the Higgs boson couplings.[6]

This paper is organized as follows. In Sec. II, we define the Higgs potential and Yukawa Lagrangian in the THDM with the softly broken Z_2 symmetry. After we derive the Yukawa couplings in the four types, we discuss the decay branching ratios of the Higgs bosons. The bounds from unitarity and vacuum stability are also discussed. In Sec. III, we study the direct search for the additional Higgs bosons at the LHC. In Sec. IV, we present expected accuracy of the precise measurement of the Higgs boson couplings at the ILC, and then we discuss how the deviation in the SM-like Higgs boson couplings are calculated in the THDMs and models with universal Yukawa couplings. Complementarity between the direct search and the indirect search at the LHC and at the ILC is discussed in Sec. IV. The conclusion is summarized in Sec. V.

II. TWO HIGGS DOUBLET MODEL

A. Lagrangian

The Higgs potential of the THDM under the softly broken Z_2 symmetry to avoid FCNC at the tree level and the CP invariance is given by [9,43,65,66]

$$\begin{aligned} V_{\text{THDM}} = {} & m_1^2|\Phi_1|^2 + m_2^2|\Phi_2|^2 - m_3^2(\Phi_1^\dagger\Phi_2 + \text{H.c.}) \\ & + \frac{1}{2}\lambda_1|\Phi_1|^4 + \frac{1}{2}\lambda_2|\Phi_2|^4 + \lambda_3|\Phi_1|^2|\Phi_2|^2 \\ & + \lambda_4|\Phi_1^\dagger\Phi_2|^2 + \frac{1}{2}\lambda_5[(\Phi_1^\dagger\Phi_2)^2 + \text{H.c.}], \end{aligned} \tag{3}$$

where Φ_1 and Φ_2 are the isospin doublet scalar fields with $Y = 1/2$ for which Z_2 transformation is given as $\Phi_1 \to +\Phi_1$ and $\Phi_2 \to -\Phi_2$. The two Higgs doublet fields can be parametrized as

[5] In Fig. 1.20 in the ILC Higgs White Paper [51], we have shown the expected excluded parameter space in the type-II and type-X THDMs at the LHC. We update this analysis with more detailed explanations.

[6] In Figs. 1.17 and 1.18 in the ILC Higgs White Paper [51], we have shown the deviation in the $hf\bar{f}$ and hVV couplings in the THDMs and in the models with universal modification of the $hf\bar{f}$ couplings. We update the plots for the $hf\bar{f}$ and hVV couplings with more detailed explanations by using the latest data [64].

TABLE I. Four types of the charge assignment of the Z_2 symmetry.

	Φ_1	Φ_2	u_R	d_R	ℓ_R	Q_L, L_L
Type-I	+	−	−	−	−	+
Type-II	+	−	−	+	+	+
Type-X	+	−	−	−	+	+
Type-Y	+	−	−	+	−	+

$$\Phi_i = \begin{bmatrix} w_i^+ \\ \frac{1}{\sqrt{2}}(h_i + v_i + iz_i) \end{bmatrix}, \quad (i = 1, 2), \tag{4}$$

where v_1 and v_2 are the VEVs of two doublet fields. They are related to the Fermi constant G_F by $v^2 \equiv v_1^2 + v_2^2 = (\sqrt{2}G_F)^{-1}$. The ratio of the two VEVs is defined as $\tan\beta = v_2/v_1$.

The mass eigenstates for the scalar bosons are obtained by the orthogonal transformations as

$$\begin{pmatrix} w_1^\pm \\ w_2^\pm \end{pmatrix} = R(\beta)\begin{pmatrix} G^\pm \\ H^\pm \end{pmatrix}, \qquad \begin{pmatrix} z_1 \\ z_2 \end{pmatrix} = R(\beta)\begin{pmatrix} G^0 \\ A \end{pmatrix},$$
$$\begin{pmatrix} h_1 \\ h_2 \end{pmatrix} = R(\alpha)\begin{pmatrix} H \\ h \end{pmatrix},$$
$$\text{with} \quad R(\theta) = \begin{pmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{pmatrix}, \tag{5}$$

where $G^\pm$ and G^0 are the Nambu-Goldstone bosons absorbed by the longitudinal component of $W^\pm$ and Z, respectively. The masses of $H^\pm$ and A are calculated as

$$m_{H^+}^2 = M^2 - \frac{v^2}{2}(\lambda_4 + \lambda_5), \qquad m_A^2 = M^2 - v^2\lambda_5, \tag{6}$$

where $M^2 \equiv m_3^2/(\sin\beta\cos\beta)$ describes the soft breaking scale of the Z_2 symmetry [66]. The masses for the CP-even Higgs bosons h and H and the mixing angle α are given by

$$m_H^2 = \cos^2(\beta-\alpha)M_{11}^2 + \sin^2(\beta-\alpha)M_{22}^2 - \sin 2(\beta-\alpha)M_{12}^2, \tag{7}$$

$$m_h^2 = \sin^2(\beta-\alpha)M_{11}^2 + \cos^2(\beta-\alpha)M_{22}^2 + \sin 2(\beta-\alpha)M_{12}^2, \tag{8}$$

$$\tan 2(\beta-\alpha) = \frac{2M_{12}^2}{M_{22}^2 - M_{11}^2}, \tag{9}$$

where

$$M_{11}^2 = v^2(\lambda_1\cos^4\beta + \lambda_2\sin^4\beta) + \frac{v^2}{2}\bar{\lambda}\sin^2 2\beta, \tag{10}$$

$$M_{22}^2 = M^2 + v^2(\lambda_1 + \lambda_2 - 2\bar{\lambda})\sin^2\beta\cos^2\beta, \tag{11}$$

$$M_{12}^2 = \frac{v^2}{2}(-\lambda_1\cos^2\beta + \lambda_2\sin^2\beta)\sin 2\beta + \frac{v^2}{2}\bar{\lambda}\sin 2\beta\cos 2\beta, \tag{12}$$

with $\bar{\lambda} \equiv \lambda_3 + \lambda_4 + \lambda_5$. We define the range of $\beta - \alpha$ to be $[0, \pi/2]$ or $[\pi/2, \pi]$, which for a given positive value of $\sin(\beta-\alpha)$, $\cos(\beta-\alpha)$ is positive or negative, respectively.

The Yukawa Lagrangian under the Z_2 symmetry is given by

$$\mathcal{L}_{\rm THDM}^Y = -Y_u\overline{Q_L}\tilde{\Phi}_u u_R - Y_d\overline{Q_L}\Phi_d d_R - Y_\ell\overline{L_L}\Phi_\ell\ell_R + \text{H.c.}, \tag{13}$$

where $\Phi_{u,d,\ell}$ are either Φ_1 or Φ_2 and $\tilde{\Phi}_u = i\tau_2\Phi_u^*$. There are four independent ways of the charge assignment of the Z_2 symmetry as summarized in Table I, which are named type-I, type-II, type-X, and type-Y Yukawa interactions according to Ref. [40]. After we specify the types of Yukawa interactions, the Yukawa coupling constants are expressed in the mass eigenstate of the Higgs bosons as

$$\begin{aligned}\mathcal{L}_{\rm THDM}^Y = &-\sum_{f=u,d,e}\frac{m_F}{v}(\xi_h^f\bar{f}fh + \xi_H^f\bar{f}fH - i\xi_A^f\bar{f}\gamma_5 fA) \\ &+\left[\frac{\sqrt{2}V_{ud}}{v}\bar{u}(m_u\xi_A^u P_L + m_d\xi_A^d P_R)dH^+ \right. \\ &\left. +\frac{\sqrt{2}m_\ell\xi_A^e}{v}\bar{\nu}P_R eH^+ + \text{H.c.}\right],\end{aligned} \tag{14}$$

where $P_{L,R} = (1\mp\gamma_5)/2$, and the factors ξ_ϕ^f ($\phi = h, H$, and A) are listed in Table II. We note that the ξ_h^f and ξ_H^f are rewritten by

$$\begin{aligned}\xi_h^f &= \sin(\beta-\alpha) + 2T_3^f\xi_A^f\cos(\beta-\alpha), \\ \xi_H^f &= \cos(\beta-\alpha) - 2T_3^f\xi_A^f\sin(\beta-\alpha),\end{aligned} \tag{15}$$

where $T_3^f = 1/2(-1/2)$ for $f = u$ (d, e).

TABLE II. The mixing factors in each type of Yukawa interaction in the THDMs [40].

	ξ_h^u	ξ_h^d	ξ_h^ℓ	ξ_H^u	ξ_H^d	ξ_H^ℓ	ξ_A^u	ξ_A^d	ξ_A^ℓ
Type-I	$\cos\alpha/\sin\beta$	$\cos\alpha/\sin\beta$	$\cos\alpha/\sin\beta$	$\sin\alpha/\sin\beta$	$\sin\alpha/\sin\beta$	$\sin\alpha/\sin\beta$	$\cot\beta$	$-\cot\beta$	$-\cot\beta$
Type-II	$\cos\alpha/\sin\beta$	$-\sin\alpha/\cos\beta$	$-\sin\alpha/\cos\beta$	$\sin\alpha/\sin\beta$	$\cos\alpha/\cos\beta$	$\cos\alpha/\cos\beta$	$\cot\beta$	$\tan\beta$	$\tan\beta$
Type-X	$\cos\alpha/\sin\beta$	$\cos\alpha/\sin\beta$	$-\sin\alpha/\cos\beta$	$\sin\alpha/\sin\beta$	$\sin\alpha/\sin\beta$	$\cos\alpha/\cos\beta$	$\cot\beta$	$-\cot\beta$	$\tan\beta$
Type-Y	$\cos\alpha/\sin\beta$	$-\sin\alpha/\cos\beta$	$\cos\alpha/\sin\beta$	$\sin\alpha/\sin\beta$	$\cos\alpha/\cos\beta$	$\sin\alpha/\sin\beta$	$\cot\beta$	$\tan\beta$	$-\cot\beta$

After taking the same rotation of the scalar bosons given in Eq. (5), the Higgs gauge gauge-type terms are expressed by

$$\mathcal{L}_{\rm kin}^{\phi VV} = [\sin(\beta-\alpha)h + \cos(\beta-\alpha)H] \times \left(\frac{m_W^2}{v} W^{+\mu} W_\mu^- + \frac{1}{2}\frac{m_Z^2}{v} Z^\mu Z_\mu\right). \quad (16)$$

Here, we comment on two important limits: the *SM-like limit* and the *decoupling limit* [65], which are realized by taking $\sin(\beta-\alpha)\to 1$ and $M^2\to\infty$, respectively. In the former limit, as seen in Eqs. (14), (15), and (16), the strength of the Yukawa interaction and the gauge interaction of h become the same as in the SM. We thus define h as the SM-like Higgs boson that should be identified as the discovered Higgs boson with the mass of around 126 GeV, and all the other Higgs bosons, $H^\pm$, A, and H are regarded as the additional Higgs bosons. On the other hand, in the decoupling limit, all the masses of additional Higgs bosons become infinity as long as we take the SM-like limit. As a result, only the mass of h remains at the electroweak scale.

If we consider the case without the SM-like limit, we cannot take the decoupling limit. This can be seen by looking at Eq. (9), which tells us that, in order to keep a fixed nonzero value of $\tan 2(\beta-\alpha)$, we need sizable contributions from M_{11}^2 and M_{12}^2 to cancel a large value of M_{22}^2 by the M^2 term in Eq. (11). However, as seen in Eqs. (10) and (12), M_{11}^2 and M_{12}^2 are given like a form of $\lambda_i v^2$ so that when these terms are too large they make λ coupling constants, which are disfavored by the constraints from perturbative unitarity, too large [67,68]. Therefore, there is an upper limit for the mass of additional Higgs bosons at which we retain the deviation from the SM-like limit.

B. Vacuum stability and unitarity

To keep a stability of the vacuum, the Higgs potential should be bounded from below in any directions with a large value of scalar fields. The sufficient condition is given by [69,70]

$$\lambda_1 > 0, \qquad \lambda_2 > 0,$$
$$\sqrt{\lambda_1\lambda_2} + \lambda_3 + \mathrm{MIN}(0, \lambda_4+\lambda_5, \lambda_4-\lambda_5) > 0. \quad (17)$$

In addition, the magnitude of several combinations of the quartic Higgs coupling constants are constrained by unitarity. When we consider the elastic scatterings of two-body boson states, there are 14 neutral, 8 singly charged, and 3 doubly charged channels. After the diagonalization of the T matrix for the S-wave amplitude of these processes, we obtain the 12 independent eigenvalues [68] as

$$x_1^\pm = \frac{1}{32\pi}[3(\lambda_1+\lambda_2) \pm \sqrt{9(\lambda_1-\lambda_2)^2 + 4(2\lambda_3+\lambda_4)^2}], \quad (18)$$

$$x_2^\pm = \frac{1}{32\pi}\left[(\lambda_1+\lambda_2) \pm \sqrt{(\lambda_1-\lambda_2)^2 + 4\lambda_4^2}\right], \quad (19)$$

$$x_3^\pm = \frac{1}{32\pi}\left[(\lambda_1+\lambda_2) \pm \sqrt{(\lambda_1-\lambda_2)^2 + 4\lambda_5^2}\right], \quad (20)$$

$$x_4^\pm = \frac{1}{16\pi}(\lambda_3 + 2\lambda_4 \pm 3\lambda_5), \quad (21)$$

$$x_5^\pm = \frac{1}{16\pi}(\lambda_3 \pm \lambda_4), \quad (22)$$

$$x_6^\pm = \frac{1}{16\pi}(\lambda_3 \pm \lambda_5). \quad (23)$$

For each eigenvalue, we impose the following criterion[7]:

$$|x_i^\pm| \le \frac{1}{2}. \quad (24)$$

As we mentioned in the previous subsection, the unitarity and vacuum stability bounds can be used to obtain the upper limit on the mass of additional Higgs bosons when $\sin(\beta-\alpha)$ deviates from unity. We introduce the scaling factor κ_V defined by the ratio of the hVV coupling constant to the corresponding SM value, which coincides with $\sin(\beta-\alpha)$ at the tree level. In Fig. 1, we show the upper limit of m_A from the unitarity and vacuum stability bounds for given values of $1-\kappa_V$ and $\tan\beta$. The value of M is scanned over the range of $m_A \pm 500$ GeV. To avoid the constraint from the rho parameter, we take $m_{H^+} = m_A$ in these plots so that the one-loop corrections to the rho parameter from the additional Higgs boson loops become zero due to the custodial symmetry in the Higgs potential [29–35]. The value of m_H is taken to be the same as m_A (scanned over the range of $m_A \pm 500$ GeV) in the solid (dotted) curves. The left and right panels show the cases with $\cos(\beta-\alpha) > 0$ and $\cos(\beta-\alpha) < 0$, respectively. It is seen that the maximal allowed value of m_A gets larger when the deviation in κ_V from unity gets small. Therefore, larger deviations in the hVV coupling constant give a severe upper bound on masses for additional Higgs bosons.

In Fig. 2, we show the $\tan\beta$ dependence of the upper limit of m_A from the unitarity and vacuum stability bounds for a given value of $1-\kappa_V$. The other parameters are taken to be the same as in Fig. 1.

C. Decay of the Higgs bosons

In this subsection, we discuss the decays of Higgs bosons with the four types of Yukawa interaction in the THDM. The decay property can be drastically different between the case with $\sin(\beta-\alpha)=1$ and that with $\sin(\beta-\alpha)\neq 1$ [40]. When the SM-like limit is taken, the additional Higgs

[7]Constraints on the parameter space using scale-dependent coupling constants were studied in the THDM in Refs. [70,71].

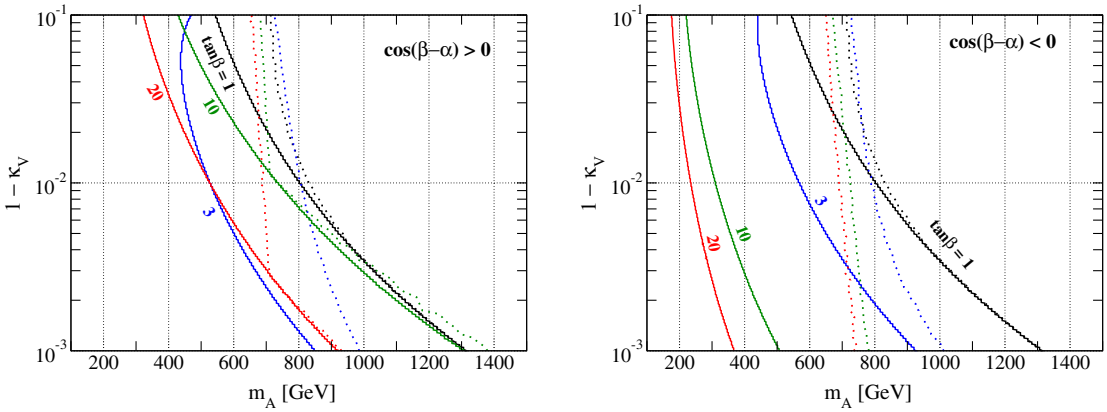

FIG. 1 (color online). Upper limit of $1-\kappa_V$ as a function of m_A for each value of $\tan\beta$ from the constraints of unitarity and vacuum stability in the case in which M is scanned over the range of $m_A \pm 500$ GeV and $m_{H^+} = m_A$. The left and right panels, respectively, show the results with $\cos(\beta-\alpha) > 0$ and $\cos(\beta-\alpha) < 0$. The solid curves show the case with $m_H = m_A$, while the dotted curves show the result with m_H to be scanned over the range of $m_A \pm 500$ GeV.

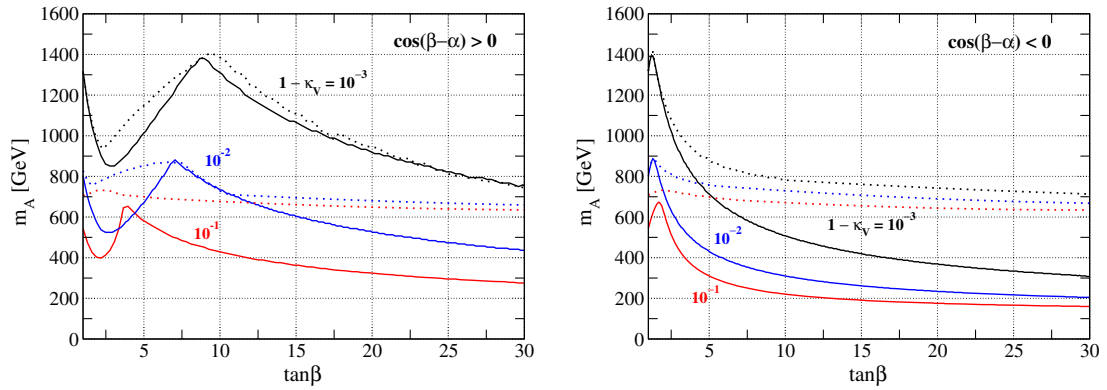

FIG. 2 (color online). Upper limit of m_A as a function of $\tan\beta$ for each value of $1-\kappa_V$ from the constraints of unitarity and vacuum stability in the case in which M is scanned over the range of $m_A \pm 500$ GeV and $m_{H^+} = m_A$. The left and right panels, respectively, show the results with $\cos(\beta-\alpha) > 0$ and $\cos(\beta-\alpha) < 0$. The solid curves show the result with $m_H = m_A$, while the dotted curves show the result with m_H to be scanned over the range of $m_A \pm 500$ GeV.

bosons can dominantly decay into a fermion pair for which the decay branching ratio strongly depends on the type of Yukawa interactions and $\tan\beta$. On the other hand, when we take $\sin(\beta-\alpha) \neq 1$, H can decay into the gauge boson pairs W^+W^- and ZZ and the SM-like Higgs boson pair hh, where these decay rates are proportional to $\cos^2(\beta-\alpha)$. At the same time, $H^\pm$ and A can decay into $W^\pm$ and Z associated with the SM-like Higgs boson h for which the decay amplitudes are also proportional to $\cos(\beta-\alpha)$ [53–55,72].

To calculate the decay rates, we use the following inputs from the Particle Data Group (PDG) [20]:

$$m_Z = 91.1876\ \text{GeV}, \quad m_W = 80.385\ \text{GeV},$$
$$G_F = 1.1663787 \times 10^{-5}\ \text{GeV}^{-2}, \quad m_t = 173.07\ \text{GeV},$$
$$\alpha_s(m_Z) = 0.1185, \quad V_{cb} = 0.0409, \quad V_{ts} = 0.0429. \tag{25}$$

The running quark masses at the scale of m_Z are quoted from Ref. [73] as

$$\bar{m}_b = 3.0\ \text{GeV}, \quad \bar{m}_c = 0.677\ \text{GeV}, \quad \bar{m}_s = 0.0934\ \text{GeV}. \tag{26}$$

The mass of the SM-like Higgs boson h is taken to be 126 GeV in the following calculations.

All the other parameters shown in Eq. (25) are quoted from the PDG [20]. We note that the effects of Cabibbo-Kobayashi-Maskawa matrix elements V_{cb} and V_{ts} appear in the $H^\pm \to cb$ and $H^\pm \to ts$ decays. For simplicity, we take all the masses of additional Higgs bosons to be the same; i.e., $m_{H^+} = m_A = m_H (\equiv m_\Phi)$. In that case, there are four free parameters in the Higgs potential, which are chosen as m_Φ, M^2, $\tan\beta$, and $\sin(\beta-\alpha)$.

We here comment on the $H^\pm \to W^\pm Z$ and $H^\pm \to W^\pm\gamma$ processes. The $H^\pm W^\mp \gamma$ vertex is obtained at the one-loop

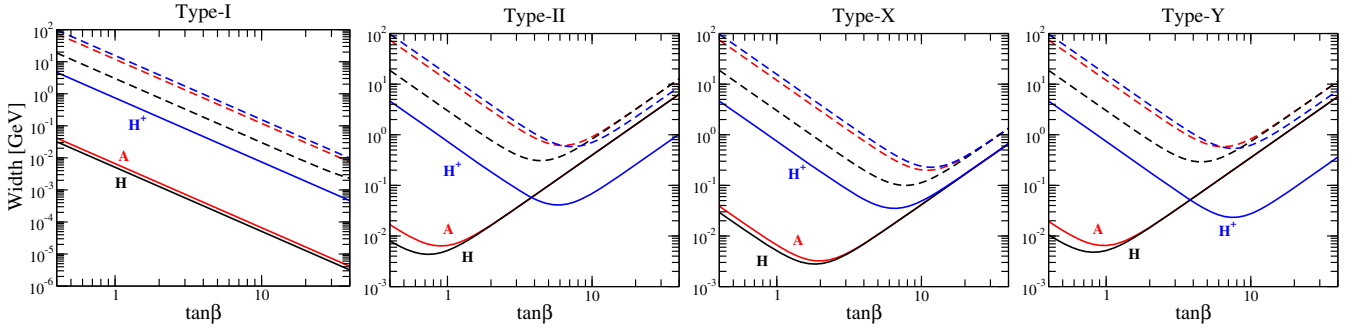

FIG. 3 (color online). Total widths for H, A, and $H^{\pm}$ as a function of $\tan\beta$ in the case of $\sin(\beta-\alpha)=1$. The solid and dashed curves, respectively, show the results with $m_{\Phi}=M=200$ GeV and $m_{\Phi}=M=400$ GeV.

level, and its magnitude is suppressed due to the $U(1)_{\rm em}$ gauge invariance. This nature does not depend on a model. On the other hand, in the THDM, although the $H^{\pm}W^{\mp}Z$ vertex appears at the one-loop level, it can enhance if there is a large violation of the custodial symmetry. As we discussed in the Introduction, the mass splitting between the top and bottom quarks breaks the custodial symmetry, and it gives the $(m_t-m_b)^2$ dependence in the one-loop corrected rho parameter. A similar effect appears in the $H^{\pm}W^{\mp}Z$ vertex [74]. In addition, when the mass splitting

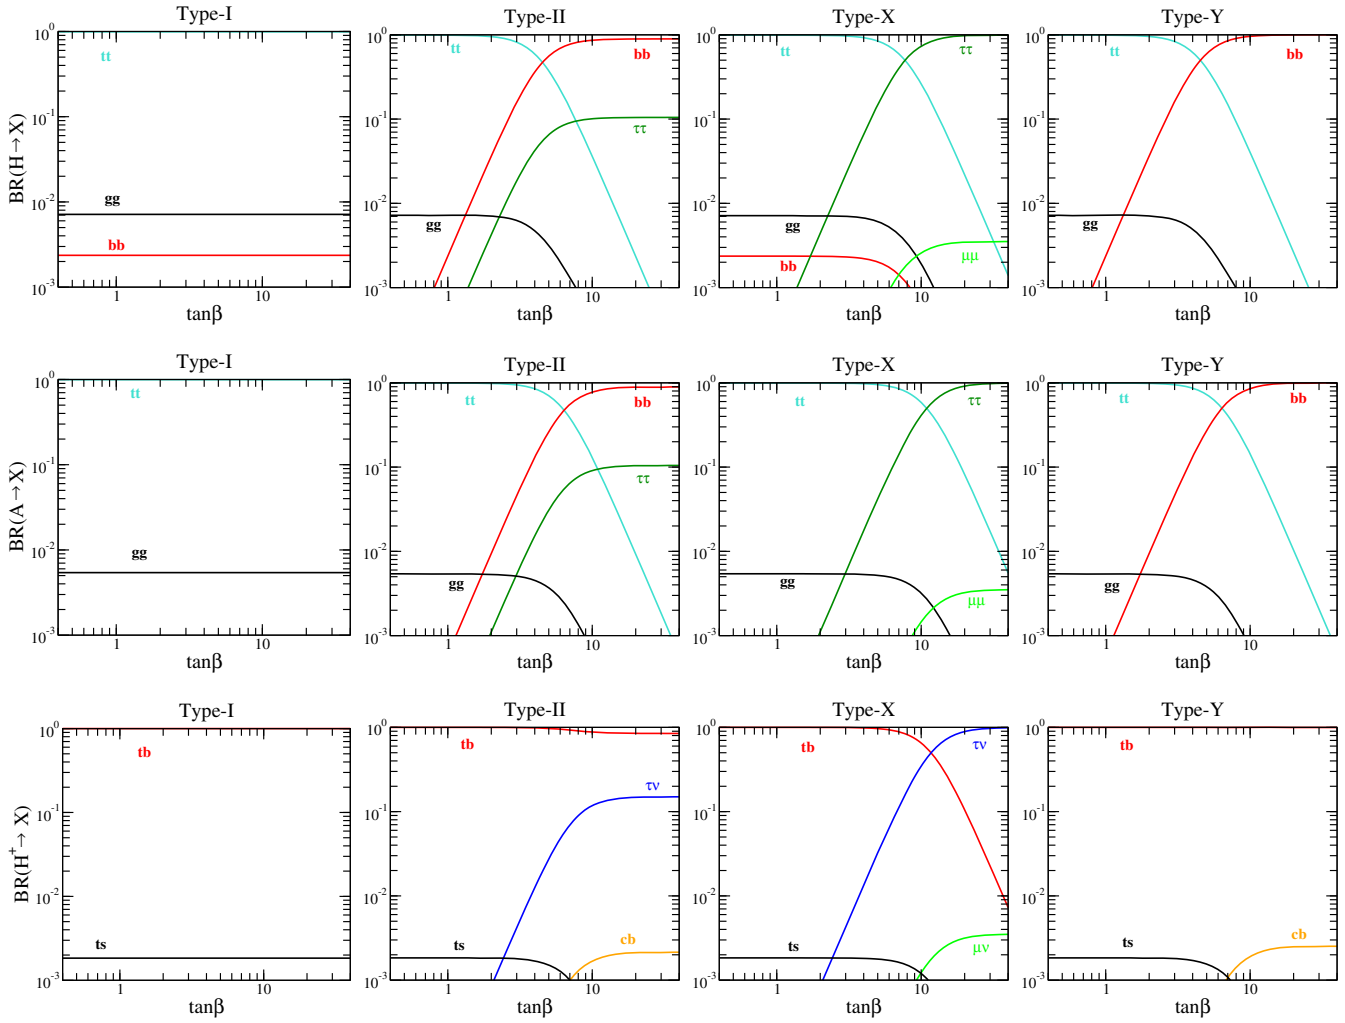

FIG. 5 (color online). Decay branching ratios for H, A, and $H^{\pm}$ as a function of $\tan\beta$ in the case of $m_{\Phi} = M = 400$ GeV and $\sin(\beta - \alpha) = 1$.

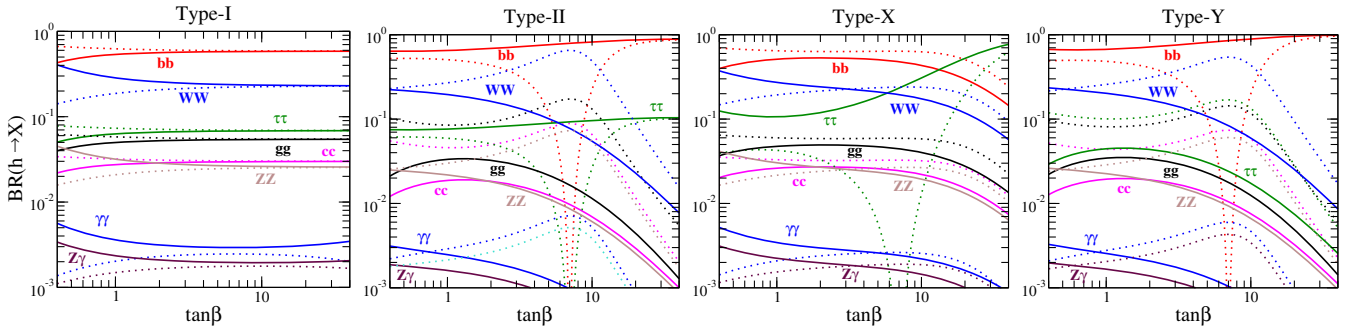

FIG. 6 (color online). Decay branching ratios for h as a function of $\tan\beta$ in the case of $m_{\Phi} = M = 200$ GeV and $\sin(\beta - \alpha) = 0.99$. The solid and dashed curves respectively show the cases with $\cos(\beta - \alpha) < 0$ and $\cos(\beta - \alpha) > 0$.

between $H^{\pm}$ and A is given, which breaks the custodial symmetry in the Higgs potential, the $H^{\pm}W^{\mp}Z$ vertex can be enhanced due to the $(m_{H^+} - m_A)^2$ dependence. In Ref. [75], full one-loop calculation of the $H^{\pm}W^{\mp}Z$ vertex was done. It was shown that the branching ratio of $H^{\pm} \to W^{\pm}Z$ can be $\mathcal{O}(10^{-2})$ in the case of $m_{H^+} = 300$ GeV when the mass splitting between $H^{\pm}$ and A is taken to be $\mathcal{O}(100)$ GeV. In the following calculation, we assume $m_{H^+} = m_A$ so that only the top and bottom quarks loop contribution to the $H^{\pm} \to W^{\pm}Z$ vertex is important. In this

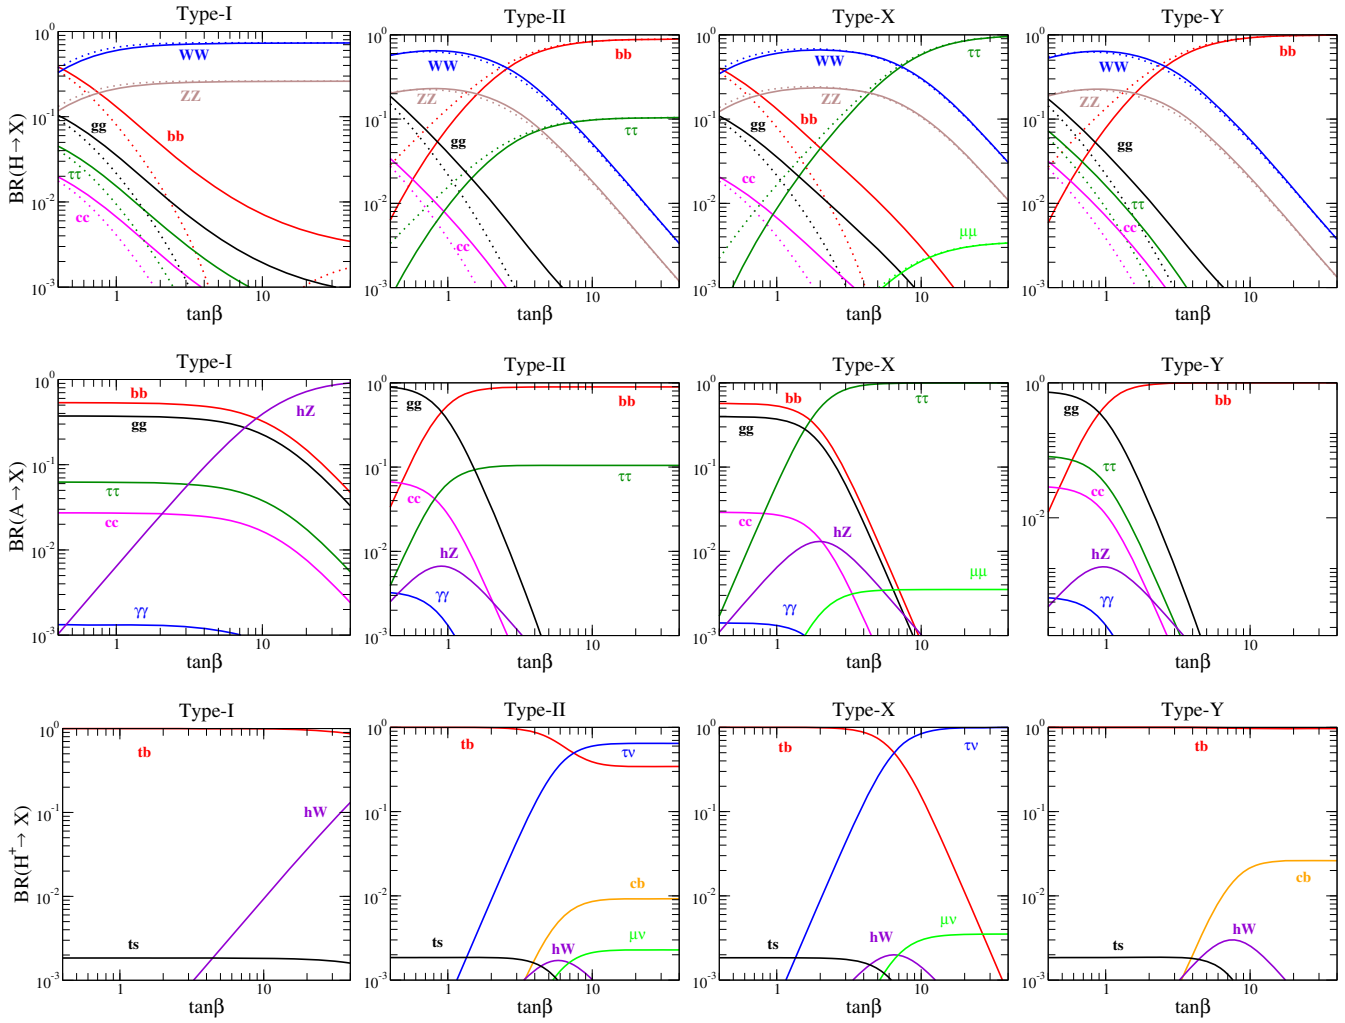

FIG. 7 (color online). Decay branching ratios for H, A, and $H^{\pm}$ as a function of $\tan\beta$ in the case of $m_{\Phi} = M = 200$ GeV and $\sin(\beta-\alpha) = 0.99$. For the H decay, the solid and dashed curves, respectively, show the cases with $\cos(\beta-\alpha) < 0$ and $\cos(\beta-\alpha) > 0$.

case, typical values of the branching fractions of $H^{\pm} \to W^{\pm}Z$ and $H^{\pm} \to W^{\pm}\gamma$ are smaller than $\mathcal{O}(10^{-3})$ and $\mathcal{O}(10^{-5})$, respectively.[8] We thus safely neglect these modes in the following calculation.

First, we show the total widths for H, A, and $H^{\pm}$ in Fig. 3 as a function of $\tan\beta$ in the case of $\sin(\beta-\alpha) = 1$. The solid (dashed) curves show the results with $m_{\Phi} = M = 200(400)$ GeV. Except in the type-I THDM, the widths have a minimum in a certain value of $\tan\beta$ because the sum of the decay rates of the fermion pair mode are given by terms proportional to $\cot^2\beta$, $\tan^2\beta$ and those without $\tan\beta$ dependence. In the type-I THDM, all the decay rates with the fermion pair final state are suppressed by $\cot^2\beta$ so that the widths monotonously decrease when $\tan\beta$ gets larger values. In the type-X THDM, all the widths for H, A and $H^{\pm}$ approach roughly the same value in the high $\tan\beta$ region for a fixed value of m_{Φ}. This can be understood in such a way that the decay rate of $H^{\pm} \to tb$ mainly deviates the width of $H^{\pm}$ from that of H and A, which can be neglected in the high $\tan\beta$ region in the type-X THDM. In the type-I THDM, although the decay rate of $H^{\pm} \to tb$ is suppressed as in the type-X THDM, all the other fermion pair decay modes are also suppressed at the same time. Therefore, the $H^{\pm} \to tb$ decay is not negligible in the type-I THDM, and then it deviates the width of $H^{\pm}$ from that of H and A.

In Fig. 4, we show the decay branching fractions of H (top panels), A (middle panels), and $H^{\pm}$ (bottom panels) as a function of $\tan\beta$ in the case of $\sin(\beta-\alpha) = 1$ and $m_{\Phi} = M = 200$ GeV. It is seen that only in the type-X THDM H and A can mainly decay into $\tau^+\tau^-$ in the case of

[8] If the Higgs sector contains *exotic* Higgs fields for which the isospin is larger than 1/2, the $H^{\pm}W^{\mp}Z$ vertex appears at the tree level [76]. The magnitude depends on VEVs from exotic Higgs fields that are usually severely constrained by the rho parameter. In the GM model and in the doublet-septet model, such a VEV can be taken as $\mathcal{O}(10)$ GeV. Therefore, measuring the $H^{\pm}W^{\mp}Z$ vertex can be a probe of exotic Higgs sectors. The feasibility study for the measurement of the vertex was performed in Ref. [77] at the LHC and in Ref. [78] at the ILC.

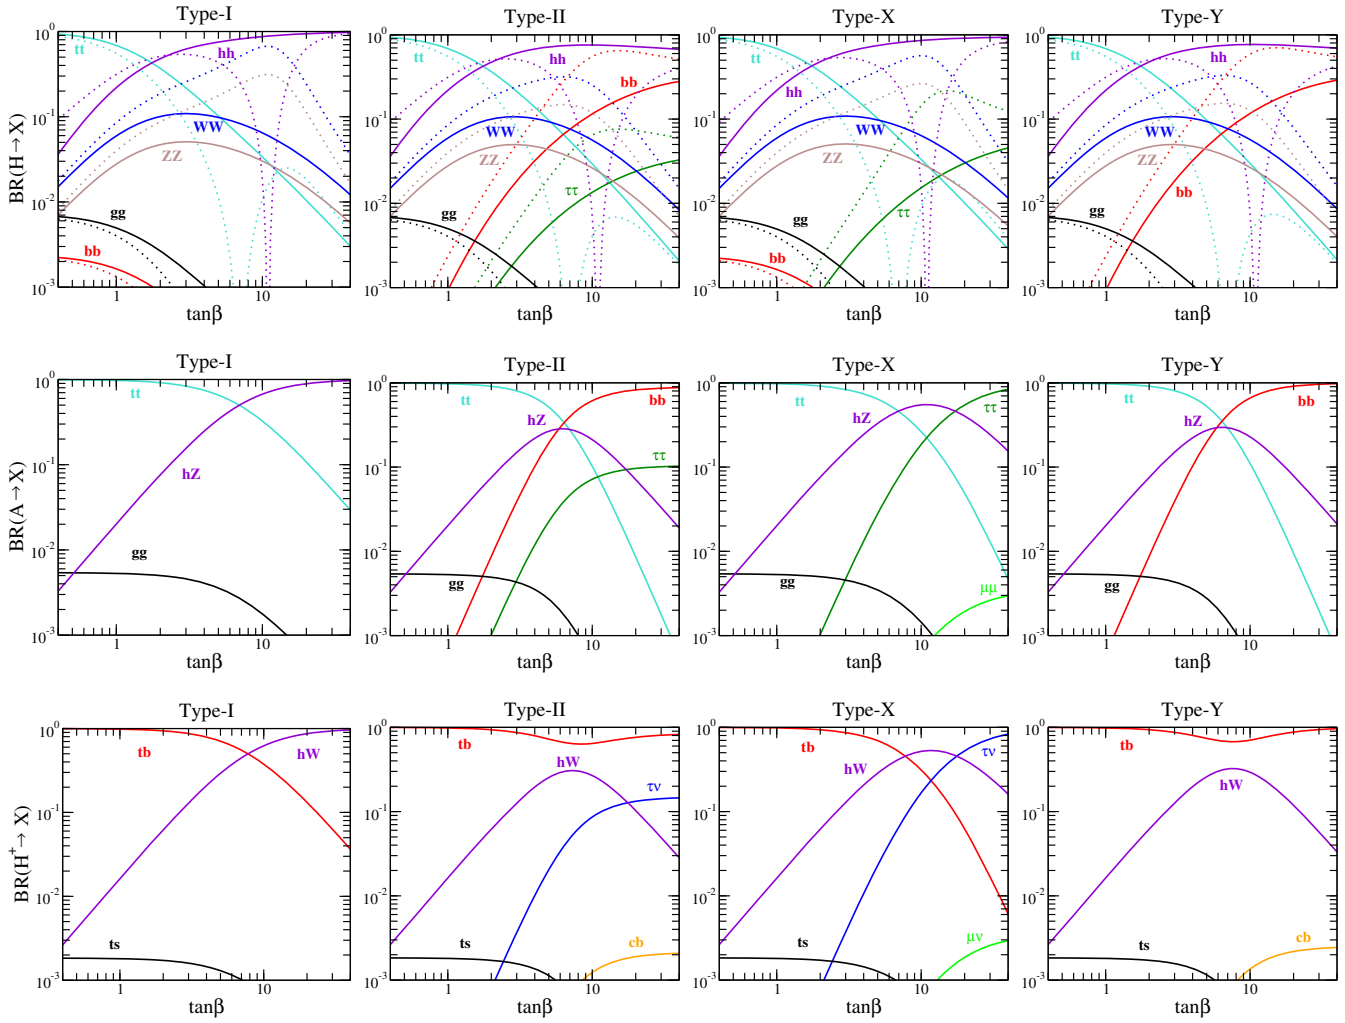

FIG. 8 (color online). Decay branching ratios for H, A, and $H^{\pm}$ as a function of $\tan\beta$ in the case of $m_{\Phi} = M = 400$ GeV and $\sin(\beta-\alpha) = 0.99$. For the H decay, the solid and dashed curves, respectively, show the cases with $\cos(\beta-\alpha) < 0$ and $\cos(\beta-\alpha) > 0$.

$\tan\beta \gtrsim 3$. Besides, H and A can also decay into $\mu^+\mu^-$ with about 0.3% in the type-X THDM. Regarding the $H^{\pm}$ decay, although the main decay mode is basically tb in all the types, that is replaced by $H^{\pm} \to \tau^{\pm}\nu$ in the type-II and type-X THDMs with $\tan\beta \gtrsim 7$.

Similarly, Fig. 5 shows the branching fractions of H, A, and $H^{\pm}$ in the case of $m_{\Phi} = M = 400$ GeV and $\sin(\beta-\alpha) = 1$. In all the types of THDMs, H and A mainly decay into the top pair in the lower $\tan\beta$ region. However, that is replaced by $b\bar{b}$ ($\tau^+\tau^-$) in the type-II and type-Y (type-X) THDMs with $\tan\beta \gtrsim 5$ ($\tan\beta \gtrsim 8$). The decay of $H^{\pm}$ does not change so much from that in the case of $m_{\Phi} = M = 200$ GeV. Notice here that the magnitude relation between the branching fraction of $H/A \to gg$ and that of $H/A \to b\bar{b}$ is flipped compared to the results in Fig. 4 except in the type-II and type-Y THDMs with $\tan\beta \gtrsim 1$. We note that, in the case of $\sin(\beta-\alpha) = 1$ and $m_H = m_A$, only the difference between the decay rate of $H \to f\bar{f}$ and that of $A \to f\bar{f}$ appears in the power of the phase space factor; i.e., that is the cubic (linear) power for H (A) [9]. Thus, the decay rate of $A \to f\bar{f}$ is slightly larger than that of $H \to f\bar{f}$. Moreover, the decay rates of loop-induced modes such as the decays into gg, $\gamma\gamma$, and $Z\gamma$ are different between H and A because of the CP property.

Next, we show the branching fractions in the case without taking the SM-like limit, e.g., $\sin(\beta-\alpha) = 0.99$. In this case, the sign of $\cos(\beta-\alpha)$ can affect decay properties for the CP-even Higgs bosons so that we consider both the cases with $\cos(\beta-\alpha) < 0$ and $\cos(\beta-\alpha) > 0$.

In Fig. 6, the branching fractions for the SM-like Higgs boson h is shown as a function of $\tan\beta$ in the case of $m_{\Phi} = M = 200$ GeV. For the h decay, the m_{Φ} and M parameters affect the $H^{\pm}$ loop contribution to the decay rates of $h \to \gamma\gamma$ and $h \to Z\gamma$. When we take a larger value of m_{Φ} keeping $m_{\Phi} = M$, the $H^{\pm}$ loop contribution vanishes. The solid and dashed curves, respectively, show the

cases with $\cos(\beta-\alpha)<0$ and $\cos(\beta-\alpha)>0$. We can see that several fermionic decay channels vanish at $\tan\beta\simeq 7$ in the case of $\cos(\beta-\alpha)>0$ in the type-II, type-X, and type-Y THDMs. Let us explain this behavior by introducing δ defined by $\sin(\beta-\alpha)=1-\delta$. When $\delta\ll 1$, the ξ_h^f and ξ_H^f factors in Eq. (15) can be approximately expressed by

$$\xi_h^f \simeq 1+\mathrm{Sign}[\cos(\beta-\alpha)]2\sqrt{2\delta}T_3^f\xi_A^f,$$
$$\xi_H^f \simeq \mathrm{Sign}[\cos(\beta-\alpha)]2\sqrt{2\delta}-2T_3^f\xi_A^f. \quad (27)$$

From Table II, we can obtain $\xi_h^f\simeq 1-\mathrm{Sign}[\cos(\beta-\alpha)]\sqrt{2\delta}\tan\beta$ for $f=b$ $(f=\tau)$ in type-II and type-Y (type-II and type-X) THDMs. Thus, when $\cos(\beta-\alpha)$ is positive, and δ is taken to be 0.01, ξ_h^f becomes zero at around $\tan\beta=7$. We note that the ξ_h^f factor can be -1 in the case of $\cos(\beta-\alpha)<0$, in which the sign of Yukawa coupling constant is opposite compared to the SM value. Signatures of additional Higgs bosons in the parameter regions with $\xi_h^f\simeq -1$ have been studied in Ref. [56], and the testability of the sign of Yukawa couplings has been investigated at a future linear collider in Ref. [57].

The branching fractions for the additional Higgs bosons are also shown in Fig. 7 in the case of $m_\Phi=M=200$ GeV, and those in the case of $m_\Phi=M=400$ GeV are shown in Fig. 8. For the H decay, we use the solid and dashed curves, respectively, to show the cases with $\cos(\beta-\alpha)<0$ and $\cos(\beta-\alpha)>0$. It can be seen that the gaugephobic nature of H is lost, and the $H\to W^+W^-/ZZ$ modes can be dominate. Regarding the A and $H^\pm$ decays, the $A\to hZ$ and $H^\pm\to hW^\pm$ modes are added to the case with $\sin(\beta-\alpha)=1$. When we consider heavier case of H, $m_\Phi=M=400$ GeV, the $H\to hh$ mode for which the decay rate is proportional to $\cos^2(\beta-\alpha)$ is kinematically allowed. This can be the main decay mode as we can see in the top panels in Fig 8.

We comment on the case without degeneracy in mass of the additional Higgs bosons. In that case, heavier additional Higgs bosons can decay into lighter ones associated with a gauge boson even in the SM-like limit. For instance, when $m_H>m_A$, the $H\to AZ^{(*)}$ mode is allowed. Recently, signatures from $H\to AZ$ and $A\to HZ$ decays have been studied at the LHC in Ref. [55].

III. DIRECT SEARCH FOR ADDITIONAL HIGGS BOSONS AT THE LHC

At the LHC with the collision energy of 7 and 8 TeV, so far, there is no report for a discovery of new particles other than a Higgs boson, and only exclusion bounds for masses of hypothetical particles are obtained.

First of all, we review the current bounds on parameter space in the THDMs from 7 and 8 TeV data at the LHC. The signal of neutral Higgs bosons in the $\tau^+\tau^-$ decay mode has been searched for in the inclusive production and bottom quark-associated production processes [10,11]. For the type-II THDM, bounds on $\tan\beta$ have been obtained for given values of m_A, e.g., $\tan\beta\lesssim 10$ for $m_A=300$ GeV and $\tan\beta\lesssim 40$ for $m_A=800$ GeV [11]. In addition, the searches for the $b\bar{b}$ decay of neutral Higgs bosons in the bottom quark-associated process have been performed [12]. The $b\bar{b}$ decay mode gives a rather weaker bound on $\tan\beta$ compared to the $\tau^+\tau^-$ decay mode. These bounds can be used to constrain parameter regions in both the type-II and type-Y THDMs. Furthermore, for $\sin(\beta-\alpha)<1$, searches for the $H\to W^+W^-$ signal have been performed [13], and a bound on the m_H-$\cos\alpha$ plane is obtained for given values of $\tan\beta$. This bound is not sensitive to the type of Yukawa interaction. In Ref. [14], $H\to hh$ and $A\to Zh$ decays have been searched, and bounds on the cross section times branching ratio have been obtained. These can be translated into the exclusion regions in the $\cos(\beta-\alpha)$-$\tan\beta$ plane for given values of $m_{H/A}$ for each type of Yukawa interaction.

In the following, we discuss expected excluded regions on the m_A-$\tan\beta$ plane at the LHC with the collision energy of 14 TeV. We first focus on the search for H and A by using the tau decay from the gluon fusion and bottom quark-associated production processes as

$$gg\to\phi^0\to\tau^+\tau^-, \quad (28)$$

$$gg\to b\bar{b}\phi^0\to b\bar{b}\tau^+\tau^-, \quad (29)$$

where $\phi^0=H$ or A. The cross sections for the above processes can be estimated by[9]

$$\sigma(gg\to\phi^0)=\frac{\Gamma(\phi^0\to gg)}{\Gamma(h_{\rm SM}\to gg)_{m_{\phi^0}}}\sigma(gg\to h_{\rm SM})_{m_{\phi^0}}, \quad (30)$$

$$\sigma(gg\to b\bar{b}\phi^0)=(\xi_d^{\phi^0})^2\sigma(gg\to b\bar{b}h_{\rm SM})_{m_{\phi^0}}, \quad (31)$$

where $h_{\rm SM}$ is the SM Higgs boson. In Eq. (30), $\Gamma(h_{\rm SM}\to gg)_{m_{\phi^0}}$ and $\sigma(gg\to h_{\rm SM})_{m_{\phi^0}}$ are, respectively, the decay rate of $h_{\rm SM}\to gg$ and the cross section of the gluon fusion process by taking the mass of $h_{\rm SM}$ to be replaced by the mass of ϕ^0 (m_{ϕ^0}). We use the values of the gluon fusion cross section in the SM at 14 TeV from Ref. [79]. In Eq. (31), $\sigma(gg\to b\bar{b}h_{\rm SM})_{m_{\phi^0}}$ is the cross section for the bottom quark-associated production of $h_{\rm SM}$ with the mass of $h_{\rm SM}$ to be replaced by m_{ϕ^0}. We calculate $\sigma(gg\to b\bar{b}h_{\rm SM})_{m_{\phi^0}}$ by using CalcHEP [80] with CTEQ6L [81] for the parton distribution functions (PDFs).

The signal and background analyses for these processes have been done in the MSSM in Refs. [82,83]. The signal significances for the processes expressed in Eqs. (30) and

[9]Regarding Eq. (31), the equation for $\phi^0=A$ holds when the bottom quark mass in the phase space function is neglected.

(31) are given in the case of $\tan\beta = 10$ and several fixed masses of A with the collision energy of 14 TeV and the integrated luminosity of 30 fb^{-1}. In Table III, the significance for each fixed value of m_A is listed, where $\mathcal{S}^{\phi^0}_{\rm MSSM}$ and $\mathcal{S}^{b\bar{b}\phi^0}_{\rm MSSM}$ are, respectively, the significances for the gluon fusion process and the bottom quark-associated process. These significances evaluated in the MSSM can be converted into those in the THDMs by using the equations

$$\mathcal{S}^{\phi^0}_{\rm THDM} = \mathcal{S}^{\phi^0}_{\rm MSSM} \times \frac{\sum_{\phi^0=H,A}\sigma(gg\to\phi^0)\times\mathcal{B}(\phi^0\to\tau^+\tau^-)|_{\rm THDM}}{\sum_{\phi^0=H,A}\sigma(gg\to\phi^0)\times\mathcal{B}(\phi^0\to\tau^+\tau^-)|_{\rm MSSM}} \times \sqrt{\frac{\mathcal{L}}{30\ {\rm fb}^{-1}}}, \tag{32}$$

$$\mathcal{S}^{b\bar{b}\phi^0}_{\rm THDM} = \mathcal{S}^{b\bar{b}\phi^0}_{\rm MSSM} \times \frac{\sum_{\phi^0=H,A}\sigma(gg\to b\bar{b}\phi^0)\times\mathcal{B}(\phi^0\to\tau^+\tau^-)|_{\rm THDM}}{\sum_{\phi^0=H,A}\sigma(gg\to b\bar{b}\phi^0)\times\mathcal{B}(\phi^0\to\tau^+\tau^-)|_{\rm MSSM}} \times \sqrt{\frac{\mathcal{L}}{30\ {\rm fb}^{-1}}}, \tag{33}$$

where $\mathcal{L}$ is the assumed integrated luminosity. In the above expression, when m_{ϕ^0} is taken in the range of $X \le m_{\phi^0} \le Y$, where X and Y are values of m_A listed in Table III, we use the values of $\mathcal{S}^{\phi^0}_{\rm MSSM}$ and $\mathcal{S}^{b\bar{b}\phi^0}_{\rm MSSM}$ given in the case with $m_A = X$. The combined significance is calculated by

$$\mathcal{S}_{\rm comb} = \sqrt{(\mathcal{S}^{\phi^0}_{\rm THDM})^2 + (\mathcal{S}^{b\bar{b}\phi^0}_{\rm THDM})^2}, \tag{34}$$

and the expected excluded region with the 95% C.L. is obtained by requiring $\mathcal{S}_{\rm comb} \ge 2$. In the following analysis, we assume $m_A = m_H$ and $\sin(\beta-\alpha) = 1$, and we sum over the processes in Eqs. (30) and (31) mediated by H and A. These assumptions are valid as long as we consider the case with $m_A \gtrsim 150$ GeV, because in the MSSM, $m_H \simeq m_A$ and $\sin(\beta-\alpha) \simeq 1$ are the good approximations in that case.

In Fig. 9, we show the expected excluded regions by using Eq. (34) in the type-II (left panel) and type-X (right panel) THDMs. The blue and red shaded regions are, respectively, the excluded regions assuming $\mathcal{L}$ to be 300 fb^{-1} and 3000 fb^{-1}. In the type-II THDM, the exclusion reach of m_A increases when a larger value of $\tan\beta$ is taken because the cross sections of the bottom quark-associated processes are enhanced due to the coefficient $\xi^b_H = \xi^b_A = \tan\beta$, and the branching fraction of $\phi^0 \to \tau^+\tau^-$ is approaching 10% in high $\tan\beta$ regions as shown in Figs. 4 and 5. On the other hand, in the type-X THDM, both the gluon fusion and the bottom quark-associated production cross sections are suppressed by $\cot^2\beta$ as $\tan\beta$ gets larger, while the branching fraction of $\phi^0 \to \tau^+\tau^-$ increases. Consequently, the cross section times branching ratio takes the maximal obtained at $\tan\beta \simeq 12$, and then $m_A \simeq 600$ GeV can be excluded assuming $\mathcal{L} = 3000$ fb^{-1}. When $\mathcal{L} = 300$ fb^{-1} is assumed, the excluded reach is settled to be 500 GeV in the region of $6 \lesssim \tan\beta \lesssim 20$ in spite of the fact that the cross section has the maximal value at around $\tan\beta = 12$. This can be understood in such a way that the quoted significance $\mathcal{S}^{\phi^0}_{\rm MSSM}$ given in Table III is changed at $m_A = 500$ GeV, and the combined significance $\mathcal{S}_{\rm comb}$ defined in Eq. (34) cannot exceed 2 even in the case with $\tan\beta \simeq 12$. This behavior should vanish by the detailed background analysis with smaller intervals of m_A.

TABLE III. Significance for the gluon fusion process $\mathcal{S}^{\phi^0}_{\rm MSSM}$ and the bottom quark-associated process $\mathcal{S}^{b\bar{b}\phi^0}_{\rm MSSM}$ in the MSSM with $\tan\beta = 10$ at the LHC with the collision energy of 14 TeV and the integrated luminosity of 30 fb^{-1} quoted from Refs. [82,83].

m_A (GeV)	150	200	300	400	450	500
$\mathcal{S}^{\phi^0}_{\rm MSSM}$ [83]	5.6	5.8	1.7	1.1		0.2
$\mathcal{S}^{b\bar{b}\phi^0}_{\rm MSSM}$ [82]	8.0		2.1		1.1	

This result is the updated version of Fig. 1.20 in the ILC Higgs White Paper [51]. In the previous figure, the excluded regions have been derived by using only one value of the significance for the gluon fusion and bottom quark-associated processes with $m_A = 150$ GeV from Ref. [82]. In the current version, we use several values of the significance as shown in Table III.

If we take $\sin(\beta-\alpha) \neq 1$, the contribution from H (A) can drastically decrease because the branching fraction of the $H(A) \to \tau^+\tau^-$ mode significantly decreases due to the $H \to VV$ and $H \to hh$ $(A \to hZ)$ modes as seen in Fig. 6. In such a case, the $H \to ZZ \to 4\ell$ and $A \to hZ \to b\bar{b}\ell\ell$ channels can be important instead of the $\tau^+\tau^-$ mode. In fact, these searches have been studied with the LHC data [4,14]. The performance of the HL-LHC has also been evaluated in Refs. [49]. These results show that masses of $\sim$1 TeV could be explored for $1-\kappa_V \gtrsim 10^{-2}$ with low $\tan\beta \lesssim 3$ [49]. Thus, the parameter space allowed by theoretical consistencies can be fully probed by future LHC data for $1-\kappa_V \gtrsim 10^{-2}$.

Next, we consider the Drell-Yan production;

$$pp \to Z^* \to HA. \tag{35}$$

For given values of the masses for H and A, this cross section is purely determined by the gauge coupling constant so that the cross section does not depend on the type

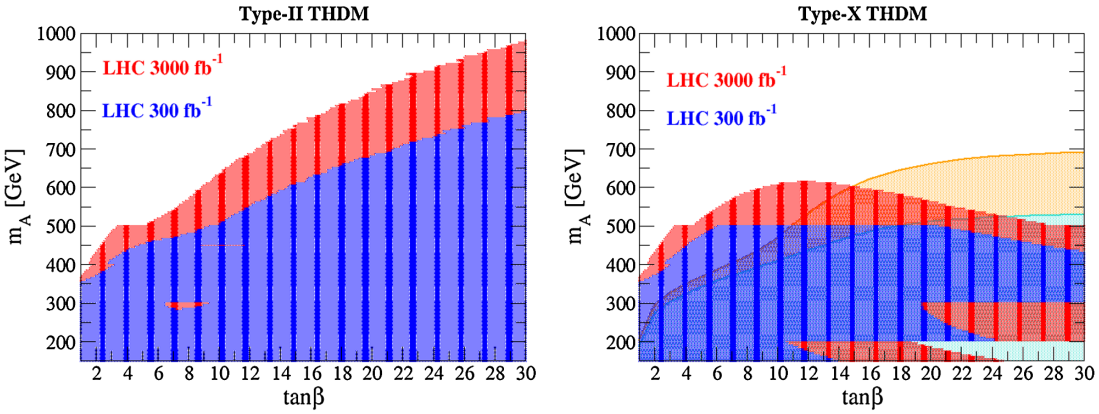

FIG. 9 (color online). Expected excluded regions on the $\tan\beta$-m_A plane at the 95% C.L. from the $gg \to \phi^0 \to \tau^+\tau^-$ and $gg \to b\bar{b}\phi^0 \to b\bar{b}\tau^+\tau^-$ processes by using Eqs. (33) and (34) in the case of $m_A = m_H$ and $\sin(\beta - \alpha) = 1$. The left and right panels show the results in the type-II and type-X THDMs, respectively. The blue (red) shaded regions are excluded regions assuming the integrated luminosity to be 300 fb^{-1} (3000 fb^{-1}). In the right panel, the constraint from the $q\bar{q} \to HA \to \tau^+\tau^-\tau^+\tau^-$ processes is also shown by the light colored regions in the type-X THDM.

of Yukawa interactions. When both H and A decay into the tau pairs, the 4-τ final state is obtained. The cross section of the 4τ process can be large in the type-X THDM as compared to the other three types of THDMs due to the enhancement of the branching fraction of $H/A \to \tau^+\tau^-$ for large $\tan\beta$ [40]. We thus focus on the 4τ signature from the HA production to test the type-X THDM in the following. Analyses on the $pp \to HH^\pm$ and $AH^\pm$ resulting the 3τ signature have been studied in Ref. [84], where the same order bounds on $m_{H^\pm}$ can be obtained.

We estimate the cross section by using the leading-order expression with the CTEQ6L PDFs [81], where the scale of them is set to $\mu = m_H$. The event rates of the $HA \to 4\tau$ signal are obtained by multiplying the production cross section by the branching ratios of H and A into $\tau^+\tau^-$. Furthermore, by using the kinematical distributions of the decay products of τ's that are calculated by PYTHIA [85] and TAUOLA [86], we estimate the efficiency of detecting the signal events after the acceptance and kinematical cuts given in Ref. [84] for all the final states leading from the decays of the four τ's, such as four τ jets, three τ jets plus one lepton, etc. The significance for detecting the $HA \to 4\tau$ process is estimated for a given value of the integrated luminosity, by combining the significance of all the channels in which each significance is evaluated as $S = \sqrt{2[(s+b)\ln(1+s/b) - s]}$ with s and b being the expected numbers of the signal and background events after the cuts, respectively.

In the right panel of Fig. 9, the expected exclusion regions are shown on the $\tan\beta$-m_A plane in the type-X THDM from the $pp \to HA \to 4\tau$ process. The cyan and orange shaded regions are excluded at the 95% C.L. assuming the integrated luminosity to be 300 fb^{-1} and 3000 fb^{-1}, respectively. The search potential is significantly improved for the large $\tan\beta$ regions due to the enhancement of the decay branching ratios of H and A into the $\tau^+\tau^-$ final state. For $\tan\beta \gtrsim 20$, the discovery regions arrive at around $m_A = 500$ GeV for 300 fb^{-1}, while those arrive at around 700 GeV for 3000 fb^{-1}.

We note that the τ-jet tagging efficiency shall worsen at the high-luminosity run of the LHC due to the participation of many hadrons in an event that prevents the isolation requirement in the τ-jet tagging procedure [87]. Therefore, the expected significance may be reduced for the channels with high τ-jet multiplicity, since the τ-jet tagging efficiency used in our analysis is based on the PYTHIA simulation; see Ref. [84]. Although we have not studied this issue seriously, it can be important at the high-luminosity run of the LHC.

In the end of this section, we would like to mention the direct search potential for H and A in the type-I and type-Y THDMs. In the type-I THDM, the Yukawa interactions for the additional Higgs bosons are getting weak for large $\tan\beta$, so it is difficult to generate new bosons via the Yukawa interaction. In type-Y THDM, only the down-type quark Yukawa interactions are enhanced by $\tan\beta$. Since the process $pp \to HX, AH(H, A \to b\bar{b})$ are enhanced for large $\tan\beta$, the cross section times the branching ratio are constrained [12]. The bounds are much weaker than those from $H/A \to \tau^+\tau^-$ decay channels in type-II and type-X THDMs. The analysis with data for high-luminosity running will push these bounds substantially.

Finally, we comment on the constraint from flavor experiments. It is well known that the mass of $H^\pm$ in the type-II THDM is severely constrained by the precise measurements of the $b \to s\gamma$ process [37,38,88,89], where the $H^\pm$ loops contribute to this process in addition to the W boson loop contribution. A lower bound has been found to be $m_{H^+} \gtrsim 380$ GeV (95% C.L.) in the type-II THDM at the next-to-next-to-leading order [89]. In the type-I THDM, the bound from $b \to s\gamma$ is important only in the case with low $\tan\beta$; namely, the bound on m_{H^+} is stronger than the Large Electron

TABLE IV. Expected precisions on the Higgs boson couplings and total width from a constrained seven-parameter fit quoted from Table 1–20 in Ref. [52].

Positron Collider bound of around 80 GeV [20] when $\tan\beta < 2.5$ is taken [89]. The type-Y and type-X THDMs receive similar constraints as in the type-II and type-I THDMs, respectively, because of the same structure of quark Yukawa interactions. Bounds from the other observables such as $B \to \tau\nu$ [90,91], $\tau \to \mu\nu\bar{\nu}$ [91,92], and the muon anomalous magnetic moment [93,94] have been discussed in the type-II THDM. In Ref. [95], constraints from various flavor experiments have been studied in the four types of Yukawa interactions of the THDM. Excluded parameter regions are shown on the m_{H^+}-$\tan\beta$ plane. The bound on m_{H^+} can be converted into that on the masses of neutral Higgs bosons from the electroweak precision data. Although such a constraint can be stronger than that from the direct search as shown in Fig. 9, it is important to search for additional Higgs bosons independently on the flavor experiments.

IV. PRECISION MEASUREMENTS FOR THE HIGGS BOSON COUPLINGS AND FINGERPRINTING EXTENDED HIGGS MODELS

In this section, we discuss the deviation in the SM-like Higgs boson couplings in the THDMs and also in the other models with universal Yukawa couplings. In a model with extended Higgs sectors, the Higgs boson couplings can deviate from the SM values as we already have discussed in Sec. II in the THDMs as an example. Therefore, extended Higgs sectors can be indirectly tested by measuring the deviation of various Higgs boson couplings. Furthermore, the pattern of the deviation strongly depends on the structure of the Higgs sector so that we can discriminate various Higgs sectors by comparing the predicted pattern of the deviations with the measured one.

We here define the scaling factors by normalizing the coupling constant of the SM Higgs boson that will be precisely determined by future collier experiments:

$$\mathcal{L} = \kappa_V h\left(\frac{n_W^2}{v} W^{+\mu} W_\mu^- + \frac{1}{2}\frac{m_Z^2}{v} Z^\mu Z_\mu\right) - \sum_f \kappa_f h \frac{m_f}{v} \bar{f} f. \tag{36}$$

These measured values should be compared with corresponding values in extended Higgs models. In the THDM, κ factors are given at the tree level by

$$\kappa_f = \xi_h^f, \qquad \kappa_V = \sin(\beta - \alpha), \tag{37}$$

where ξ_h^f are listed in Table II. We also discuss the other extended Higgs sectors with universal Yukawa coupling constants; i.e., κ_f for any fermion f are modified in the same way in the end of this section.

The scaling factors will be measured accurately at future collider experiments such as the HL-LHC and the ILC. In Table IV, we give a brief summary of expected sensitivities on the (SM-like) Higgs boson coupling constant at various future experiments. The ranges shown for the LHC and HL-LHC represent the conservative and aggressive scenarios for systematic and theory uncertainties. ILC numbers assume (e^-, e^+) polarizations of $(-0.8, 0.3)$ at 250 and 500 GeV and $(-0.8, 0.2)$ at 1000 GeV, plus a 0.5% theory uncertainty.

A. Higgs boson couplings in the THDMs

We first consider the deviations in the Higgs boson coupling constants in the THDMs. From Table II, it can be seen that all the four types of Yukawa interaction have different combinations of ξ_h^f for $f = u, d$, and e when $\sin(\beta - \alpha) \neq 1$. Therefore, the direction and magnitude of modifications for κ_f are different in four types of Yukawa interactions.

In Figs. 10 and 11, the scaling factors are shown for each type of Yukawa interaction in the THDMs as functions of κ_V^2 and $\tan\beta$. When κ_V^2 is determined, there still is a sign ambiguity for $\cos(\beta - \alpha)$. Thus, we separately plot model predictions for $\cos(\beta - \alpha) < 0$ in Fig. 10 and for $\cos(\beta - \alpha) > 0$ in Fig. 11. Note that the Higgs sector in the MSSM predicts a negative value of $\cos(\beta - \alpha)$. In the left (right) panels, the scaling factors of THDMs are given in the κ_d–κ_ℓ (κ_u–κ_ℓ) plane. Because of the simple scaling in Table II, the predictions in the κ_u–κ_d plane are obtained by interchanging the type-X and type-Y THDMs in the right panels. For illustration purposes only, we slightly shift lines along with

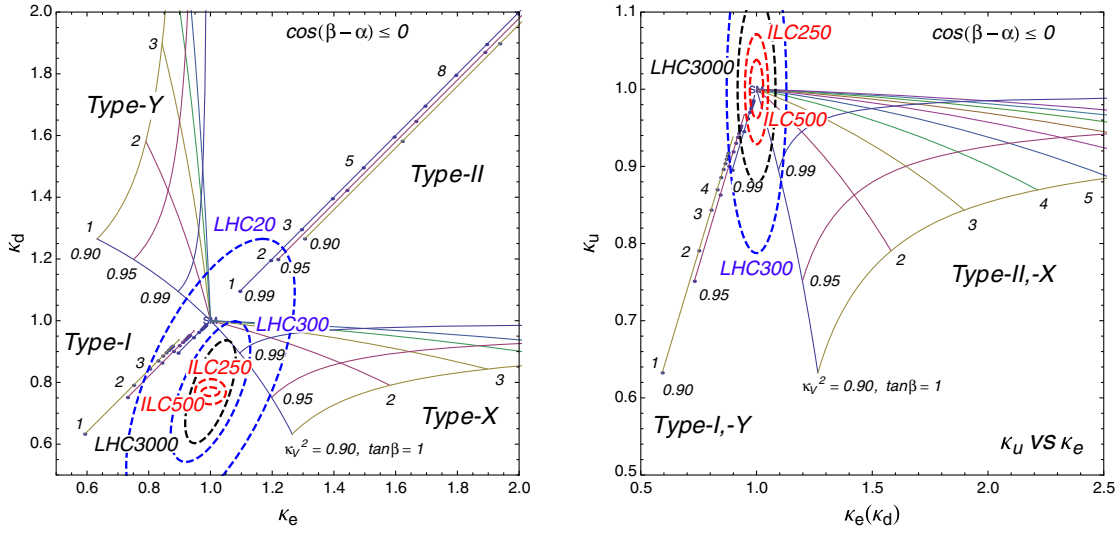

FIG. 10 (color online). The scaling factors for the Yukawa interaction of the SM-like Higgs boson in THDMs in the case of $\cos(\beta-\alpha) < 0$.

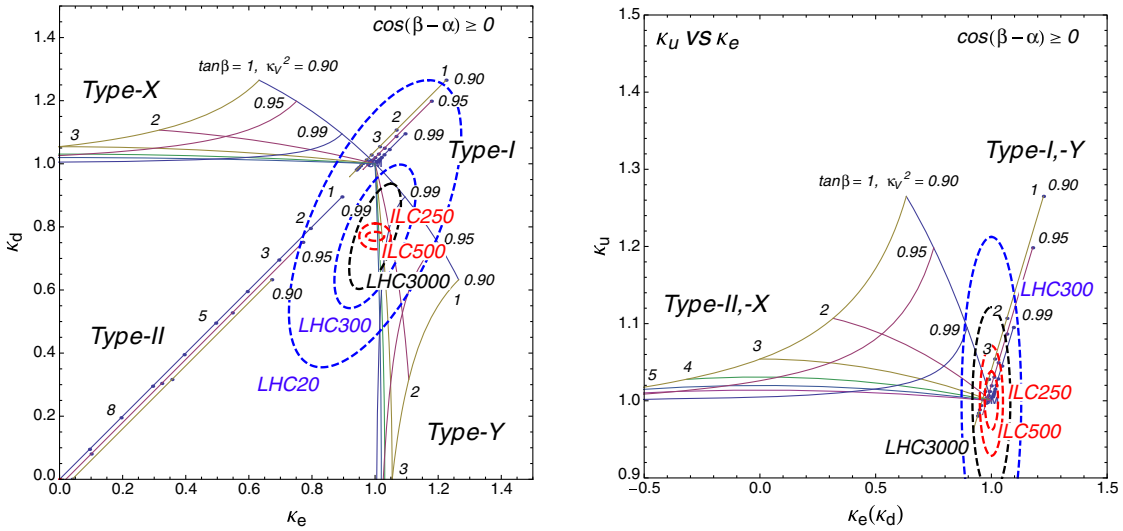

FIG. 11 (color online). The scaling factors for the Yukawa interaction of the SM-like Higgs boson in THDMs in the case of $\cos(\beta-\alpha) > 0$.

$\kappa_x = \kappa_y$ in order to show $\tan\beta$ dependence for fixed κ_V^2 to avoid confusion. The largest contour (LHC20) denotes the current LHC bound at the 68% C.L., where the central values and the correlations are taken from Ref. [64]. We also present the projection at the HL-LHC ($\sqrt{s} = 14$ TeV) with an integrated luminosity of 300 fb^{-1} (LHC300) and 3000 fb^{-1} (LHC3000), where the same central values and the correlations are adopted. The ILC prospects are also shown for ILC250 and ILC500, where the collision energy is 250 GeV and 500 GeV, and the integrated luminosity is 250 fb^{-1} and 500 fb^{-1}, respectively. Each of the THDMs predicts quite a different region, which can be discriminated by the precision measurement of the SM-like Higgs boson coupling constants.

We note that, through the precision measurement of the branching ratios of the SM-like Higgs boson, not only the discrimination of the type of Yukawa interaction but also the determination of $\tan\beta$ in an indirect way can be accomplished [96]. The later complements the determination of $\tan\beta$ by using additional Higgs boson production directly [97].

B. Models with universal Yukawa couplings

We consider Higgs sectors with a universal shift in the Yukawa coupling constants. Such a situation can be realized in a Higgs sector composed of only one doublet field, e.g., a model with a scalar doublet plus singlets,

triplets, and higher isospin multiplets, or in a Higgs sector with multidoublet fields but only one of them giving all the fermion masses, e.g., the type-I THDM. In the following, we first discuss the doublet-singlet model, the type-I THDM, and the doublet-septet model, and then we consider the GM model as models with $\rho_{\text{tree}} = 1$. We note that these extended Higgs sectors can predict larger deviations in the hVV couplings as compared to those in models with $\rho_{\text{tree}} \neq 1$ because an amount of the deviation depends on an additional VEV for which the magnitude is constrained by the rho parameter if it causes $\rho_{\text{tree}} \neq 1$.

In the doublet-singlet model and the soublet-septet model, an isospin singlet field with $Y = 0$ and an isospin septet field with $Y = 2$ are contained, respectively, in addition to the doublet scalar field Φ with $Y = 1/2$. The type-I THDM was already defined in Sec. II. From Eq. (2), a VEV from the additional scalar multiplet does not change ρ_{tree} from the SM value.

Except the VEV of the singlet scalar field, all the VEVs from the additional Higgs multiplet v_{ext} contribute to the electroweak symmetry breaking. They satisfy $v^2 = v_0^2 + (\eta_{\text{ext}} v_{\text{ext}})^2$, where v_0 is the VEV of Φ and $\eta_{\text{ext}} = 1$ and 4 in the type-I THDM and the doublet-septet model, respectively. It is convenient to define the ratio of the VEVs as $\tan\beta = v_0/(\eta_{\text{ext}} v_{\text{ext}})$.

There are two CP-even scalar states in these three models, and they are mixed with the angle α as

$$\begin{pmatrix} h_{\text{ext}} \\ h_0 \end{pmatrix} = R(\alpha) \begin{pmatrix} H \\ h \end{pmatrix}, \tag{38}$$

where h_0 and h_{ext} denote the CP-even scalar components from Φ and an additional scalar multiplet, respectively. The h and H fields are the mass eigenstates, and we assume that h is the observed Higgs boson with the mass of about 126 GeV.

Next, we discuss the GM model for which the Higgs sector is composed of a real ($Y = 0$) and a complex ($Y = 1$) triplet scalar field in addition to Φ. When the VEVs of two triplet fields are aligned to be the same ($= v_{\text{ext}}$), $\rho_{\text{tree}} = 1$ is satisfied, where the contributions to the deviation in ρ_{tree} from unity by the triplet VEVs are cancelled with each other. The value of η_{ext} defined in the above is given as $2\sqrt{2}$.

In the GM model, there are three CP-even scalar states from Φ and two triplets. They are mixed with each other as [98]

$$\begin{pmatrix} \xi_r \\ h_0 \\ \chi_r \end{pmatrix} = \begin{pmatrix} 0 & \frac{1}{\sqrt{3}} & -\sqrt{\frac{2}{3}} \\ 1 & 0 & 0 \\ 0 & \sqrt{\frac{2}{3}} & \frac{1}{\sqrt{3}} \end{pmatrix} \times \begin{pmatrix} \cos\alpha & -\sin\alpha & 0 \\ \sin\alpha & \cos\alpha & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} H \\ h \\ H_5 \end{pmatrix}, \tag{39}$$

where ξ_r and χ_r are, respectively, the CP-even scalar components in the $Y = 0$ and $Y = 1$ triplet Higgs fields and H_5 is the neutral component of the custodial SU(2) 5-plet Higgs boson.

In Table V, we list the scaling factors κ_f and κ_V in terms of α and β in the four models. In the doublet-singlet model, κ_f and κ_V have the same expression $\cos\alpha$ because both the Yukawa interaction and the gauge interaction originate from the doublet Higgs field, and they are suppressed by the same origin, i.e., the mixing between doublet and singlet fields.

In the type-I THDM, both the Yukawa couplings and the gauge couplings are suppressed by κ_f and κ_V, respectively. However, $\kappa_f \neq \kappa_V$ is generally allowed unlike the doublet-singlet model. We have already mentioned in Sec. II A that we can take the SM-like limit by $\sin(\beta - \alpha) \to 1$, where both κ_f and κ_V become unity. A similar limit can be defined in the doublet-singlet model by taking $\alpha \to 0$.

In the GM model and the doublet-septet model, the VEV of the additional multiplet affects the electroweak symmetry breaking in a different way from that by the doublet Higgs field; i.e., η_{ext} in the GM model and the doublet-septet model are different in the type-I THDM. As a result, κ_V can be larger than 1 (see Table V). This is a unique feature to identify these models. Furthermore, the limit of $\kappa_f \to 1$ and $\kappa_V \to 1$ is taken by setting $\beta = 0$ and $\alpha = -\pi/2$, which corresponds to the special case in the type-I THDM.

In Fig. 12, we show predictions of the scaling factors κ_f and κ_V for each value of α and β in the models with universally modified Yukawa couplings. If we vary α and β,

TABLE V. The fraction of the VEVs $\tan\beta$ and the scaling factors κ_f and κ_V in the extended Higgs sectors with universal Yukawa couplings.

Model	$\tan\beta$	κ_f	κ_V
Doublet-singlet	$\cdots$	$\cos\alpha$	$\cos\alpha$
Type-I THDM	v_0/v_{ext}	$\cos\alpha/\sin\beta = \sin(\beta-\alpha) + \cot\beta\cos(\beta-\alpha)$	$\sin(\beta-\alpha)$
GM	$v_0/(2\sqrt{2}v_{\text{ext}})$	$\cos\alpha/\sin\beta$	$\sin\beta\cos\alpha - \frac{2\sqrt{6}}{3}\cos\beta\sin\alpha$
Doublet-septet	$v_0/(4v_{\text{ext}})$	$\cos\alpha/\sin\beta$	$\sin\beta\cos\alpha - 4\cos\beta\sin\alpha$

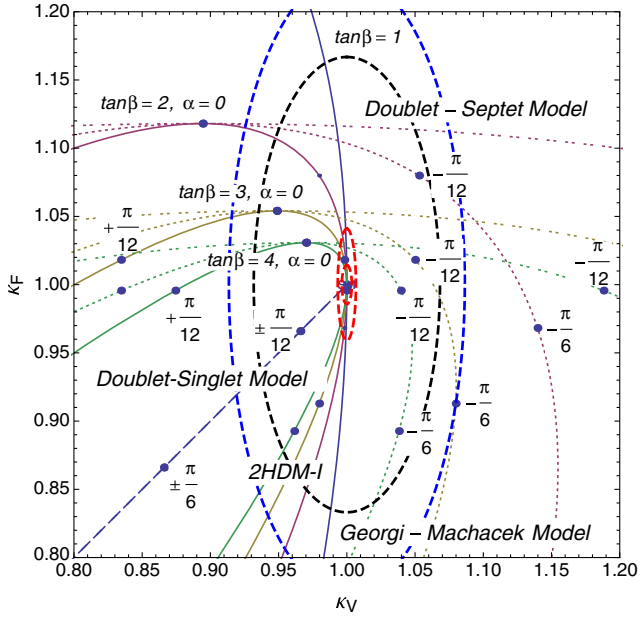

FIG. 12 (color online). The scaling factors κ_f and κ_V in models with universal Yukawa coupling constants.

a model-dependent area (line), which is a distinctive prediction of the models, is drawn. Note that predictions are the same at $\alpha = 0$ in the type-I THDM, the GM model, and the doublet-septet model. From the current LHC data, the scaling factors are obtained at about 20% accuracy at 1σ. It is not sufficient to distinguish these models at this moment. Improvements of the (SM-like) Higgs boson coupling measurements at the HL-LHC and also at the ILC may resolve model predictions.

V. DISCUSSIONS

We here discuss complementarity of precision measurements of the coupling constants of the discovered Higgs boson h and direct searches of additional Higgs bosons at the LHC. In addition, we also discuss the importance of direct searches of additional Higgs bosons at the ILC. A key role is taken by the deviation in the coupling constant of h to weak gauge bosons from the SM prediction, $\delta\kappa_V = 1 - \kappa_V$. When nonzero $\delta\kappa_V$ is found at future colliders, that is identified as an evidence of nonstandard effects mainly due to additional Higgs bosons. By combining the theoretical constraints from perturbative unitarity and vacuum stability, we obtain the upper limit of the energy scale at which evidence of nonstandard Higgs sectors should appear. We first discuss the complementarity in the THDMs and then in the other models later.

For $\delta\kappa_V \gtrsim 5\%$, which is the expected accuracy at the LHC with 300 fb^{-1} [50–52], m_A should be less than about 700 GeV from the conditions of perturbative unitarity and vacuum stability under the assumptions of $m_{H^+} = m_A$ with varying M and m_H in the $m_A \pm 500$ GeV range. In such a case, it is expected that the LHC direct search can find evidence of additional Higgs bosons simultaneously. For $m_A \lesssim 500$ GeV, direct production at the ILC experiment with $\sqrt{s} = 1$ TeV will also be useful to explore the properties of additional Higgs bosons [59]. On top of above, the precision measurement of the couplings of h at the ILC will be the most powerful tool to discriminate types of Yukawa interaction as shown in Figs. 10 and 11.

For $\delta\kappa_V \gtrsim 0.4\%$, which is the expected accuracy at the ILC with $\sqrt{s} = 500$ GeV and $\mathcal{L} = 500$ fb^{-1} [50–52], m_A should be less than 1 TeV from the conditions of perturbative unitarity and vacuum stability under the assumptions of $m_{H^+} = m_A$ with varying M and m_H in the $m_A \pm 500$ GeV range. In such a case, there is a possibility that the direct search at the LHC cannot find any evidence of additional Higgs bosons. In other words, the LHC direct search combined with the constraints from perturbative unitarity and vacuum stability cannot exclude the extended Higgs sector that predicts $\delta\kappa_V \lesssim 0.4\%$. At the ILC, at least the precision measurement of the couplings of h can indicate evidence of the extended Higgs sector. Even in such a situation, as we have shown in the last section, the model discrimination and parameter determination will be still possible by using only the fingerprinting of the deviation of the couplings of h. Furthermore, an upper limit of the mass scale of additional Higgs bosons can be set by the constraints from perturbative unitarity and vacuum stability, while the lower limit is given by the direct search at the LHC. Therefore, we could conclude the existence of the nonstandard Higgs sector at a certain energy scale. This energy scale will be crucial information to design next-generation future colliders.

The accuracy of the $\delta\kappa_V$ measurement can be improved at the ILC with 1 TeV and 1 ab^{-1}, and the indirect upper limit of the mass scale can be slightly extended accordingly. For $\delta\kappa_V \lesssim 0.2\%$, which is beyond the accuracy of the coupling measurement of h at the ILC with $\sqrt{s} =$ 1 TeV and $\mathcal{L} = 1$ ab^{-1} [50–52], the upper limit of the mass scale cannot be obtained from the conditions of perturbative unitarity and vacuum stability. In this case, we cannot separate the extended Higgs sector from the SM from the coupling measurements of h. Therefore, the decoupling limit of the extended Higgs sector cannot be excluded. There are possibilities that the additional Higgs bosons can be discovered at the LHC or the ILC, since the small deviation in κ_V does not necessarily mean the large mass of additional Higgs bosons in the extended Higgs sector. We note that the direct production of additional Higgs bosons at the LHC and the ILC also have the power to discriminate the models of extended Higgs sectors, such as the type of Yukawa sector in the THDMs [59], etc.

To compare the precisely measured values of the Higgs boson couplings, precise calculations in each given model are essentially important. One-loop corrections to the hVV coupling constants have been calculated in Ref. [66], and

those to $hf\bar{f}$ coupling constants have been calculated in Ref. [99] in the THDM. Magnitudes of these corrections due to the additional Higgs boson loops are respectively given to be maximally about 1% and 5% for the hVV and $hf\bar{f}$ couplings under the constraint from perturbative unitarity and vacuum stability. Therefore, the pattern of the deviations in the $hf\bar{f}$ shown in Figs. 10 and 11 does not change even including radiative corrections. However, if the $hf\bar{f}$ couplings are determined with an order of 1% accuracy under the situation in which the deviation in hVV couplings is also found, we may be able to determine not only the type of Yukawa interactions but also some inner parameters such as M^2 in the THDMs. In addition to the hVV and $hf\bar{f}$ couplings, one-loop corrections to the hhh coupling, for which the amount can be significant due to the nondecoupling effect of the additional Higgs bosons, are also important. In Refs. [66,100], it has been shown that the size of the correction can be $\mathcal{O}(100)\%$ under the constraint from perturbative unitarity [68] and vacuum stability [69,70]. By studying the correlation among the deviations in the hhh [66,100], $h\gamma\gamma$ [61,101–103], and $hZ\gamma$ [103,104] couplings from the SM predictions, we can extract properties of additional Higgs bosons running in the loop such as the electric charge, the isospin, and the nondecoupling nature.

Finally, we mention models other than the THDMs. In the doublet-singlet model [60], both the hVV and $hf\bar{f}$ coupling constants are suppressed by the same factor. Therefore, $\kappa_V = \kappa_f < 1$ can be indirect evidence for this model. Detection of an additional CP-even scalar boson, for which the Yukawa and gauge interactions are given only from the mixing with the doublet Higgs field, can be a direct search for the model. The GM model [22] and the doublet-septet model [61–63] have a unique pattern of the deviation in the Higgs boson couplings; namely, κ_V can be larger than unity [63], which is a crucial property to identify these models. In addition, multicharged, e.g., doubly charged, Higgs bosons can significantly contribute to the deviation in the loop-induced $h\gamma\gamma$ and $hZ\gamma$ couplings. When multicharged scalar bosons are discovered, it can be a direct test of these models. Phenomenology of such additional scalar bosons has been discussed in the GM model [105–107] and in the doublet-septet model [108] at the LHC. Measuring the $H^{\pm}W^{\mp}Z$ vertex [77,78] is also an important probe as discussed in Sec. II C.

In this paper, we concentrate on the models with $\rho_{\text{tree}} = 1$. However, we here shortly comment on the Higgs triplet model (HTM) as an important example for models with $\rho_{\text{tree}} \neq 1$, because it is deduced from the type-II seesaw mechanism [109]. In the HTM, although deviations in the hVV and $hf\bar{f}$ couplings cannot be so large due to the constraint from the rho parameter, those in the loop-induced $h\gamma\gamma$ [110–113] and $hZ\gamma$ [111–113] couplings can be significant by the doubly charged Higgs boson $H^{\pm\pm}$ loop. The one-loop corrections to the hhh coupling can also be large as calculated in Refs. [27,114] due to the nondecoupling effect of additional Higgs bosons similarly to the THDM. The correlation among the deviations in the decay rate of $h \to \gamma\gamma$ and the hhh coupling constants[10] from the SM values have been investigated in Ref. [27]. A direct search for $H^{\pm\pm}$ can be an important clue to test the model with the $Y = 1$ triplet field, which can decay into the same-sign dilepton [115–120] and the same-sign diboson [121,122] depending on the magnitude of the triplet VEV.[11]

VI. CONCLUSIONS

We have discussed the determination of the extended Higgs sector by combining the direct and indirect searches for additional Higgs bosons at future collider experiments. Direct searches of the additional Higgs bosons provides the clear evidence for extended Higgs sectors. Focusing on the THDM with the softly broken Z_2 symmetry, we have studied the expected exclusion regions in the m_A-$\tan\beta$ plane at the LHC with the 14 TeV run with 300 fb^{-1} and 3000 fb^{-1} data. For the neutral Higgs boson searches, we have shown that the mass scale up to several hundreds GeV to TeV can be explored at the LHC, depending on the type of Yukawa interaction and parameters such as $\tan\beta$ and $\sin(\beta - \alpha)$. For the indirect searches of additional Higgs bosons via coupling constants of the SM-like Higgs bosons, we have considered various models for the extended Higgs sector, such as the THDMs with four types of Yukawa interactions, the doublet-singlet model, the doublet-septet model, and the GM model, as typical models that predict $\rho_{\text{tree}} = 1$. We have demonstrated that there exists a variety of patterns in the deviations in the SM-like Higgs boson couplings to the gauge bosons and fermions from the SM prediction depending on the structure of the Higgs sector. Therefore, we can fingerprint the nonminimal Higgs sector by detecting the pattern of deviations in an excellent precision at future colliders.

Taking into account the theoretical constraints on the model, such as perturbative unitarity and vacuum stability, the complementarity between the direct searches and the indirect searches can be understood to identify the nonminimal Higgs sector. Observation of the deviation in the coupling constant of the SM-like Higgs boson to the weak gauge bosons plays a key role, which also affects the strategy of the direct search of additional Higgs bosons at colliders. First of all, we have to keep in mind that there exists a decoupling limit in extended

[10]The deviation in the hhh coupling at the tree level is much suppressed by the triplet VEV similar to the hVV and $hf\bar{f}$ as mentioned above.

[11]If there is a mass difference between $H^{\pm\pm}$ and the singly charged scalar components, the cascade decay of $H^{\pm\pm}$ associated with the W boson is possible [123].

Higgs sectors in the limit of $\delta\kappa_V \to 0$, where the SM is a good description as a low-energy effective theory up to much higher scales than the electroweak scale. On the other hand, if a relatively large deviation of $\delta\kappa_V$ is observed, the mass scale of the additional Higgs bosons is bounded from the above by using the argument of perturbative unitarity and vacuum stability so that the direct discovery of them can be highly expected. If a small deviation is observed at the ILC, the direct discovery of the additional Higgs boson can be difficult. Even in such a situation, the fingerprinting of the SM-like Higgs boson couplings can be a solid and powerful tool to explore the extended Higgs sector.

ABSTRACT

When the doubly-charged Higgs bosons $H^{\pm\pm}$ mainly decay into the same-sign dilepton, a lower bound on the mass is around 400 GeV by the current LHC data. On the other hand, no such bound has been reported by using the data at LEP and at the LHC for the case where the same-sign diboson decay $H^{\pm\pm} \to W^{\pm(*)}W^{\pm(*)}$ is dominant. We study limits on the mass for such a case by using the current experimental data. From the precise measurement of the total width of the Z boson at the LEP experiment, the mass below 43 GeV is excluded with the 95% confidence level. It turns out that the results from four charged-lepton searches at LEP do not provide any significant constraint. We show that a new lower bound is obtained in the diboson decay scenario at the LHC with the collision energy to be 7 TeV and the integrated luminosity to be 4.7 fb^{-1}. By using the data of the same-sign dilepton events, the lower limit is found to be 60 GeV at the 95% confidence level. By the extrapolation of the data to 20 fb^{-1} with the same collision energy, the lower limit is evaluated to be 85 GeV.

A Higgs boson has been discovered with the mass around 126 GeV in the diphoton and the four lepton channels at the LHC [1]. Observed properties of the boson are consistent with those of the Higgs boson predicted in the standard model (SM). However, this fact does not necessarily mean that the Higgs sector is the minimal one assumed in the SM. There is no fundamental principle for such a form with an isospin doublet scalar field. In fact, extended Higgs sectors with more scalar fields are often introduced in new physics models beyond the SM, which are motivated to explain phenomena such as neutrino oscillation [2,3], the existence of dark matter [4] and the baryon asymmetry of the Universe [5]. The SM-like Higgs boson can also appear in these extended Higgs sectors. Therefore, by exploring the extra Higgs bosons at collider experiments, the structure of the Higgs sector can be determined, and thereby the new physics model can be probed.

The Higgs triplet model (HTM) is one of the simple but important extended Higgs sectors. It can provide the origin of tiny neutrino masses with the type-II seesaw mechanism [2]. The Higgs sector is composed of an isospin triplet field (Δ) with hypercharge $Y = 1$ and a doublet field (Φ) with $Y = 1/2$. The generated neutrino masses are proportional to the vacuum expectation value (VEV) of the triplet field v_Δ. It is well known that v_Δ is constrained to be much smaller than the VEV of the doublet field v_ϕ by the electroweak precision data at the LEP/SLC experiments [6]. One of the striking features of the model is the appearance of the doubly- ($H^{\pm\pm}$) and singly-charged ($H^{\pm}$) Higgs bosons in addition to two CP-even Higgs bosons (h and H) and the CP-odd Higgs boson (A). The discovery of these particles, especially $H^{\pm\pm}$, is essentially important to identify the model.

These additional Higgs bosons can be produced by collider experiments if kinematically accessible [7–11]. The main decay mode of $H^{\pm\pm}$ strongly depends on v_Δ. They decay into the same-sign dilepton when v_Δ is smaller than about 0.1 MeV, which can be a clear signature for the discovery. Searches for $H^{\pm\pm}$ have been performed at LEP, Tevatron and the LHC. Since $H^{\pm\pm}$ have not been discovered yet, lower limits for the mass of $H^{\pm\pm}$ are obtained to be 409 GeV, 398 GeV and 375 GeV in the case where the branching fraction of $H^{\pm\pm} \to e^\pm e^\pm$, $H^{\pm\pm} \to \mu^\pm\mu^\pm$ and $H^{\pm\pm} \to e^\pm\mu^\pm$ are respectively assumed to be 100% [12]. On the contrary, when v_Δ is much greater than 0.1 MeV, the decays into diboson $H^{\pm\pm} \to W^{\pm(*)}W^{\pm(*)}$ are dominant.[1] They can be identified by the same-sign dilepton with the missing energy signature via the leptonic decay of the W bosons. Although this scenario is equivalently important to the case of the dilepton decay from the theoretical point

[1] When $H^\pm$ is lighter than $H^{\pm\pm}$, the main decay mode of $H^{\pm\pm}$ is $H^{\pm\pm} \to W^{\pm(*)}W^{\pm(*)}$ or $H^{\pm\pm} \to W^{\pm *}H^\pm$, depending on the mass difference and v_Δ [10,11].

of view [8,9], to our knowledge no substantial bound has been reported for the $H^{\pm\pm}$ search via the decay of $H^{\pm\pm} \to W^{\pm(*)}W^{\pm(*)}$.

In this Letter, we discuss limits on the mass for the case of the diboson decay scenario by using the current data at LEP and the LHC. First, we consider the constraint from the precise measurement of the total width of the Z boson at the LEP experiment [13], and then we evaluate the lower limit for the mass of $H^{\pm\pm}$ by using the data of the same-sign dilepton events at the LHC with the collision energy to be 7 TeV and the integrated luminosity to be 4.7 fb^{-1} [14]. Finally, we extrapolate the results for the limit with the 20 fb^{-1} data.

The most general potential in the HTM is given by

$$\begin{aligned} V =& m^2\Phi^\dagger\Phi + M^2\,\mathrm{Tr}\big(\Delta^\dagger\Delta\big) + \big[\mu\Phi^T i\tau_2\Delta^\dagger\Phi + \mathrm{h.c.}\big] \\ &+ \lambda_1\big(\Phi^\dagger\Phi\big)^2 + \lambda_2\big[\mathrm{Tr}\big(\Delta^\dagger\Delta\big)\big]^2 + \lambda_3\,\mathrm{Tr}\big[\big(\Delta^\dagger\Delta\big)^2\big] \\ &+ \lambda_4\big(\Phi^\dagger\Phi\big)\,\mathrm{Tr}\big(\Delta^\dagger\Delta\big) + \lambda_5\Phi^\dagger\Delta\Delta^\dagger\Phi. \end{aligned} \tag{1}$$

The scalar fields Φ and Δ can be parameterized as

$$\Phi = \begin{bmatrix} \phi^+ \\ \frac{1}{\sqrt{2}}(\phi + v_\phi + i\chi) \end{bmatrix}, \qquad \Delta = \begin{bmatrix} \frac{\Delta^+}{\sqrt{2}} & \Delta^{++} \\ \Delta^0 & -\frac{\Delta^+}{\sqrt{2}} \end{bmatrix}, \tag{2}$$

with $\Delta^0 = (\delta + v_\Delta + i\eta)/\sqrt{2}$. The VEVs satisfy $v^2 \equiv v_\phi^2 + 2v_\Delta^2 = (\sqrt{2}G_F)^{-1} = (246\ \mathrm{GeV})^2$, where G_F is the Fermi constant. The mass eigenstates of the physical scalar bosons are obtained by introducing the mixing angles α, β and β', and their formulae are expressed in terms of the parameters in the potential [15].

The electroweak rho parameter is predicted to deviate from unity in the HTM by $\rho \simeq 1 - 2v_\Delta^2/v^2$. Since the experimental value of the rho parameter is close to unity; i.e., $\rho_{\mathrm{exp}} = 1.0004^{+0.0003}_{-0.0004}$ [13], v_Δ must be less than about 3.5 GeV at 95% confidence level (CL). Under $v_\Delta \ll v$, six physical scalar states; $H^{\pm\pm}$ ($= \Delta^{\pm\pm}$), $H^\pm$, A and H are almost composed of the component scalar fields from Δ, so that we call them as the triplet-like Higgs bosons. On the other hand, h can be regarded as the SM-like Higgs boson.

The mass difference between $H^{\pm\pm}$ and $H^\pm$ is given by

$$m_{H^{++}}^2 - m_{H^+}^2 \simeq m_{H^+}^2 - m_H^2 \simeq -\frac{\lambda_5}{4}v^2, \tag{3}$$

with $m_A^2 \simeq m_H^2$. There are three patterns of the mass spectrum for the triplet-like Higgs bosons. In the case with $\lambda_5 = 0$, all the triplet-like Higgs bosons are degenerate in mass. On the other hand, in the case of $\lambda_5 > 0$ ($\lambda_5 < 0$), the mass spectrum is $m_A > m_{H^+} > m_{H^{++}}$ ($m_{H^{++}} > m_{H^+} > m_A$). We call this mass spectrum as Case I (Case II) [11].

Neutrino masses can be deduced via v_Δ as [2]

$$(\mathcal{M}_\nu)_{ij} = \sqrt{2}h_{ij}v_\Delta, \tag{4}$$

where the Yukawa coupling constants h_{ij} are defined by

$$\mathcal{L}_Y = h_{ij}\overline{L_L^{ic}}i\tau_2\Delta L_L^j + \mathrm{h.c.} \tag{5}$$

Eq. (4) tells us that the magnitude of the Yukawa coupling h_{ij} is determined by a fixed value of v_Δ, because the value of the left-hand side of the equation is given from neutrino data [13].

The decay property of $H^{\pm\pm}$ strongly depends on v_Δ and the mass spectrum of the triplet-like Higgs bosons. When we consider the degenerate case or Case I, the dominant decay modes are $H^{\pm\pm} \to \ell^\pm\ell^\pm$ or $H^{\pm\pm} \to W^{\pm(*)}W^{\pm(*)}$ in the case of $v_\Delta \lesssim 0.1$ MeV or $v_\Delta \gtrsim 0.1$ MeV, respectively. On the other hand, in Case II, above two main decay modes can be replaced by the cascade decay mode; i.e., $H^{\pm\pm} \to W^{\pm*}H^\pm \to W^{\pm*}W^{\pm*}H/A$.

We here focus on the scenario where $H^{\pm\pm} \to W^{\pm(*)}W^{\pm(*)}$ are dominant, so that we consider Case I or the degenerate case with $v_\Delta \gtrsim 0.1$ MeV. We then discuss the bound for $m_{H^{++}}$ by using the current experimental data.

The LEP experiment was operated with the electron–positron collision energy to be at the Z boson mass (LEP I) and to be up to about 209 GeV (LEP II).

From the LEP I experiment, the total width of the Z boson has been precisely measured, and it can be used to constrain $m_{H^{++}}$ whose value is smaller than the half of m_Z, independently of the decay modes of H^{++}. The total decay width of the Z boson receives the sizable correction from the partial width for this decay mode as

$$\Gamma_{Z\to H^{++}H^{--}} = \frac{G_F m_Z^3}{6\pi\sqrt{2}}\big(1 - 2s_W^2\big)^2\left(1 - \frac{4m_{H^{++}}^2}{m_Z^2}\right)^{\frac{3}{2}},$$

where s_W is the sine of the weak mixing angle. Using the current experimental data for the Z boson width, $\Gamma_Z(\mathrm{exp}) = 2.4952 \pm 0.0023$ GeV, and the SM prediction, $\Gamma_Z(\mathrm{SM}) = 2.4960 \pm 0.0002$ GeV [13], we obtain the lower bound for $m_{H^{++}}$ to be 42.9 GeV with the 95% CL.

Because there is no study to directly search for the same-sign diboson signal at the LEP II experiment, we here employ the results for the four charged-lepton mode $e^+e^- \to Z^*/\gamma^* \to \ell^+\ell^+\ell^-\ell^-$ [16] in order to get bounds on $m_{H^{++}}$. The upper bound on the number of anomalous events can be applied to the case of the same-sign diboson decay scenario; i.e., $e^+e^- \to H^{++}H^{--} \to W^{+(*)}W^{+(*)}W^{-(*)}W^{-(*)}$. Because of the suppression of the signal cross section by the fourth power of the leptonic branching fraction of $W^\pm$, no substantial bound for $m_{H^{++}}$ can be obtained by using the data from Ref. [16].

Consequently, the Γ_Z measurement gives a bound $m_{H^{++}} > 43$ GeV from the LEP I data. On the other hand, no bound is obtained from the four charged-lepton data at LEP II in our scenario. By carefully analyzing the hadronic events, a better bound could be obtained.

Let us consider whether the mass bound can be taken or not by using the current LHC data. The main production mode for $H^{\pm\pm}$ at the LHC is the pair production $pp \to \gamma^*/Z^* \to H^{++}H^{--}$ and the associated production $pp \to W^{\pm*} \to H^{\pm\pm}H^\mp$. The production cross sections for both the vector boson fusion $qQ \to q'Q'H^{\pm\pm}$ and the weak boson associated production $qQ \to W^{\pm*} \to H^{\pm\pm}W^\mp$ are proportional to v_Δ^2, so that these modes are less significant because of $v_\Delta \ll v$. We note that there is the other production mechanism $qQ \to q'Q'H^{\pm\pm}A/H$ which is the unique process whose difference of the electric charge between produced scalar bosons is two. However, the cross section of this mode is small.

The signal processes are expected to be as follows:

$$\begin{aligned} &pp \to H^{++}H^{--} \to W^+W^+W^-W^- \to \ell^\pm\ell^\pm\not{E}_T + X, \\ &pp \to H^{\pm\pm}H^\mp \to W^\pm W^\pm + X \to \ell^\pm\ell^\pm\not{E}_T + X. \end{aligned} \tag{6}$$

The signal cross section before taking any kinematical cuts can be estimated by

$$\begin{aligned} \sigma\big(\ell^\pm\ell^\pm\not{E}_T + X\big) =& \big[\sigma\big(H^{++}H^{--}\big) + \sigma\big(H^{\pm\pm}H^\mp\big)\big] \\ &\times \mathrm{BR}\big(H^{\pm\pm} \to \ell^\pm\ell^\pm\nu\nu\big), \end{aligned} \tag{7}$$

where $\ell^\pm$ denote $e^\pm$ or $\mu^\pm$. The signal cross section of inclusive H^{++} (H^{--}) production is evaluated to be 0.72 (0.52) pb at the leading order assuming $m_{H^{\pm\pm}} = m_{H^\pm} = 100$ GeV with the collision energy to be 7 TeV. The branching ratio of the $H^{\pm\pm}$ decay can be calculated as a square of that of $W^\pm$ for $m_{H^{\pm\pm}} > 2m_W$. However, it

Table 1
Signal cross sections of the process in Eq. (6) for the $\mu^+\mu^+$ channel for fixed values of $m_{H^{++}}$ in each step of the kinematic cuts. The decay width of $H^{\pm\pm}$ is calculated in the case of $v_\Delta = 1$ GeV for reference.

$m_{H^{++}}$ [GeV]	40	50	60	70	80	90	100
Width [eV]	3.58×10^{-4}	1.89×10^{-3}	7.70×10^{-3}	2.69×10^{-2}	8.63×10^{-2}	0.320	1.86
Basic cut [fb]	20.9	16.7	13.0	10.1	7.63	4.95	2.78
$M_{\ell\ell}$ cut [fb]	16.3	14.8	12.2	9.69	7.45	4.87	2.74

is no longer valid for $m_{H^{\pm\pm}} < 2m_W$, because at least one of the W bosons is off-shell. For $m_{H^{\pm\pm}} < 2m_W$, the branching ratios of the same-flavor dilepton decays are enhanced due to the interference of crossing diagrams.

We here consider the bound for $m_{H^{++}}$ in the diboson decay scenario by using the results of the same-sign dilepton search reported by the ATLAS Collaboration [14] with the collision energy to be 7 TeV and the integrated luminosity to be 4.7 fb^{-1}. The 95% CL upper limit N_{95} for the event number of the process including the same-sign dilepton in the final states is listed in Ref. [14]. The limit is separately given into $e^\pm e^\pm$, $\mu^\pm\mu^\pm$, and $e^\pm\mu^\pm$ channels after imposing the several choices of the invariant mass cuts for the same-sign dilepton system. The 95% CL limit for the fiducial cross section $\sigma_{95}^{\rm fid}$ is obtained by

$$\sigma_{95}^{\rm fid} = \frac{N_{95}}{\int \mathcal{L}\,dt \times \varepsilon_{\rm fid}}, \tag{8}$$

where $\varepsilon_{\rm fid}$ is the efficiency for detecting events and $\int \mathcal{L}\,dt$ is the integrated luminosity of 4.7 fb^{-1}. In Ref. [14], the efficiency values are taken as 43% for the ee channel, 55% for the $e\mu$ channel and 59% for the $\mu\mu$ channel.[2] We find that the data for the $\mu^+\mu^+$ channel with the invariant mass cut $M_{\ell\ell} > 15$ GeV is the most effective choice to extract the more severe constraint on $m_{H^{++}}$. Therefore, we intend to bound $m_{H^{++}}$ by comparing $\sigma_{95}^{\rm fid}$ for the $\mu^+\mu^+$ channel with the uncertainty of $\varepsilon_{\rm fid}$ to the signal cross section.

In the numerical evaluation, m_{H^+} is taken to be the same as $m_{H^{++}}$ to maximize the signal cross section. In order to generate the signal events, we use `MadGraph5` [17] and the `CTEQ6L` parton distribution functions [18]. We impose the following basic cuts according to Ref. [14] for each muon:

$$|\eta| < 2.5, \qquad p_T > 20\ \text{GeV}, \tag{9}$$

where η and p_T are the pseudorapidity and the transverse momentum, respectively. Furthermore, in order to compare it to $\sigma_{95}^{\rm fid}$, we impose the same invariant mass cut $M_{\ell\ell} > 15$ GeV. In Table 1, the cross sections after imposing the basic cut and the invariant mass cut are shown. The signal cross section takes its maximum value at around $m_{H^{++}} = 40$ GeV, because the cross section for the lower mass cases is much suppressed by the invariant mass cut. We also list the values for the decay width of $H^{\pm\pm}$ for $v_\Delta = 1$ GeV, by which one can recognize that $H^{\pm\pm}$ can decay inside the detector.

In Fig. 1, the same results are plotted as a function of $m_{H^{++}}$. The light shaded (orange colored in the web version) band gives the 95% CL upper limit for the fiducial cross section with 4.7 fb^{-1}. It can be seen that the HTM with the diboson decay scenario is excluded when $m_{H^{++}}$ is lower than about 60 GeV. We emphasize that this is the first substantial mass bound from the current LHC data, which is stronger than that obtained via the Γ_Z data at the LEP experiment. The dark shaded (red colored in the web version) band is obtained by extrapolating the data to those for 20 fb^{-1}, where the cross section $\sigma_{95}^{\rm fid}$ is expected to be smaller by a factor 2. This shows that the lower limit of $m_{H^{++}}$ becomes about 85 GeV with the accumulated integrated luminosity 20 fb^{-1}.

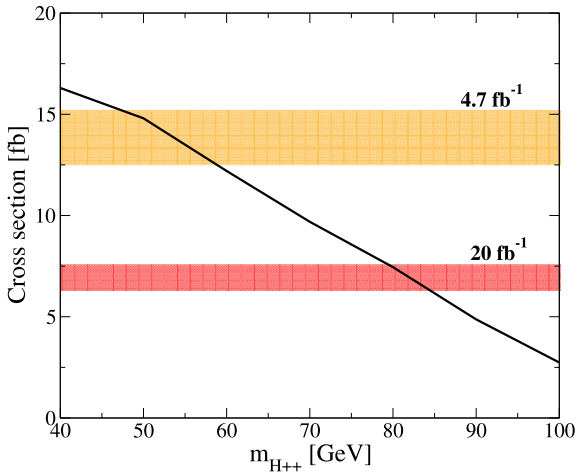

Fig. 1. The signal cross section after the $M_{\ell\ell}$ cut as a function of $m_{H^{++}}$ with the collision energy to be 7 TeV. The light (dark) shaded band shows the 95% CL (expected) upper limit for the cross section from the data for the $\mu^+\mu^+$ channel with the integrate luminosity to be 4.7 fb^{-1} (20 fb^{-1}). The width of the bands comes from the uncertainty of $\varepsilon_{\rm fid}$ for the $\mu\mu$ system between 59% and 72% [14].

Finally, we remark that the lower bound obtained in this Letter can be improved by the followings: (i) the signal cross section is calculated at the leading order, which can be modified by a factor of 1.2–1.3 [19] with higher order corrections, (ii) although we have studied the same-sign dileptons only from the decay of $H^{\pm\pm}$, they can also appear in the decay of $H^\pm$; e.g., $H^\pm \to W^\pm Z \to \ell^\pm\ell^+\ell^-\nu$. However, the decay of $H^\pm$ strongly depends on the mass difference, so that we here neglect these contributions as a conservative assumption for simplicity, (iii) a requirement of relatively hard jets in the same-sign dilepton events, like the analysis in Ref. [9], can enhance the significance of finding signal events from the background. The mass bound could be improved by such an optimized analysis with the same data set.

In conclusion, we have studied the lower limit for $m_{H^{++}}$ in the diboson decay scenario where $H^{\pm\pm} \to W^{\pm(*)}W^{\pm(*)}$ is dominant by using the experimental data. By the LEP data for Γ_Z the mass below 43 GeV is excluded with the 95% CL, and the results from four charged-lepton searches do not provide any significant constraint. We have found that a new lower bound is obtained to be about 60 GeV at the 95% CL by using the current LHC data for the same-sign dilepton events with the collision energy to be 7 TeV and the integrated luminosity to be 4.7 fb^{-1}. This is the first substantial bound on $m_{H^{++}}$ from the LHC data. We have also shown by the extrapolation that the lower limit of $m_{H^{++}}$ becomes about 85 GeV with the accumulated integrated luminosity 20 fb^{-1}. When the LHC will rerun with the energy of 14 TeV, a more stronger bound can be obtained.

[2] In fact, $\varepsilon_{\rm fid}$ depends on the observed transverse momentum for charged leptons. According to Ref. [14], $\varepsilon_{\rm fid}$ for $e^\pm e^\pm$, $\mu^\pm\mu^\pm$, and $e^\pm\mu^\pm$ channels can be changed in the ranges of 43–65%, 59–72% and 55–70%, respectively. In the derivation of $\sigma_{95}^{\rm fid}$, $\varepsilon_{\rm fid}$ is chosen to be the lowest value in Ref. [14].

研究成果

1.研究開始当初の背景

本研究の開始当初の背景は、LHC 実験によって、ヒッグス粒子や、超対称性粒子やそれにとって代わる標準理論を超える新粒子が発見されることを見越して、LHC の次の世代の衝突型加速器である ILC などで期待される物理を研究し、それを踏まえた測定器の開発を行うというものであった。研究開始当初はヒッグス粒子は発見されておらず、ILC のほかにも SLHC と呼ばれるさらに高エネルギーのハドロンコライダーも考慮した。当初はシリコン・タングステンのサンドイッチ電磁カロリメータだけでなく、シンチレータを用いた電磁カロリメータやハドロンカロリメータも考慮した。

2．研究の目的

本課題の目的は、LHC でのテラスケールでの物理成果をさらに大きく展開するための次世代エネルギーフロンティアの準備研究である。具体的には、LHC での成果を踏まえて、次に重要となる SLHC、LHC、LC 等の次世代計画における物理準備研究を行い、その鍵となる新たな検出器開発を行なった。次世代計画には、加速器・検出器技術に革新的な新技術が不可欠である。本課題では、次世代カロリメータの開発を行いプロトタイプの製作・性能の評価を行なった。これらの研究は、真空の構造、超高エネルギーでの力の統一、宇宙物理へ更なる展開を次世代実験で行う為に重要な役割を果たした。本課題のメンバーは、コライダー実験での豊富な経験を持ち、SLHC やリニアコライダー測定器の技術開発や物理研究を国際コミュニティーの中で主導的に行い、高い評価を得てきた。LHC でのテラスケール物理の成果と将来計画にむけて研究を始める

準備を行ってきた。

3．研究の方法

LHC でのテラスケール物理の成果を真空の構造、超高エネルギーでの力の統一、宇宙物理へ大きく展開するために、以下の 3 つの物理研究(3-5)を進め、同時にこの研究を実現するために必須の次世代カロリメータ開発(1-2)を行なった。

(1) 光電子増倍管に取って代わる安価な光デバイス MPPC を用いた高細分ストリップシンチレータを用いたサンプリング型カロリメータを開発した。PPC は出力が飽和しないようにピクセルを細分化しダイナミックレンジの向上を行った。またカロリメータとして均一な性質となるような、光学的接続やエレクトロニクスの開発を行い、プロトタイプを製作した。

(2) (1)で開発した高細分カロリメータでジェット中の粒子を粒子単位で観測しエネルギーフローを計算するアルゴリズムの開発を行なった。 σ E/E=30%/E(GeV)1/2 以下の高い精度でのエネルギー測定と、O(1)%のヒッグス崩壊分岐比測定を可能にする方法を開発した。

(3) ILC や SHLC での研究でヒッグス自己結合定数を測定する方法を開発した。高いバックグラウンドを除くため高性能カロリメータ開発と粒子識別能力向上の両面で研究を進めた。

(4) SLHC で色を持った重い超対称性粒子の性質、ILC で軽い電弱超対称性粒子の性質を探る研究を行い、両方の研究を統合して初めて超対称性の全貌を探ることができ、LHC での成果を反映させて詳細で新しい研究を行なった。

(5) SLHC で WW 散乱の精密観測を通して新たな質量獲得システムの研究を行なった。

4．研究成果

本課題では LHC でのヒッグス粒子の発見によって重要性を増した国際リニアコライダー(ILC)計画の推進のために多くの研究を行ってきた。

(1) LHC の 2 光子の不変質量分布で 750 GeV 近くに新粒子の兆候があった。この背後の物理を ILC で精査する方法を開発。この他に、超対称性などの兆候が LHC で見えた時に、ILC での詳細研究によって、超対称性の破れや暗黒物質の解明の方法を開発。

(2) ILC ビーム収束系の local chromatic correction と呼ばれるビームオプティクスを確立した。KEK の ILC のための試験加速器 ATF2 において、世界で最小の縦方向ビームサイズ σy=41nm 測定した。また、2 バンチのビームを ATF でつくり 1 バンチ目の測定でフィードバックをかけ 2 バンチ目のビームジッターを減らすことに成功。

(3) ILC のシリコン電磁カロリメータの詳細設計において安価でかつ性能を落とさないための素子のスペックを研究した。また、素子の放射線耐性を神戸大学の中性子ビームを用いて精査。十分な耐性があることを検証。ドイツ DESY においてプロトタイプのビームテストに成功。

(4) τ のハドロンへの崩壊の再構成は、重いヒッグス粒子などの CP 混合の決定に重要である。ILC での衝突点の位置、荷電粒子の軌道、π^0 からの光子の電磁カロリメータでのシャワーの測定を用いて、いかなる τ のハドロン崩壊も再構成できることを証明。

ABSTRACT

We present a method for the reconstruction of events containing hadronically decaying τ leptons at collider experiments. This method relies on accurate knowledge of the τ production vertex and precise measurement of its decay products. The method makes no assumptions about the τ kinematics, and is insensitive to momentum loss along the beam direction. We demonstrate the method using $e^+e^- \to \mu^+\mu^-\tau^+\tau^-$ events fully simulated in the ILD detector.

1. Introduction

Studies of final states including τ leptons are of interest at current and future collider experiments; as an example, the dominant leptonic decay of the Higgs boson is to a τ pair. A new generation of high energy particle colliders [1–4] is presently under study. A key scientific aim of these facilities is to measure the Higgs boson's properties with great precision, important aspects of which involve measurements of the τ final state. An example is the use of measurements of the τ spin state to probe the CP nature of the Higgs boson. The detectors being designed for use at these accelerators will be equipped with vertex detectors providing unprecedented impact parameter resolution (see *e.g.* [5]), giving rise to intriguing possibilities in the reconstruction of relatively long-lived states such as the τ lepton.

We report on a method which uses a high-precision vertex detector together with other tracking and calorimetric detectors to fully reconstruct the kinematics of events containing hadronically decaying τs (*i.e.* decays in which only one ν is produced) in an unbiased way. We outline previously used techniques for the kinematic reconstruction of single-ν τ decays in Section 2. In Section 3 we define a new procedure which, in certain topologies, can fully reconstruct the τ kinematics with significantly less stringent assumptions than previous approaches. This new method is then applied to $e^+e^- \to \mu^+\mu^-\tau^+\tau^-$ events in Section 4, and we conclude in Section 5.

2. Previous approaches to τ pair reconstruction

In the case of events containing a pair of τ leptons each decaying to a single neutrino, the following method, which assumes knowledge of the rest-frame and invariant mass of the τ pair, but no knowledge about the τ production vertex, is often used at lepton colliders (*e.g.* [6,7]). The τ-pair rest-frame can be assumed to be the centre-of-mass of the colliding beams (in the case of the $e^+e^- \to \tau^+\tau^-$ process), or the frame recoiling against particles produced in conjunction with the τ pair, as in the case $e^+e^- \to \mu^+\mu^-\tau^+\tau^-$. The τ decay products are then boosted into the assumed τ pair rest frame, in which the energy of the τs is defined by the assumed invariant mass of the τ pair. The τ mass then constrains the τ momentum to be at a fixed angle to the momentum of its hadronic decay products, defining a cone around the hadronic momentum. The two cones in an event, one per τ, have either 0, 1, or 2 intersections, corresponding to the possible solutions for the τ momenta.

At hadron colliders, the unknown net momentum along the beam direction results in less available information to constrain the event kinematics. The invariant mass of τ pairs can be partially estimated using the invariant masses of visible decay products and the missing transverse energy, or by applying the approximation that the ν from τ decay is collinear with the visible τ decay products [8]. Another approach is to combine the measured momenta of visible τ decay products with constraints on the τ mass and global event transverse momentum balance, resulting in an under-constrained system. The likelihood of the various τ decay topologies allowed by the constraints can then be used to choose a best solution, or alternatively to associate a weight to each solution *e.g.* [9–11].

If the τ production vertex is precisely known, the use of the impact parameters of the charged τ daughters (prongs) brings additional information. The knowledge of the production vertex can come from the reconstruction of particles recoiling against the τs, or from *a priori* knowledge of the interaction point, if the size of the interaction region is sufficiently smaller than the impact parameters of the τ decay products. The use of the impact parameter vectors of charged τ daughters, without full reconstruction of τ decay kinematics, in the analysis of Higgs boson CP properties has been described in *e.g.* [12,13], while their use in fully reconstructing di-τ systems of known invariant mass and momentum has been demonstrated in [14,15].

3. Method

In this section we present methods that can, under certain conditions, fully reconstruct a τ without assuming that it belongs to a τ pair of particular invariant mass or centre-of-mass frame. In Section 3.2 we consider the reconstruction of hadronic single prong final states, in which a single charged hadron is produced with zero or more neutral hadrons and a single neutrino. Such decays account for 49.5% of τ decays. Multiprong hadronic τ decays, in which three or more charged hadrons, zero or more neutral hadrons, and a single neutrino are produced, account for 15.3% of τ decays, are discussed in Section 3.3. Leptonic decays of the τ (35.2%) provide significantly less measurable information about its decay kinematics due to the production of two neutrinos, and are not further considered in this paper.

The method relies on precise knowledge of the τ production vertex and the charged prong trajectories, and on the reconstruction of any neutral hadrons produced in the decay. Constraints on the invariant mass and lifetime of each τ, and on the overall transverse momentum in the event, are then used to determine the τ momenta.

3.1. Tau production vertex

The uncertainty on the τ production position should be small in comparison to the decay length of the τ and the typical impact parameters of its decay products. In final states in which the τs are produced together with more than one prompt charged particle, the production vertex can be directly reconstructed on an event-by-event basis using the tracks of these particles (*e.g.* the μs in the process $e^+e^- \to \mu^+\mu^-\tau^+\tau^-$). The proposed linear electron–positron colliders [1,2] have rather small interaction regions, which may be used as an additional constraint on the interaction point, although this is not done for the results presented in this paper.

3.2. Single prong τ decays

3.2.1. Tau decay plane

In the case of single prong hadronic τ decays, the trajectory of the charged prong (helical in the usual case of a uniform magnetic field) can be used to define a plane (hereafter called the "track plane") which contains two vectors: **d**, the vector between the reconstructed interaction point (IP, assumed to be the τ production vertex) and the point on the trajectory closest to the IP (point of closest approach PCA); and **p**, the tangent to the trajectory at the PCA. In the case of linear trajectories of the τ and of the prong between the PCA and the τ decay vertex, the τ momentum, and therefore also the sum of the momenta of the other decay products of the τ (neutrinos and neutral hadrons), are constrained to lie within this plane.

The difference between the reconstructed track plane and the true τ decay plane (defined by the τ and prong momenta) depends on the decay length of the τ, the accuracy with which the IP position is known, the precision of the charged prong trajectory, and the extent to which the linear approximation of the τ and prong trajectories near the IP is valid.[1]

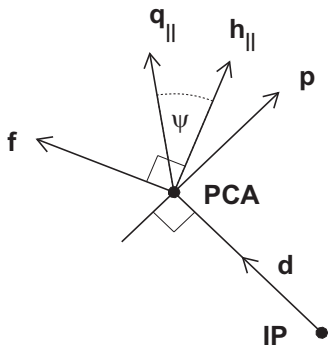

Fig. 1. Parameterisation of the neutrino momentum in the track plane ($\mathbf{q}_{\parallel}$) in terms of the vectors $\mathbf{h}_{\parallel}$ and **f**, and angle ψ. The track plane is defined by the vectors **p** and **d**.

3.2.2. Parameterisation of neutrino momentum

In this section we describe the parameterisation of the unmeasured neutrino momentum, **q**, based on the measured prong trajectory and neutral hadron momentum.

Neutral particles are measured as clusters in the calorimeters, or as identified conversions of photons into e^+e^- pairs within the tracker volume. The momentum to be associated to calorimeter clusters can be estimated by assigning the energy of the calorimeter cluster, a mass hypothesis (*e.g.* zero in the case of photon-like clusters, the K_L mass for hadronic clusters), and the direction of a straight line connecting the IP and the energy-weighted mean position of the calorimeter cluster.[2]

The three-momentum **k** of the neutral hadronic system can be decomposed into components perpendicular to and within the track plane: $\mathbf{k}_{\perp}$ and $\mathbf{k}_{\parallel}$ respectively. Since the τ momentum lies within the track plane, the hadronic momentum perpendicular to the track plane must be balanced by the neutrino, so the perpendicular component of the neutrino momentum $\mathbf{q}_{\perp} = -\mathbf{k}_{\perp}$.

The component of the neutrino momentum within the track plane can completely generally be parameterised as

$$\mathbf{q}_{\parallel} = Q \cdot (\cos\,\psi \cdot \hat{\mathbf{h}}_{\parallel} + \sin\,\psi \cdot \hat{\mathbf{f}}), \tag{1}$$

[3] where Q is the unknown magnitude of the in-plane component of the neutrino momentum, $\mathbf{h}_{\parallel}$ is the component of the total hadronic momentum ($\mathbf{h} = \mathbf{p} + \mathbf{k}$) in the track plane, and the unit vector $\hat{\mathbf{f}} \equiv \mathbf{f}/|\mathbf{f}|$, where $\mathbf{f} = \mathbf{h}_{\parallel} \times (\mathbf{d} \times \mathbf{h}_{\parallel})$, is within the plane and perpendicular to $\mathbf{h}_{\parallel}$ (Fig. 1).

Four-vectors p, k, and q corresponding to the three-momenta **p**, **k**, and **q** can be defined by means of appropriate invariant mass assumptions. The invariant mass of the sum of four-vectors p, k, and q must be equal to the τ lepton mass m_τ. This constraint allows us to write an equation involving Q and $\hat{\mathbf{q}}_{\parallel}$ (which in turn

[1] The error in this linear approximation scales as the ratio of the decay length of the τ to the radius of curvature of the prong: for a prong with $p_T = 10$ GeV/c produced by a 50 GeV τ of average lifetime, in a field of 3.5 T, this ratio is $< 10^{-3}$. An iterative approach, in which a first iteration uses the helix parameters at the PCA to the IP, while later iterations use the helix parameters at the calculated τ decay position, should reduce any sensitivity to the prong's curvature.

[2] Alternative definitions are possible: for example the line connecting a first estimate of the τ decay position to the identified start of the calorimetric shower.

[3] We define $\hat{\mathbf{x}}$ to be a unit vector parallel to **x**.

depends on ψ):

$$m_\tau^2 = (q+h)^2 = (\sqrt{Q^2+\mathbf{k}_\perp^2}+E_h)^2 - (Q\hat{\mathbf{q}}_\parallel - \mathbf{k}_\perp + \mathbf{h})^2 \quad (2)$$

where E_h is the energy of the hadronic system. This can used to solve for Q:

$$Q = \frac{1}{2a}(-b \pm \sqrt{b^2-4ac}), \quad (3)$$

where

$$a = B^2 - C^2, \quad b = 2AB, \quad c = A^2 - C^2\mathbf{k}_\perp^2, \quad (4)$$

and

$$A = m_\tau^2 - m_h^2 - 2\mathbf{h}\cdot\mathbf{k}_\perp, \quad B = 2\hat{\mathbf{q}}_\parallel\cdot(\mathbf{h}-\mathbf{k}_\perp), \quad C = 2E_h, \quad (5)$$

where m_h is the invariant mass of the hadronic system.

There are in general two solutions of Q for each choice of ψ, which are complex in unphysical regions. Such complex solutions are rejected. In the case of two real solutions, we choose to denote the one with a higher energy neutrino in the laboratory frame as the "first" solution, and the other as the "second". The first solution at $\psi = \alpha$ corresponds to the second solution at $\psi = \pi + \alpha$, and *vice versa*. Since the angle between the neutrino and hadrons is typically small in the laboratory (due to the large boost of the τ), it is convenient to consider the solutions separately, each in the range $-\pi/2 < \psi < \pi/2$.

For each real solution of Q, the corresponding τ momentum can be calculated. In conjunction with the prong trajectory, this allows the decay length and proper decay time of the τ to be calculated. In the simple case of $k=0$ (*i.e.* no neutral hadrons in the τ decay), one solution for Q corresponds to a negative τ decay length (the intersection of the τ trajectory with that of the prong is on the "wrong" side of the IP), and can therefore be discarded. More generally, a likelihood λ that the extracted lifetime is consistent with that expected of the τ can be expressed in terms of the measured decay length of the τ in the laboratory L, its Lorentz boost (β, γ), and the mean lifetime of the τ (~ 87 μm/c): $\lambda = \exp(-L/(\beta\cdot\gamma\cdot 87\ \mu\text{m}))$ if $L > 0$, and $\lambda = 0$ otherwise.[4]

3.2.3. Choice of ψ

To determine the value of ψ, additional information is required. One possible approach would be to follow a statistical approach, applying a weight to each possible solution based on the likelihood that its decay time is consistent with that expected of the well-known τ mean lifetime, and/or that the reconstructed τ decay kinematics follow the expected distributions. If a hypothesis is made as to the energy of the τ, or on the invariant mass of a pair of τs, this can also help choose appropriate ψ solutions.

An alternative approach, followed in this paper, is to consider the environment in which the τ has been produced. We consider the class of events in which one or more single-ν decaying τ leptons have been produced in conjunction with zero or more well-measured particles, together with zero or more particles escaping along the beam-line (*e.g.* ISR photons). Examples of such processes at an electron–positron collider are two-fermion production $e^+e^- \to \tau^+\tau^-$, Higgs-strahlung $e^+e^- \to HZ \to (\tau^+\tau^-)(\mu^+\mu^-)$, and its major irreducible background $e^+e^- \to ZZ \to (\tau^+\tau^-)(\mu^+\mu^-)$. In such events, the overall p_T of the τs and other visible particles is balanced, while there may be non-zero net momentum along the beam-line due to ISR. A natural way in which to determine the ψ angles in an event (one per τ decay) is to choose that combination which minimises the magnitude of the missing transverse momentum (p_T^{miss}) in the event. This method has the advantage of making no assumptions about τ kinematics or about undetected particles escaping along the beam-line – also indispensable for application at hadron collider experiments, but does require that no additional neutrinos are produced in the same event. In the case of several solutions for which p_T^{miss} is consistent with zero, the reconstructed τ lifetimes can be used to determine the most likely one, or each solution could be weighted by a likelihood based on its lifetime and/or τ decay kinematics.

3.3. Multiprong τ decays

In the case of multiprong τ decays, the prongs can be fitted to a common vertex, whose position $\mathbf{V}$ corresponds to the point at which the τ lepton decayed. Together with a well-known production position $\mathbf{P}$, this gives an estimate of the direction of the τ momentum, in the approximation that the τ trajectory is linear.[5] The τ momentum $\mathbf{p}_\tau$ can be written as $\mathbf{p}_\tau = t\hat{\mathbf{r}}$, where t is the magnitude of the τ momentum, and $\mathbf{r} = \mathbf{V} - \mathbf{P}$.

The neutrino momentum $\mathbf{q}$ can then be written as $\mathbf{q} = \mathbf{p}_\tau - \mathbf{h}$, where $\mathbf{h}$ is the measured momentum of the visible hadronic system. Defining appropriate four-vectors q and h for the neutrino and hadronic system respectively, and requiring that the invariant mass of the decay products is equal to the τ mass m_τ, gives

$$m_\tau^2 = (q+h)^2 = (|\mathbf{q}| + E_h)^2 - (\mathbf{q}+\mathbf{h})^2 = (|t\hat{\mathbf{r}} - \mathbf{h}| + E_h)^2 - t^2, \quad (6)$$

where E_h is the energy of the hadronic system. This can be solved for t, giving

$$t = \frac{1}{2a}(b \pm \sqrt{b^2-4ac}), \quad (7)$$

where

$$a = E_h^2 - (\hat{\mathbf{r}}\cdot\mathbf{h})^2, \quad b = (\hat{\mathbf{r}}\cdot\mathbf{h})(m_\tau^2 + m_h^2),$$
$$c = -\frac{(m_\tau^2+m_h^2)^2}{4} + m_\tau^2 E_h^2. \quad (8)$$

There are in general two possible solutions for t which satisfy the m_τ constraint, however they are not guaranteed to be real. The full tau decay kinematics can be calculated for each real solution, including the decay length and proper decay time of the τ. In appropriate event topologies, the p_T^{miss} of the event can be used to choose between these two solutions, otherwise the previously introduced lifetime likelihood could be used.

Since the τ leptons produced at high energy colliders are typically highly boosted, the opening angle of the multiprong jet is usually small. As a consequence, the precision with which the τ decay vertex is reconstructed is significantly worse along direction of the τ jet than along the perpendicular directions. In the example considered later in this paper, in which τs are produced in Higgs boson decays, the length of the major axis of the vertex position error ellipsoid is typically of order 100 μm, while the other two axes have lengths of order 2 μm.

In this case, it turns out to be better to consider the major axis of the vertex error ellipsoid as a single trajectory, and to analyse the event using the procedure developed for single prong decays in the previous section. In this way, the τ decay plane is defined by the IP and the centre and major axis of the vertex ellipsoid, and the exact decay position along the major axis direction is left as a free parameter. The distance between the fitted and reconstructed vertex positions, normalised by the uncertainty on the reconstructed vertex position, can be used to define a vertex likelihood, which can be used when choosing between several possible solutions.

[4] A more sophisticated treatment would take measurement uncertainties into account, therefore allowing small negative decay length solutions.

[5] We note that the τ momentum direction can be directly measured for any decay mode if the τ decay length is sufficiently large for it to produce hits in the vertex detector.

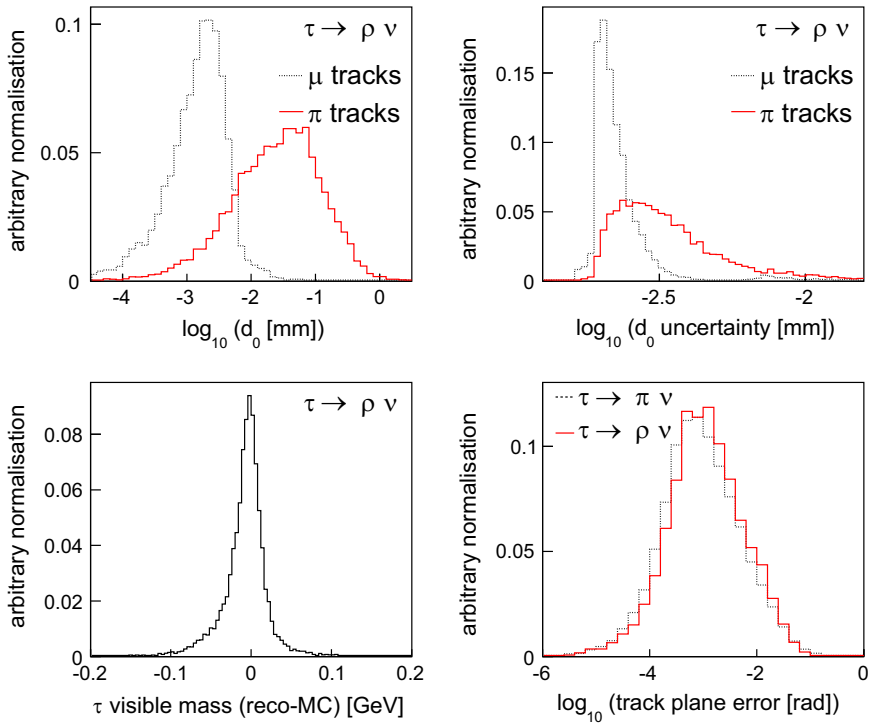

Fig. 2. Properties of the considered $e^+e^- \to \mu^+\mu^- H$ events. Top: the measured 2-d impact parameter d_0 [left] and its uncertainty [right], for prompt μ tracks, and π tracks from $\tau \to \rho\nu$ decay. Bottom left: the difference between the reconstructed and true visible τ mass in $\tau \to \rho\nu$ decays. Bottom right: the angle between the reconstructed track plane and the true direction of the τ momentum.

4. Example application

We apply this method to $e^+e^- \to \mu^+\mu^- H$ events, in which the Higgs boson decays to a pair of τs. Such events are usually selected by considering the mass recoiling against the di-μ system, which has a peak at the Higgs boson mass. However the distribution of this recoil mass has a long tail due to beamstrahlung and ISR, particularly at higher centre-of-mass energies well above threshold. If the invariant mass of the ττ system can be directly reconstructed, a rather cleaner selection of such events should be possible. The full reconstruction of the τ decay kinematics and the ττ centre-of-mass frame also allows the best use of the spin information of the τs: the properties of the τ decays can be used to define their *polarimeter vectors*, and the correlations between the τ polarimeters can be used to measure the CP-nature of the Higgs boson (*e.g.* [14]).

Events were generated at a centre-of-mass energy of 250 GeV using WHIZARD v2.2.2 [16], assuming a Higgs boson mass of 125 GeV, and including effects due to initial state radiation and beamstrahlung (by CIRCE1). The τs were decayed by TAUOLA++ v1.1.4 [17]. Three scenarios were considered: both τs decaying to $\pi^\pm\nu$; both decaying to $\pi^\pm\pi^0\nu_\tau$; and both decaying to $(a_1 \to 3\pi^\pm)\nu$. The simplest hadronic τ decay mode is $\pi^\pm\nu$, but accounts for only 11.5% of τ decays, while the $\rho\nu$ mode has the largest branching ratio of 26.0%.[6]

The resulting events we passed through the GEANT4-based MOKKA simulation of the ILD_o1_v05 detector model [5]. This model consists of a vertex detector with three double-layers of silicon pixel detectors, a silicon strip-based inner tracker and forward tracking disks, a large time projection chamber within a silicon tracking envelope, followed by highly granular calorimeters: a silicon–tungsten ECAL and scintillator-iron HCAL. These are placed within a solenoid producing a 3.5 T magnetic field, surrounded by an instrumented iron flux return yoke. The simulated energy deposits within the active detectors were passed through the standard ILD digitisation procedures to simulate detector signals.

4.1. Event reconstruction

The standard ILD reconstruction software was used to reconstruct charged particle tracks and calorimeter clusters. For the results shown in this paper, the reconstructed tracks were associated to primary muons and charged pions from τ decays on the basis of matching to the simulated particle directions. In a full analysis, muon and pion identification should be performed. This is rather simple task in detectors with highly granular calorimeters such as ILD, which should not present any great difficulties. Distributions of the impact parameter in the plane perpendicular to the beam d_0, and of its uncertainty, are shown in Fig. 2 for both prompt μ tracks and π tracks from τ decay. The two μ tracks were fitted to a common vertex to measure the event IP using the LCFIVERTEX [18] package, achieving a typical precision on the IP position of better than 3 μm in all three dimensions.

Clusters identified in the electromagnetic calorimeter by the GARLIC [19] and PANDORAPFA [20] algorithms were treated as photon candidates. Each cluster was assigned a momentum with magnitude equal to the reconstructed cluster energy and direction parallel to a line joining the nominal IP and the energy-weighted mean position of the cluster. Clusters were associated to π^0s and their parent τs based on matching the cluster momentum direction to the simulated photon directions. Events were rejected if not all the simulated μ, π and photons could be matched to reconstructed particles. Such cases are typically due to imperfect reconstruction algorithms or the interactions of particles in the tracker volume.

In order to improve the effective photon energy resolution, clusters associated to a π^0 were subjected to a constrained

[6] The vast majority of $\tau \to \pi^\pm\pi^0\nu_\tau$ decays proceed via the $\rho^\pm$, so we use $\rho\nu$ as shorthand for $\pi^\pm\pi^0\nu_\tau$ in this paper.

kinematic fit imposing the π^0 mass by varying their energies. No special effort was made to correct invariant mass biases occurring when reconstructing two overlapping clusters from π^0 decay. Fig. 2 shows the precision with which the visible invariant mass is reconstructed in $\tau \to \rho\nu$ decays. The accuracy with which the reconstructed track plane approximates the true τ decay plane is demonstrated in the bottom right plot of Fig. 2, in which the "track plane error" is defined as the angle that the true τ momentum makes to the reconstructed track plane.

The reconstructed tracks from multiprong τ decays were fitted to a common vertex, again using the LCFIVERTEX package. In three-prong decays via the a_1, the ellipsoid describing the vertex position uncertainty typically has a major axis length of 100 μm, and the other two axes around 2 μm.

4.2. Dependence of p_T^{miss} and the lifetime likelihood on $\psi^{\pm}$

Fig. 3 shows the dependence of the event p_T^{miss} (defined as the magnitude of the component of $\mathbf{P} = \sum_i \mathbf{p}_i$ transverse to the beam-line, where the index i runs over the momenta $\mathbf{p}_i$ of the τs and other reconstructed particles in the event) and lifetime likelihood on the two τ decay angles $\psi^{\pm}$ in two events, one in which both $\tau \to \pi^{\pm}\nu$, the other in which both $\tau \to \rho\nu$. The distributions are shown for the case in which the first Q solution is used for each τ (which is where the best solution was found in these two events). Four minima at which $p_T^{miss} \sim 0$ are seen, one in each quadrant. The lifetime likelihood (shown for the same Q solution), together with the p_T^{miss} at the minimum, allows the best minimum to be chosen.

The MINUIT package in the ROOT [21] analysis framework was used to find the minima of the p_T^{miss} distributions separately in each of the four quadrants bounded by $\psi^{\pm} = 0, \pm\pi/2$, in each of the four Q-solution combinations. If no minimum was found, or either τ had a negative reconstructed decay length at the minimum, the quadrant was rejected. Of the remaining possible solutions, the one with the smallest value of p_T^{miss} was chosen.

4.3. Results

4.3.1. Single prong decays

Of events in which reconstructed objects could be unambiguously matched to simulated particles, no good solution was found in 0.4% (2.4%) of events in the $\pi^{\pm}\nu$ ($\rho\nu$) channel. This inefficiency is due to cases in which the reconstructed visible mass is larger than the τ mass, or in which no solution with positive decay length is found. In Fig. 4 we show the distribution of the chosen solutions' p_T^{miss}, for events in which both τs were forced to decay to either $\pi^{\pm}\nu$ or $\rho\nu$. A rather good minimum ($p_T^{miss} < 1$ MeV) is found in the large majority of cases, but a fraction of events have a larger p_T^{miss}. These events with large p_T^{miss} are due to mis-reconstruction of the event, and make up a larger fraction of $\rho\nu$ than $\pi^{\pm}\nu$ decays due to the relatively worse precision of the calorimeters compared to the tracker. Events in which the reconstructed p_T^{miss} is larger than around 0.5 GeV/c show a significantly wider peak in the τ–τ mass distribution, as shown in Fig. 4. The mass distribution in the case of $\pi^{\pm}\nu$ ($\rho\nu$) decays has a central peak with a Gaussian width $\sigma \sim 0.6$ GeV (1.1 GeV), and non-Gaussian tails to both higher and lower values. Of $\pi^{\pm}\nu$ ($\rho\nu$) events with $p_T^{miss} < 0.5$ GeV/c, 74% (67%) lie within 3σ, and 95% (89%) within 10 GeV, of the peak position.

The same figure also shows the reconstructed invariant mass of the two τ system in events with small or large ISR/beamstrahlung energy (demonstrating that the method is independent of the total centre-of-mass energy and boosts along the beam-line), and on the smaller of the true τ decay lengths in the laboratory (showing that events with longer decay lengths tend to be better reconstructed). Fig. 5 shows the τ pair mass in the $e^+e^- \to \mu^+\mu^- H$ event sample, and a second $e^+e^- \to \mu^+\mu^-\tau^+\tau^-$ sample in which the Higgs boson contribution was effectively turned off. Clear mass peaks due to the Higgs and Z^0 bosons can be seen, the widths of which allow a rather clean separation between these processes in both the considered τ decay modes.

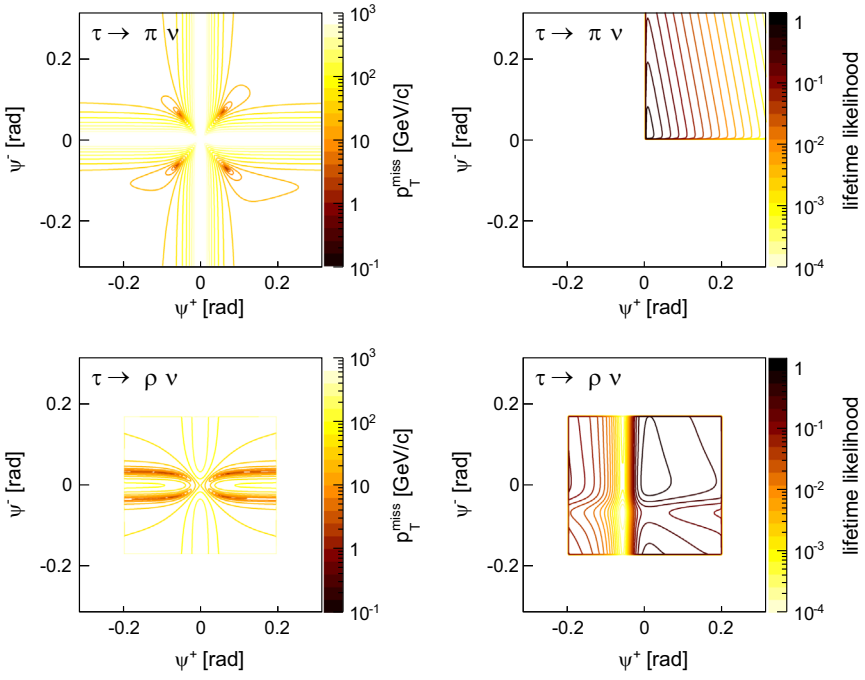

Fig. 3. Example of two $e^+e^- \to \mu^+\mu^-\tau^+\tau^-$ events in which both $\tau \to \pi^{\pm}\nu$ [top], or both $\tau \to \rho\nu$ [bottom]. Contours of p_T^{miss} [left] and lifetime likelihood [right] as a function of the two angles $\psi^{\pm}$ are shown. Regions with darker contours (lower p_T^{miss}, higher lifetime likelihood) are preferred. In the upper event no positive decay length solutions were found for $\psi^{\pm} < 0$, while in the lower event, no physical solutions were found for $|\psi^{\pm}| > \sim 0.2$.

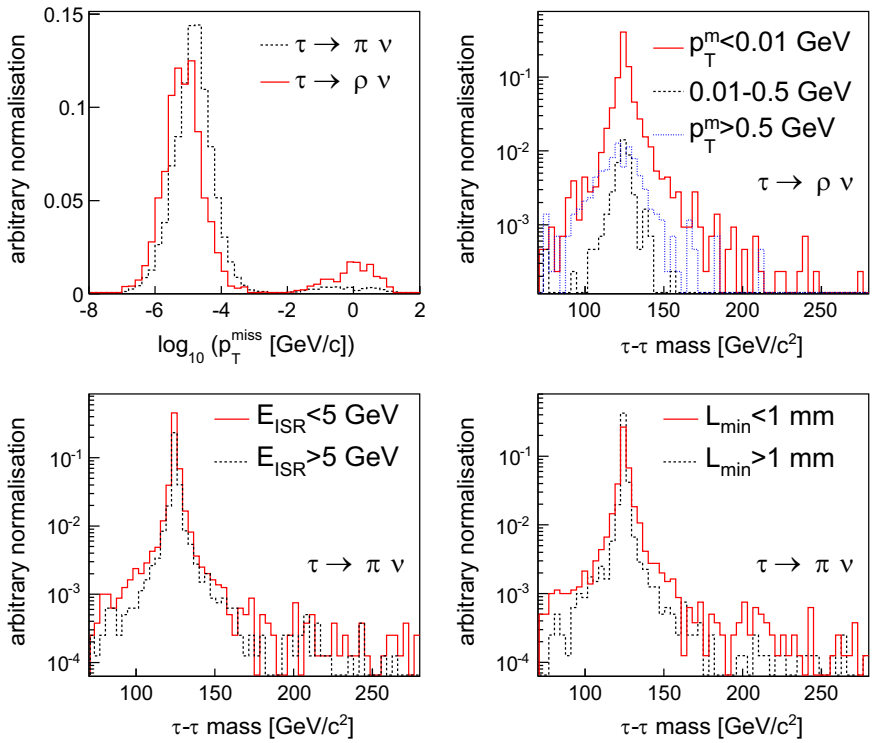

Fig. 4. Properties of the considered $e^+e^-\to\mu^+\mu^-H$ events after full τ reconstruction. The value of the event p_T^{miss} at the chosen solution [top left]. The τ pair mass distributions in different ranges of $p_T^{m(iss)}$ [top right], the total ISR/beamstrahlung energy E_{ISR} [bottom left], and L_{min}, the smaller of the two true τ decay lengths [bottom right]. Except in the top left plot, the relative normalisations of the various contributions are as in the event samples.

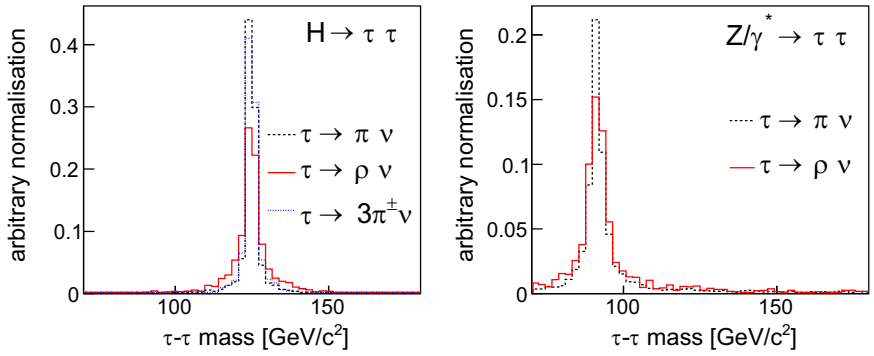

Fig. 5. The reconstructed mass of the τ pair in $e^+e^-\to\mu^+\mu^-\tau^+\tau^-$ events in which the τ pair was produced via a Higgs (left) or Z^0/γ^* (right).

4.3.2. Multiprong decays

Multiprong τ decays, studied using the $\tau\to(a_1\to3\pi^\pm)\nu$ channel, are reconstructed using two methods. In the "vertex" method, the reconstructed vertex position is directly used to constrain the τ direction, and the τ mass constraint used to find two possible solutions for the neutrino momentum. No real solution is found in around a quarter of τ decays. The event p_T^{miss} is used to choose the best solution.

In the "decay plane" method, the central position and major axis of the vertex position error ellipsoid are used to define the τ decay plane, which is then used in the same way as for single prong decays. Candidate τ solutions are required to have fitted and reconstructed τ decay vertices in the same hemisphere. The event candidate solution with smallest p_T^{miss} is selected. When using this method, no good candidate solution was identified in around 4.5% of events. Fig. 6 shows a comparison of these two multiprong methods. As well as having a much higher efficiency for identifying a solution, the "decay plane" approach results in significantly

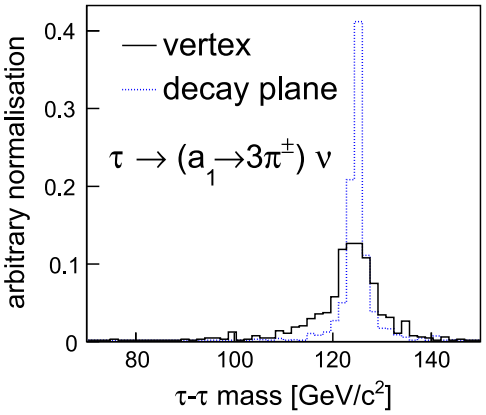

Fig. 6. The reconstructed mass of the τ pair in $e^+e^-\to\mu^+\mu^-\tau^+\tau^-$ events in which both τs decay into three charged pions. We compare the results of two τ reconstruction methods: directly using the reconstructed vertex position, and using the position and major axis of the vertex ellipsoid to define the τ decay plane.

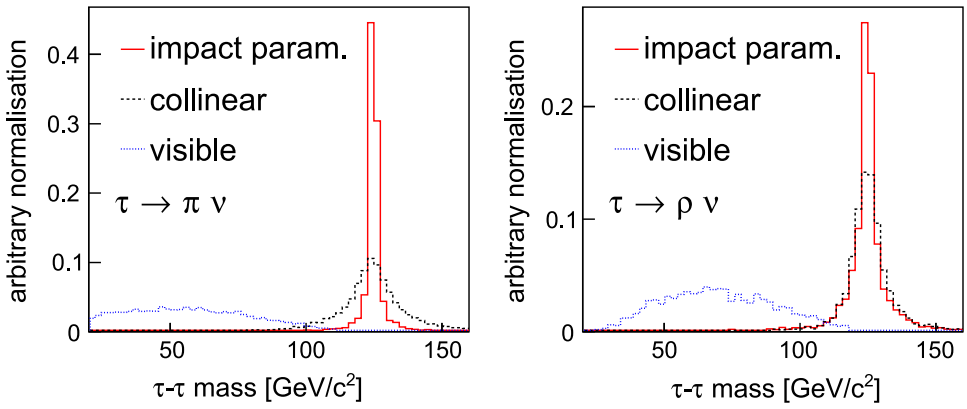

Fig. 7. Comparison of the reconstructed τ pair invariant mass using different methods: the impact parameter-based method developed in this paper, the collinear approximation, and only the visible decay products.

better mass resolution. The di-τ invariant mass distribution for multiprong a_1 decays obtained by using the "decay plane" method are compared to other decay channels in Fig. 5, showing that multiprong decays are reconstructed with a similar precision as $\tau \to \pi^{\pm} \nu$ decays.

In Fig. 7 we compare τ pair mass reconstruction using the methods developed in this paper with alternative approaches. The simplest is to use the invariant mass of only the visible decay products, therefore ignoring the neutrino contribution. This clearly underestimates the invariant mass, and results in a rather wide distribution. The collinear approximation assumes that the neutrinos are parallel to the visible tau decay products, and further requires the event's p_T to be balanced, allowing the neutrino energies to be estimated. The mass distribution resulting from the collinear approximation is peaked at the correct value, however it is significantly wider than that achieved by the methods developed in this paper. The difference in resolution is particularly significant in the $\pi^{\pm} \nu$ decay channel, where the impact parameter method gives a very sharp distribution.

5. Conclusion

An approach to the reconstruction of hadronic τs has been presented, which can be used in events in which the τ production vertex is well known, and the trajectory of its charged decay products is precisely measured. This method works only in events in which no undetected particles with significant p_T are produced together with the τs. In contrast to other methods, no assumptions are made on the centre-of-mass frame or the invariant mass of a τ-pair system, nor on the τ energies. The method is insensitive to momentum balance along the beam-line, so this method should work on *e.g.* $e^+e^- \to \mu^+\mu^- H$ events produced both near, and well above, threshold.

The example analysed in this paper, in which a τ pair recoils against a μ pair, is the case in which the event p_T^{miss} is most precisely measured. The Higgs boson will more commonly recoil against a hadronic system. These events are more difficult to reconstruct, and will have a less precisely measured p_T^{miss}. The use of a constrained kinematic fit, taking into account the resolution with which the various quantities are measured, should lead to improved results.

This reconstruction technique can be used at lepton colliders, as demonstrated in this paper, provided the precision of the tracking detectors is sufficient, particularly in the estimation of charged particle trajectories near the interaction point. To be used at hadron collider experiments, the τ decay products must be sufficiently well identified and reconstructed, and all particles produced in the same interaction unambiguously identified in order to accurately estimate the p_T^{miss} associated to the interaction. This latter point suggests that cases in which τs recoil against a relatively simple system, *e.g.* μ–μ as considered in this paper or a single high p_T jet, should be the most promising in the richer environment of hadronic collisions at high luminosity, in which multiple interactions typically occur in each event. The method is insensitive to the unknown net momentum along the beam direction inherent in hadronic collisions.

If applied to Higgs boson decays into τ leptons, the use of this method will allow clean separation of signal events from irreducible backgrounds from *e.g.* Z decays, and allow precise reconstruction of the τ spin information, providing a sensitive probe to measure the CP nature of the Higgs boson.

ABSTRACT

We describe an algorithm which has been developed to extract fine granularity information from an electromagnetic calorimeter (ECAL) with strip-based readout. Such a calorimeter, based on scintillator strips, is being developed to apply particle flow reconstruction to future experiments in high energy physics. The application of this algorithm to 100 GeV hadronic jets in an ECAL with 45×5 mm^2 transverse segmentation improves the energy resolution from 3.6% to 3.0%, to be compared to the resolution of 2.9% achieved by an ECAL with 5×5 mm^2 segmentation. The performance can be further improved by the use of 10×10 mm^2 tile-shaped layers interspersed between strip layers.

1. Introduction

In the experiments being designed for next generation particle colliders, the particle flow approach (PFA) [1,2] is the leading candidate to achieve the excellent jet energy resolution required to fully exploit the information offered by the detector and the collider. In PFA, the energy of charged particles is measured by the tracking system, which has a much better momentum resolution than the energy resolution of calorimeters: typical resolutions are $\sigma_{1/p_T} \sim 2 \times 10^{-5}$ GeV^{-1} for the tracking system, and $\sigma_E/E \sim 46\%/\sqrt{E(\mathrm{GeV})} \oplus 1.6\%$ for the HCAL response to single charged pions [3]. The calorimeters are used to estimate the energy only of neutral particles. In order to apply this approach, the calorimetric showers of each particle must be individually reconstructed. The granularity of calorimeter readout is therefore a key issue.

As an example, the sampling electromagnetic calorimeter (ECAL) with tungsten absorbers being designed for the International Large Detector (ILD, a detector being designed for use at the International Linear Collider (ILC) [3]) is optimized to have a transverse segmentation of 5 mm, corresponding to half of the Moliére radius of tungsten, and 20–30 longitudinal samplings in a total thickness of 23 X_0, giving a total of $\sim 10^8$ readout channels. The effective Moliére radius of the ECAL is around 20 mm. A readout granularity finer than 5 mm does not result in significant performance gains for jet energies of 100 GeV and below, which correspond to the most relevant jet energies for the ILC physics program [1]. One technology being developed to effectively achieve this high calorimeter granularity is based on plastic scintillator strips individually read out by miniature photon detectors, for example, pixelated photon detectors (PPD, also commonly known as SiPM) [5].

The use of long scintillator strips rather than 5×5 mm^2 tiles simplifies the design of such an ECAL, and also reduces its cost, due to the reduced number of readout channels. Successive ECAL layers have orthogonally aligned strips, giving an effective granularity close to the strip width. The CALICE collaboration has developed and constructed ECAL prototypes based on this technology, using scintillator strips of length 45 mm and width 5 or 10 mm, individually read out by PPDs [6,7].

This paper presents a reconstruction method which can be used to extract close to 5×5 mm^2 effective granularity from such long scintillator strips, and reports on measurements of its performance using events fully simulated in ILD. Details of this detector are given in the next section, the reconstruction procedure is explained in Section 3, and Section 4 describes the calibration procedure. The performance of this method on the basic detector-related measures of position resolution and two-particle separation are discussed in Sections 5 and 6, while the jet energy resolution, which affects the physics performance

of the detector, is discussed in Section 7. Finally we discuss the results in Section 8 and summarize this study in Section 9.

2. Detector model

Starting from the interaction point (IP), the ILD consists of a vertex detector, silicon tracking layers, a large time projection chamber (TPC) surrounded by additional silicon tracking detectors, a calorimeter system consisting of electromagnetic and hadronic sections, all placed within a solenoidal magnetic field of strength 3.5 T. The steel return yoke is instrumented to provide muon identification. The basic structure consists of a central, "barrel", region aligned with the beam axis, closed by two "endcaps" in the forward regions. The ECAL barrel detector has an octagonal cross-section, a length of around 5 m, and an inner radius of 1.85 m. A cylindrical coordinate system with its axis (z) aligned with the beam line is used in this paper. More details of the ILD design can be found in [3]. The ILD is simulated in MOKKA [8], a GEANT4-based simulation tool [9]. Fig. 1 *left* shows a multiple-jet event simulated in ILD.

The ILD strip-scintillator ECAL (strip-ScECAL) is a sampling calorimeter. In the simulation model used in this study, 30 sensitive layers are interleaved with tungsten plates of thickness 2.1 (4.2) mm in the inner 20 (outer nine) layers. The tungsten absorber layers correspond to a total thickness of 22 X_0, while layers of readout electronics, copper heat transfer plates, and scintillators contribute less than a single additional X_0. The total thickness of the ECAL is around 200 mm.

The sensitive layers are tiled with 45×5 mm^2 scintillator strips of thickness 1 mm. Strips are aligned orthogonally in successive layers. A dead volume of size $2.5 \times 1.0 \times 0.91$ mm^3 is implemented at the end of each scintillator strip to represent the volume occupied by the PPD, which leads to a constant term in the energy resolution. In the analyses presented in this paper, when scintillator tiles or strips with an area of less than 45×5 mm^2 are used, this dead volume is scaled by the strip area.[1] This avoids penalizing smaller cell sizes with an additional constant term to the energy resolution. Each strip is enveloped by a reflective film of thickness 57 μm. Scintillator strips and PPDs are mounted on 180×180 mm^2 "ECAL base units" (EBU), printed circuit boards which also host the front-end electronics and LEDs used for calibration.

The EBUs are arranged within mechanical structures in such a way as to avoid any projective cracks. Further technical details are available in [3]. Printed circuit boards and copper heat radiators are simulated in each detector layer. Four different scintillator tile configurations were used in this study:

1. 5×5 mm^2 tiles ("5 × 5");
2. 45×5 mm^2 strips ("45 × 5");
3. alternating layers of 5×5 mm^2 tiles and 45×5 mm^2 strips ("alt5"); and
4. alternating layers of 10×10 mm^2 tiles and 45×5 mm^2 strips ("alt10").

Successive strip layers were always orthogonally aligned. A hadronic calorimeter based on 40 layers of $30 \times 30 \times 3$ mm^3 scintillator tiles interleaved with 20 mm iron absorbers was simulated in this study.

3. Strip splitting algorithm

A simple algorithm, the Strip Splitting Algorithm (SSA), has been developed to extract fine granularity information from the long strip geometry. Each strip is split into n virtual cells along its length; n is chosen to result in approximately square virtual cells; for example, a 45×5 mm^2 strip is split into nine 5×5 mm^2 cells. A simple procedure is used to distribute the total energy E_{strip} detected by the strip among its virtual cells. A weight w_k is assigned to each virtual cell k, defined as the sum of the energies E_i of all strips in immediately neighboring layers which intersect with virtual cell k, when seen from the IP:

$$w_k = \sum_{(i\ =\ \text{intersect})} E_i \tag{1}$$

where the sum runs over strips, i, in immediately neighboring layers which intersect with the virtual cell k. The energy E_k assigned to virtual cell k is then

$$E_k = E_{\text{strip}} \frac{w_k}{\sum_{(j\ =\ \text{all virtuals})} w_j} \tag{2}$$

where the sum j runs over all virtual cells of the strip being split. Fig. 2 shows a schematic of the SSA procedure.

In the case of the alt10 model, the 10×10 mm^2 tile is first split into 2×2 virtual cells. The immediately neighboring strip layers are used to partition the tile's energy into these virtual cells using a very similar method to that defined above, making use of the strips' orthogonal orientation. In a second step, the virtual cells originating from the 10×10 mm^2 tiles are used to partition strips' energy among their virtual cells, as described above.

[1] This scaling is of course not possible in practice, although we note that techniques for the readout of scintillation light from the lower surface, which therefore avoid dead space due to the PPD, are currently being studied.

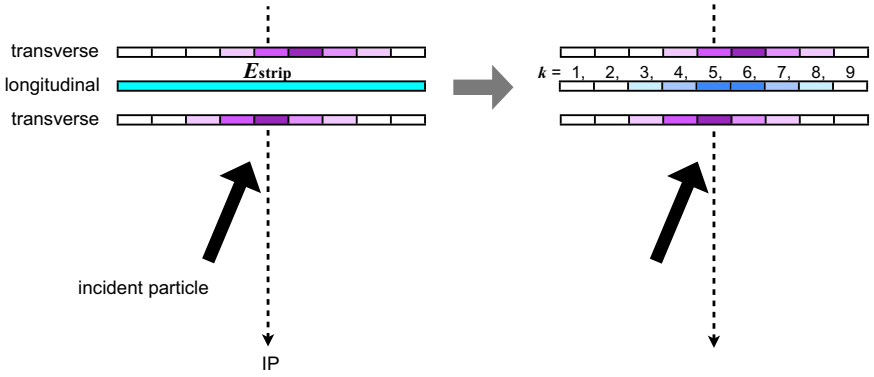

Fig. 2. A cartoon illustrating the SSA procedure. The energy, E_{strip} reconstructed in the central, "longitudinal", strip is split among virtual cells ($k = 1, \ldots, 9$) by considering the energy in the orthogonally aligned "transverse" strips in neighboring layers. More details of the procedure are given in the text.

Events were analyzed using a particle flow reconstruction algorithm. In the results presented later in this paper, the PandoraPFA algorithm [1,4] was used to analyze events, together with other standard ILD reconstruction programs (e.g. for tracking) in the MarlinReco [10] package.[2] PandoraPFA uses as input the energy and position of calorimeter deposits, as well as reconstructed charged particle tracks. When SSA was not used, PandoraPFA was passed the central position and energy of each strip (this is the simplest possible approach), while in the case of SSA, the central position and assigned energy of each virtual cell was used.

4. Calibration

Scintillator strips with an energy deposit were used to create calorimeter hits, whose energy was taken to be the energy deposited in the scintillator. No account was taken of non-linear or discretized behavior of the PPD response. In order to remove noise hits while keeping sufficient efficiency for minimum ionizing particle (MIP) detection, an energy threshold on each hit in the ECAL and HCAL was applied at a fraction of the most probable per-cell energy deposition of 10 GeV anti-muons ("MIP"). For the ScECAL, a threshold of 0.3 MIP was set for each virtual cell, while a threshold of 0.5 MIP was set when SSA was not used. For HCAL hits, a 0.3 MIP threshold was set, the default value used in PandoraPFA.

The calorimeter was calibrated by studying the energy deposited by 10 GeV photons for the electromagnetic response, and 10 GeV neutral long lived Kaons (K_L) for the hadronic response. Particles were injected from the IP in a direction almost perpendicular to the beam-line (in order to avoid the central electrode of the TPC) and uniformly distributed in azimuth. The calibration factors used to convert between the energy deposited in the scintillator and that deposited in the whole calorimeter (including the tungsten absorbers and other passive materials) were chosen to give a mean energy, after PFA reconstruction, equal to the incident particle energy. Additional calibration factors used to account for different values of the hadronic and electromagnetic responses h/e, separately defined in the ECAL and HCAL, were optimised to obtain the best jet energy resolution, according to the standard PandoraPFA procedure [4]. The ECAL was re-calibrated for each ECAL configuration, while a single HCAL calibration was used for all configurations. Apart from this calibration, the same parameters of PandoraPFA were used for all ECAL geometries.

[2] The package versions defined in ILCSoft v01-16-02 were used.

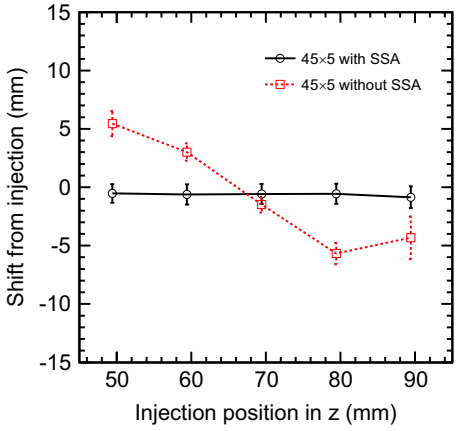

Fig. 3. Shift of reconstructed position for 10 GeV photons. The vertical error bars reflect the widths of the position shift distributions.

5. Position of clusters

The precise reconstruction of cluster positions is important in a PFA analysis to ensure good matching between tracks and calorimeter clusters. In this study, 10 GeV photons were fired into the 45×5 ECAL from the IP, varying the ECAL injection position along the z direction. The injected position was taken to be the intersection on the ECAL front face of the line joining the reconstructed cluster position[3] and the IP. Fig. 3 shows the difference between the position reconstructed by PandoraPFA and the true photon injection position, as a function of the injected position. The size of the vertical error bars reflects the width of the reconstructed position distribution.

When SSA is not used, a strong position-dependent bias of up to 5 mm is observed, corresponding to cases when the photon shower passes near the ends or center of a strip (z=68 mm corresponds to the center of strips aligned with the z axis). When SSA is used, these biases are almost completely removed, and cluster positions are reconstructed to better than 1 mm.[4]

[3] The position of a calorimetric cluster is defined as the energy-weighted mean position of its constituent hits.

[4] A small z-dependent bias remains after SSA, due to the relative position within the virtual cell. The small consistent position bias visible after SSA is due to the fact that the chosen injection positions are all in the same relative position within the virtual cells. When integrated over z, the average bias becomes effectively zero.

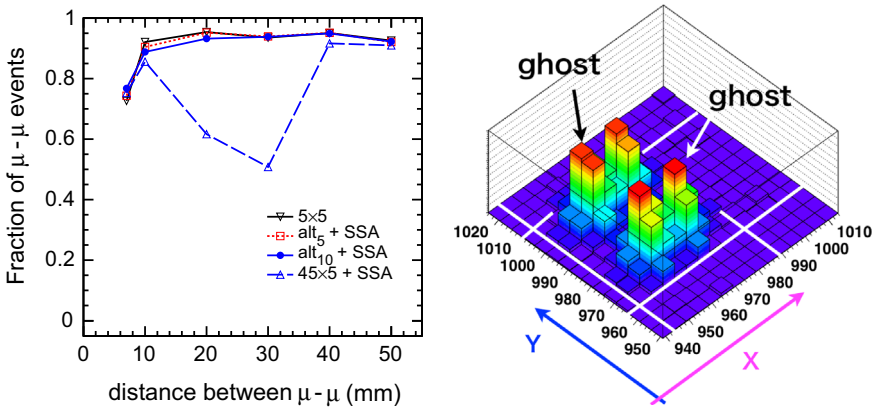

Fig. 4. *Left*: fraction of correctly reconstructed di-muon events as a function of the distance between the muons at the front face of the ECAL. *Right*: energy deposit of two electrons incident simultaneously on 45×5 strip-ScECAL reconstructed with SSA. Two of four peaks are ghosts.

6. Two-particle separation

To investigate the separation ability of the strip-ScECAL with SSA, di-muon events and π^0 decays (for photon–photon separation) were studied. These simple events serve to illustrate and investigate the phenomena of spurious "ghost" clusters which can occur when two particles are simultaneously incident in a square area whose side is shorter than the strip length. The reconstructed invariant mass of the two photons from π^0 decays provides a good test of both the photon separation and reconstruction ability.

6.1. μ–μ separation

Di-muon events provide a sensitive system for measuring two-particle separation in different ScECAL designs. The ability to reconstruct two anti-muons of momentum 10 GeV produced at IP was studied as a function of the distance between their impact positions on the ECAL surface. One muon was injected into the ECAL at a fixed point, with polar angle almost perpendicular to the beam line and azimuthal angle $\phi = \pi/2$. The second was injected to impact the ECAL surface at some distance from this point, with $\delta_{r\phi} = \delta_z = \Delta/\sqrt{2}$, where $\delta_{r\phi}$ (δ_z) is the separation between the ECAL entry points in the r–ϕ (z) direction, and Δ was scanned between 7 and 50 mm. Both injection positions were smeared by 0.2 mm on the ECAL surface in r–ϕ and z. Four thousand simulated di-muon events were analyzed using SSA and PandoraPFA.

Fig. 4 *left* shows the fraction of such events in which the two muons were reconstructed without any additional ghost calorimeter clusters, as a function of the distance between the entry points of the two muons into the ScECAL. Apart from the 45×5 strip-ScECAL with the use of SSA, all types of ScECAL have over 90% correctly reconstructed events when the distance between the two muons is larger than 10 mm. In the case of the 45×5 strip-ScECAL with the use of SSA, the fraction depends strongly on the position, with a minimum at a distance of 30 mm. This is due to the possibility of two-fold ambiguities arising in reconstruction when two particles enter a square region with size smaller than the strip length, which can lead to the formation of "ghost" clusters. Fig. 4 *right* illustrates a case in which two injected electrons produced two additional ghost clusters. At a separation of 30 mm in Fig. 4 *left*, around 25% of di-muon events in the 45×5 strip-ScECAL have a single additional reconstructed ghost cluster, and a further 25% have two ghost clusters. At distances below 30 mm, ghost clusters are more often combined with the true muon cluster. At a separation of 7 mm, the correctly identified fraction drops to around 70% for all ScECAL configuration due to the merging of nearby clusters.

The use of interleaved tile layers removes the ambiguities leading to ghosts, and dramatically improves the situation, resulting in a performance comparable to that of a tile-based ScECAL.

6.2. π^0 reconstruction to study two-photon separation

A π^0 meson decays into two photons, which can be reconstructed using only calorimeter information. The π^0 energy has a strong influence on the opening angle between the two photons, and variations in the decay angle give rise to different photon energies in the laboratory frame. Samples of π^0 decays at different energies are therefore a powerful tool to measure the ECAL performance, both in terms of pattern recognition (the ability to identify two clusters), and energy resolution (by considering the invariant mass of identified clusters). The opening angle between photons decreases as the π^0 energy increases: the most probable distance between photons from a 10 (30) GeV π^0 decay on the ECAL surface is 53 mm (17 mm).

A PandoraPFA photon cluster is required to satisfy several requirements on several observables, including the absence of associated tracks, the depth of the cluster start within the ECAL, and the angle between the reconstructed cluster axis and the line joining the cluster position to the IP [1]. Fig. 5 shows the fraction of π^0 events in which one, two, and more than two photon clusters are reconstructed in the 45×5 ScECAL, *left*, and alt10 ScECAL, *right*. At each energy 8000 π^0s were injected from the IP almost perpendicular to the beam line and with a uniform distribution in azimuthal angle. In around 9% of events, at least one of the photons from the π^0 decay converts before reaching the ECAL, and the number of events with no reconstructed photons is less than 0.5% for all π^0 energies.

The fraction of events correctly reconstructed with two photon clusters decreases strongly with increasing energy. One contribution to this decrease is the merging of nearby clusters, seen in the increase in the fraction of events in which a single photon cluster is reconstructed, understood as the effect of the decreasing distance between photons. An additional factor is the increase of events in which more than two photon clusters are reconstructed. This is seen in all geometries (5×5 m and alt10 are shown in Fig. 5), demonstrating that this is the effect of PandoraPFA clustering algorithms, rather than the effect of ghost clusters caused by the strip readout.

Fig. 6 shows various characteristics of π^0 events in which exactly two photon-like clusters were identified. Fig. 6a (b) shows the reconstructed invariant mass of such events at different π^0 energies in a 5×5 m tile-ScECAL (45×5 strip-ScECAL with SSA). Fig. 6c shows the fraction of π^0 events which have exactly two identified photon-like clusters with a reconstructed invariant mass greater than 0.1 GeV/c^2, for the four ScECAL geometries considered. The use of alternate tile layers improves

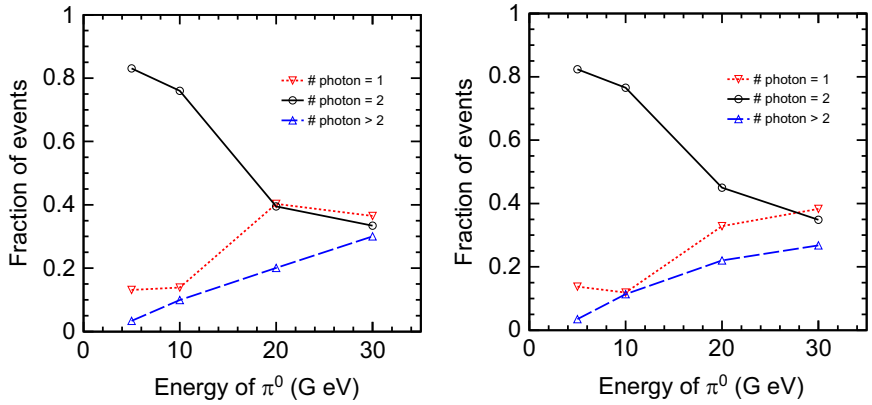

Fig. 5. The fraction of π^0 events reconstructed with one, two, and more than two photon clusters, in the 5×5 mm^2 ScECAL *left* and alt10 strip-ScECAL *right* geometries. No requirements are made on the energy or invariant mass of identified photons. The statistical uncertainties are not visible on this scale.

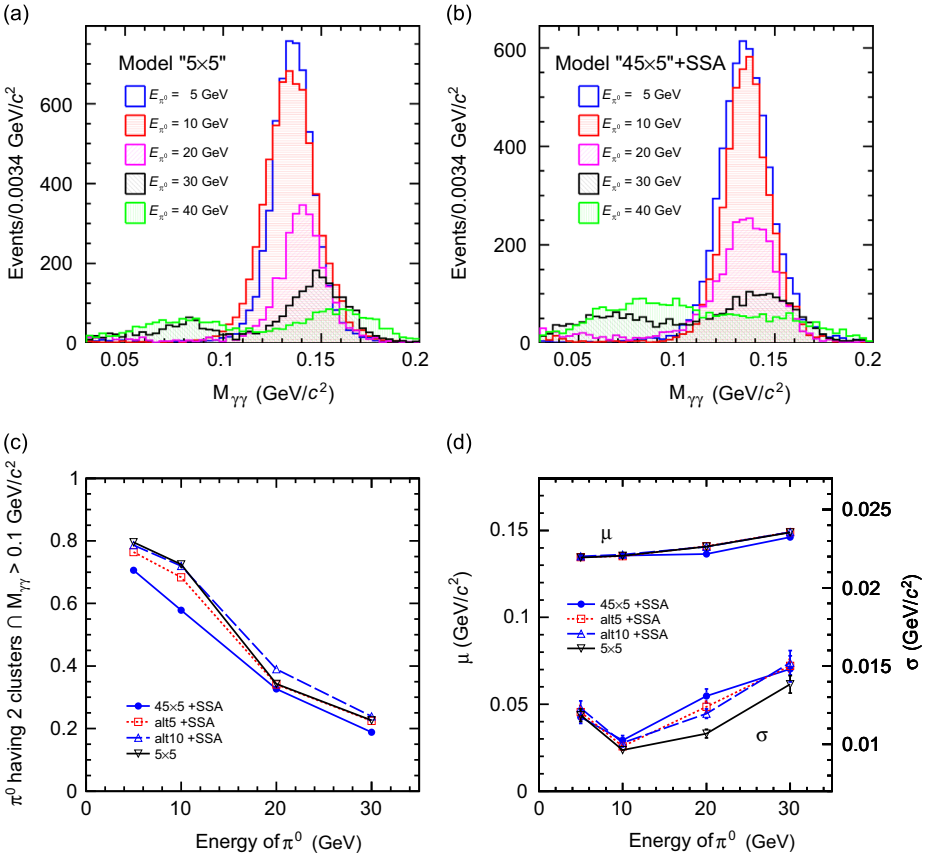

Fig. 6. Reconstructed invariant mass $M_{\gamma\gamma}$ at different π^0 energies, for events with two reconstructed photon like clusters in (a) the 5×5 tile-ScECAL, (b) 45×5 strip-ScECAL, (c) the fractions of such events, in the four ECAL types, having $M_{\gamma\gamma} > 0.1$ GeV/c^2, and (d) the mean (μ) and width (σ) of a Gaussian fit to the reconstructed $M_{\gamma\gamma}$ distributions as a function of the π^0 energy. Vertical bars show statistical uncertainties only.

the performance compared to a purely strip-based geometry, as was also seen in the case of di-muon events. The fact that the alt10 model gives statistically significantly better results than alt5 at energies of 10 and 20 GeV is unexpected, and not yet fully understood. Fig. 6d shows the means and standard deviations of Gaussian fits to the invariant mass spectra for π^0 of different energies, reconstructed in different ScECAL geometries. SSA was used in all models except the 5×5 tile-ScECAL.

These studies show that some level of π^0 reconstruction is possible at energies of up to $\sim$30 GeV using the clustering algorithms implemented in PandoraPFA. No large performance differences were seen between the four considered ECAL geometries.

7. Jet energy resolution

The reconstruction of the energy of two-jet events is an important benchmark test of the PFA. Samples of $10^4 e^+e^- \to q\bar{q}$ ($q = u, d, s$) events were fully simulated in ILD at center-of-mass energies of 91.2, 200, 360, and 500 GeV, and then reconstructed using MarlinReco, including SSA and PandoraPFA.

To evaluate the jet energy resolution, only events in which both quarks were produced in the barrel region ($|\cos(\theta)| < 0.7$) were considered. The total reconstructed event energy E_{jj} is defined as the sum of the energies of all particles reconstructed by PandoraPFA. The distribution of this event energy is used to determine "RMS90(E_{jj})",

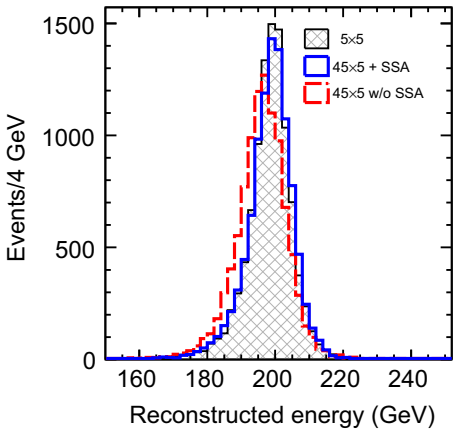

Fig. 7. Reconstructed energy in $q\bar{q}$ events at 200 GeV, for the 5×5 mm^2 ScECAL and the 45×5 mm^2 strip-ScECAL with and without the use of SSA.

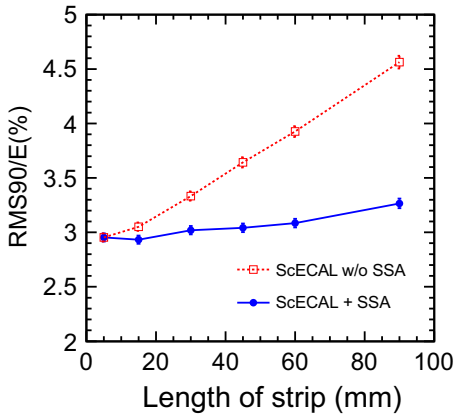

Fig. 8. Estimated single jet energy resolution RMS90/E of jets produced in $q\bar{q}$ events at a center-of-mass energy of 200 GeV.

defined as the root mean square of the smallest range of the E_{jj} distribution which contains at least 90% of events. The single jet energy resolution "RMS90" is estimated by dividing "RMS90(E_{jj})" by $\sqrt{2}$. This RMS90 measure is useful to describe the generally non-Gaussian energy distributions with small, but long, tails obtained by PFA, since it makes no assumptions about the shape of the distribution, and also avoids giving undue weight to events far in the tails.

At lower jet energies, where single particles are well separated in the calorimeters, the energy resolution is dominated by the single particle response of the calorimeters. For higher energy jets, in which the average distance between particles in the calorimeters is smaller, the so-called "confusion" term becomes important. Confusion is due to the mis-association of fragments of charged particle showers to neutral clusters, and vice versa, which leads to a over- or under-counting of energy, leading to a degradation in jet energy resolution. The relative contributions of the single particle calorimetric response and confusion in hadronic jets become comparable at energies of around 100 GeV [1].

7.1. Energy spectra

Fig. 7 shows the total reconstructed energy (E_{jj}) at a center-of-mass energy of 200 GeV when using the 5×5 and 45×5 Sc-ECAL models, with and without the use of SSA. The shape of the energy spectrum for the 45×5 Sc-ECAL is noticeably improved by the use of SSA, and comes close to that of the 5×5 model.

7.2. Dependence on strip length

The dependence of the jet energy resolution at a center-of-mass energy of 200 GeV on the strip length is shown in Fig. 8. The same strip width of 5 mm was used in all models. The strong degradation in performance with increasing strip length seen when SSA is not used is almost completely mitigated by the use of SSA. The difference in jet energy resolution between a ScECAL using 5×5 tiles and one using strips of length up to 60 mm is almost negligible.[5]

7.3. Comparison of 5×5, 45×5, and 15×15 ScECAL models

Fig. 9 shows the jet energy resolution as a function of jet energy for a 45×5 strip-ScECAL without and with SSA, and 15×15 and 5×5 tile-ScECAL models. At smaller jet energies, below 100 GeV, the jet energy resolution is dominated by the intrinsic single-particle resolution, giving a resolution which improves with increasing energy. At energies above 100 GeV, the confusion between charged and neutral calorimeter clusters becomes significant, leading to a degradation of resolution with increasing energy for all ScECAL geometries. The jet energy of the 45×5 strip-ScECAL is significantly improved by using SSA, especially at and above 100 GeV, indicating that confusion is decreased by SSA. A tile of 15×15 has the same area as a 45×5 strip, however it is clear that the jet energy resolution when using the strip geometry is significantly better (by up to 0.5 percentage points (p.p.)), demonstrating the real merit of a strip-based geometry used in conjunction with SSA. The degradation in jet energy resolution between the 5×5 and 45×5 (with SSA) models is rather small, less than 0.25 p.p. for 45 GeV and 250 GeV jets, and around 0.1 p.p. for jets between 100 and 200 GeV.

7.4. Jet energy resolution of strip-tile-ScECAL

As discussed in Section 6.1, the major problem faced by a strip-based ECAL is the formation of ghost clusters. Therefore, the use of interleaving tile layers is expected to improve the jet energy resolution.

Fig. 10 compares the jet energy resolutions of 45×5, alt5, and alt10 models. The performance of the alt5 and alt10 models are almost identical. At jet energies of up to 100 GeV, they give almost the same performance as the 5×5 model, while at higher energies the performance lies approximately half way between the 5×5 and 45×5 models.

8. Discussion

SSA successfully extracts fine granularity information, at an effective scale close to that of the strip width, from a strip-based calorimeter. This motivates the development of scintillator strip-based calorimeters, with their advantages of less readout channels and lower cost, for a wide range of experiments.

The small degradation in jet energy resolution, of around 0.2 p.p., when going from a 5×5 tile-ScECAL to a 45×5 strip-ScECAL can be largely recovered by the use of tile layers interleaved between the strip layers. These tile layers prevent the formation of ghost clusters, as has been demonstrated in the reconstruction of a simple di-muon system. Tile layers with a granularity of 10×10 mm^2 have been shown to work well. The use of such a tile size is technically feasible. The use of 5×5 mm^2 tiles, which have the same area as the 45×5 mm^2 strips currently being used in a prototype ScECAL, and

[5] Note that this assumes a uniform response along the strip length. Response non-uniformities will favor shorter strips.

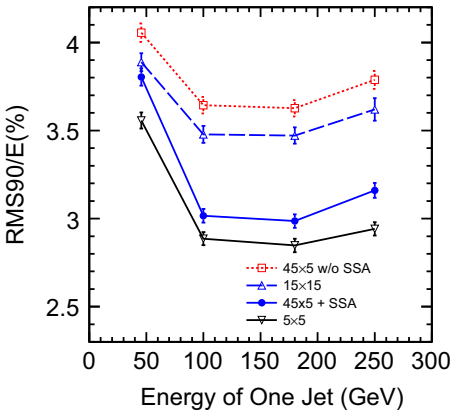

Fig. 9. Single jet energy resolution of as function of jet energy for different tile- and strip-ScECALs.

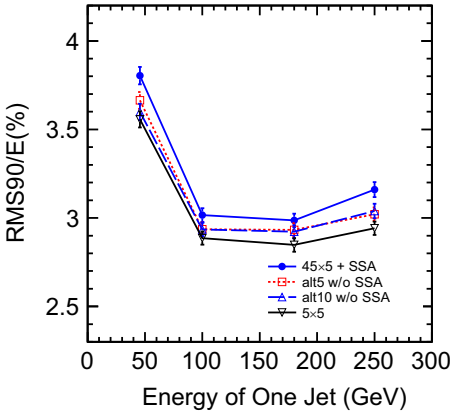

Fig. 10. Single jet energy resolution as a function of jet energy for 45×5, alt5, alt10, and 5×5 ScECAL models.

therefore the same density of readout electronics, is certainly technically feasible. Studies of reconstruction performance with such larger tiles are continuing. The use of scintillator-based 5×5 mm^2 layers is technically difficult at present, but a different technology, such as the silicon readout ECAL being developed by CALICE [11], could be used.

The MOKKA simulation model used in this study describes the detailed geometry of scintillator strips, dead volumes due to the reflector, PPD packages, radiators, circuit boards, and mechanical structures. However, effects such PPD saturation, cross-talk and dark noise phenomena, finite photo-electron statistics, and non-uniform scintillator response have not been simulated in the results presented in this paper. These effects may have some influence on the absolute energy resolutions reported in this paper, but the effect on the relative performance improvements achieved by SSA is expected to be minimal.

9. Summary

An algorithm ("SSA") to extract fine granularity from scintillator strips was developed and tested. The reconstructed position of clusters was significantly improved with SSA: the maximum shift in the reconstructed position of 10 GeV photon clusters from the true position is improved from 5 mm to sub-mm by using SSA on a 45 strip-ScECAL. The strip-ScECAL with SSA also shows comparable particle separation performance to the 5×5 mm^2 tile ScECAL in muon pair and π^0 events. Ghost clusters created when two particles impinge on a square area with a size less than the strip length are effectively removed by interleaving strip layers with square tile layers.

The energy resolution for jets of up to 250 GeV obtained with several ScECAL geometries was compared. The differences in the obtained jet energy resolutions when using a 5×5 tile-ScECAL and 45×5 strip-ScECAL with SSA reconstruction ranged from 0.15 p.p. to 0.25 p.p. This difference can be removed for jet energies below 100 GeV, or decreased to $\sim$0.1 p.p. for jet energies in the range 150–250 GeV, by alternately replacing strip layers with tile layers.

Acknowledgments

The authors would like to thank ILD group for providing essential simulation (MOKKA) and analysis tools (Marlin and PandoraPFA), and for useful discussions. John Marshall has given invaluable advice on the tuning and calibration of the PandoraPFA algorithm. Members of the CALICE collaboration, in particular the CALICE-ASIA group, and of the ILD-ASIA group, have also contributed to many important discussions. This work is supported in part by 'grant-in-aid for specially promoted research: a global research and development program of a state-of-the-art detector system for the ILC' of the Japan Society for Promotion of Science (JSPS) Grant no. 23000002).

(Received 10 September 2013; published 24 January 2014)

A novel scheme for the focusing of high-energy leptons in future linear colliders was proposed in 2001 [P. Raimondi and A. Seryi, Phys. Rev. Lett. **86**, 3779 (2001)]. This scheme has many advantageous properties over previously studied focusing schemes, including being significantly shorter for a given energy and having a significantly better energy bandwidth. Experimental results from the ATF2 accelerator at KEK are presented that validate the operating principle of such a scheme by demonstrating the demagnification of a 1.3 GeV electron beam down to below 65 nm in height using an energy-scaled version of the compact focusing optics designed for the ILC collider.

DOI: 10.1103/PhysRevLett.112.034802 PACS numbers: 41.85.-p, 29.20.Ej, 29.27.-a

Designs for the next generation of energy-frontier lepton colliders envisage the generation and collision of particle beams into the TeV energy scale [1,2]. To deliver the required rate of particle interactions to the detectors for the planned physics program, one of the most challenging technical aspects is the focusing and dynamic manipulation of the colliding particle bunches. A prototype final focus system (FFS) was constructed at the Accelerator Test

 © 2014 American Physical Society

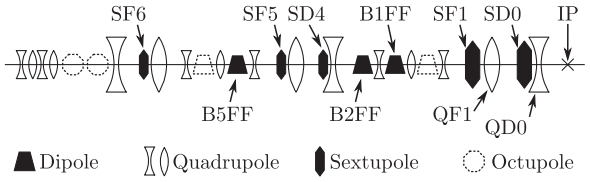

FIG. 1. Schematic of a final focus system with local chromaticity correction. Dashed components are not included in ATF2 test.

Facility (ATF) at KEK, Japan, with the primary goal of verifying a novel, so-called *local chromaticity correction* design first proposed in [3] (one of the earliest reviews of the chromatic compensation scheme can be found in [4]). The new design has many beneficial features over designs considered previously, the most notable being a considerable reduction in length. Both the proposed International Linear Collider (ILC) [1] and the Compact Linear Collider (CLIC) [2] consider this scheme in their baseline designs, although until now it has not been experimentally proven to be practically realizable. We report here results from the test accelerator ATF2 [5] taken during beam operations in 2012 and 2013. We have, on repeated occasions, reduced the 1.3 GeV electron vertical beam size down to approximately 70 nm and below, which has demonstrated the design feasibility.

A schematic of the optics layout is shown in Fig. 1. The complexity of the FFS is driven by the requirement to correct the dominant aberration necessarily present in any magnetic focusing optics: the chromaticity due to the strong final focusing magnets. The novelty of this design is to compensate for the chromaticity locally rather than using a separate optical section as considered previously. This is achieved by placing sextupoles (SD0 and SF1) adjacent to the final doublet quadrupoles which focus the beam and by intentionally introducing horizontal dispersion through the FFS using dipole magnets. The parasitic second-order dispersion is canceled by arranging for an appropriate amount of residual chromaticity to leak from upstream sections. Higher order geometric and chromogeometric aberrations are corrected using additional upstream sextupoles and manipulating the optical transfer matrices between the magnetic elements according to the recipe outlined in [6]. Refinements to the initial design were performed using a global optimization procedure as proposed in [7]. This latest procedure uses a high-order transfer map using a *polymorphic tracking code* to fully compensate second and third order aberrations in the FFS in a semiautomated fashion.

The principal goal for ATF2 was to test the FFS design relevant to ILC. To achieve this, we designed a scaled version of the FFS optics that would present a level of difficulty to "tune" the beam at the focus point comparable to ILC. With magnet strength and focus length constrained by other design considerations, the difficulty to tune the beam is related to the level of demagnification demanded of the magnetic optics, which sets the chromaticity. The beam size at the focal point increases by an amount proportional to the product of the chromaticity and energy spread of the beam. This quantity is presented in Table I (fifth line) for ILC, CLIC, and ATF2, where one can observe that FFS designs with tighter focusing requirements (smaller focal point betatron functions) lead to optics which enlarge the beam size more due to chromatic growth and require tighter control of these and other resulting aberrations. A test facility used to demonstrate the previous focusing design (FFTB [8]) is also shown for comparison. The tuning difficulty manifests itself through the required precise balancing of high-order terms in the magnetic transport lattice. The precision required for the cancellation of these effects increases with the chromaticity, which places increasing demands on the placement tolerances of the magnets as well as their magnetic field settings and quality.

TABLE I. Key FFS parameters for ILC, CLIC, ATF2, and FFTB. L^* is the distance from QD0 to the focus point, ε_y the vertical emittance, ξ_y the vertical chromaticity, σ_E is the rms energy spread, σ_y the rms vertical beam size, and β^* the focal point beta function. The "pushed" optics demonstrates the tightest focusing possible by the ATF2 machine and is of future interest to show performance in conditions more applicable to the CLIC collider design [10].

	ILC (TDR 500 GeV)	ATF2	FFTB	ATF2 (pushed)	CLIC (CDR 3 TeV)

[c]March 2013 results and configuration of ATF2 with bunch charge 80–130 pC.

When one calculates these tolerances (as for ATF2 in [9]), it is apparent that the tolerances are beyond our ability to achieve through standard survey and magnet engineering capabilities (with some magnets requiring submicron placement and/or few parts-per-million field strength settings). For the optics to work as required, we are reliant upon a series of complex online beam tuning procedures outlined below.

The ATF2 experimental FFS was constructed as a new extraction beam line to the existing ATF damping ring (DR) facility at KEK and was completed in December 2008. The ATF DR is a ~140 m circumference electron ring fed by an *s*-band linear accelerator which is used to accelerate the electron bunches produced by an rf gun to 1.3 GeV. In the normal ATF2 mode of operation, the DR delivers bunches of electrons with 1.6 nC charge at 3.12 Hz to the extraction system with typically measured (corrected) emittances of 2 nm rad × 12 pm rad (horizontal and vertical dimensions, respectively). ATF2 is also used as a general-purpose R&D facility, with emphasis on the development of state-of-the-art beam diagnostic devices applicable for use in the next generation of linear colliders. Another noteworthy aspect of ATF2 is the unique way it is managed and operated in an international context: hardware construction, support and operation, operations shifts, software controls, and data analyses were all achieved through a collaborative international team spread across a globally diverse set of institutes.

The ATF2 beam line contains seven dipoles, three septa, 49 quadrupoles, five sextupoles, four skew sextupoles, and 25 corrector magnets. The quadrupoles and dipole bends for the main part of the FFS were purpose designed and built for ATF2, whilst the other magnets were reused from the old ATF extraction line and from the FFTB experiment at SLAC [11]. The beam line can be considered to consist of two sections: the extraction line (EXT) and the FFS. These are depicted in Fig. 2 which also shows the locations of key diagnostic and correction systems. The EXT is used for the extraction and manipulation of the beam out of the DR and preparing it for injection into the FFS beam line, i.e., for correcting residual energy dispersion, cross-plane coupling, and any mismatch from design in the phase space of the incoming beam.

The floor of ATF has been specially prepared, with deep concrete piles, to be vibrationally stable and have a good coherence length (~4 m for relevant frequencies). Additionally, work has been undertaken to ensure the stability of the final doublet (FD: SF1, QF1, SD0, and QD0) support table [12]. The FD elements are attached to a rigid honeycomb block and bolted to the floor, using a thin layer of beeswax between the steel plate support at the base of the block and the floor to ensure good mechanical coupling. Measurements were made demonstrating the relative vibrations between QF1, QD0, and the focal point were within tolerance (~ < 10 nm). A new design of high accuracy, high availability power supply system was installed [13] to satisfy the main field tolerances for ATF2 magnets [9] and to test the high availability requirements for future linear collider magnets. Each quadrupole and sextupole magnet in the FFS was mounted on a 3-axis mover system (horizontal, vertical, and roll directions) [14]. This system is used to align the FFS using the beam, to counter thermal drift, long-period ground motion, etc., and to calibrate the attached cavity beam position monitors (BPMs).

The beam orbit is monitored by a system of stripline (EXT, resolution 1–5 μm [15]), *c*-and *s*-band cavity (FFS, resolution 40–200 nm [16]) BPMs. Also, there is a doublet of *c*-band cavities at the focal point with a demonstrated resolution of < 5 nm [17]. The key properties of the BPMs are high resolution, charge independence, and gain stability (~1% per run period).

The tuning process starts within the EXT [18]: During the extraction process from the DR, the beam develops cross-plane coupling as well as horizontal and vertical energy dispersion that is outside the acceptance bandwidth of the FFS. The energy dispersion is corrected using a pair of quadrupole magnets and a pair of skew-quadrupole magnets within the dispersive part of the EXT. Changes in incoming beam phase space and cross-plane coupling are measured using a system of four beam profile devices which measure the optical transition radiation produced when the beam passes through thin metallic targets sequentially inserted into the path of the beam [19]. This system is capable of measuring and correcting the incoming vertical emittance at the 10% level. The phase space is corrected using an online beam model to adjust nine quadrupole magnets in the beginning section of the EXT. The coupling correction is especially important given the high horizontal to vertical aspect ratio of the beam (270:1 at the FFS focal point). To correct the coupling, the online model is used to compute a correction using four skew-quadrupole magnets in the EXT. The energy dispersion is typically corrected below 5 mm everywhere and

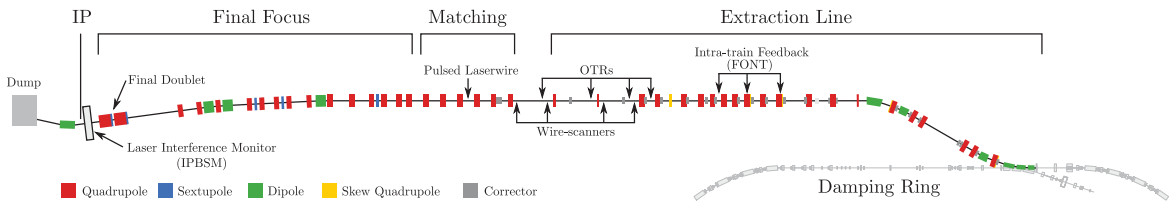

FIG. 2. The extraction line and final focus section of ATF2 after extraction from the damping ring.

the coupling corrected such that the measured beam ellipses on the optical transition radiation screens are corrected at the 0.1 degree level, and the beam phase space (matching) corrected to a *BMAG* [20] mismatch parameter of better than 1%. Simulations have shown this level of correction (the process and accuracy is similar to the simulated correction in the ILC beam delivery system) to be adequate for the FFS tuning to be successfully applied.

The tuning of the FFS ([18,21]) starts with the process of beam-based alignment. This utilizes the magnet movers, correction dipole magnets, and BPMs to align the beam close to the magnetic field centers of the magnets whilst ideally maintaining a straight beam trajectory through the whole system. It is especially important to have an orbit initially close to the field centers of the sextupole magnets. This is achieved by making use of the parabolic orbit response to horizontal and vertical motion of the sextupole magnets. Also of importance during the beam-based alignment procedure is achieving a beam orbit well centered in areas of the beam line with discontinuities to minimize wakefield effects. Careful steering was also important to minimize background signals in the focal point beam size monitor detectors. First-order correction for aberrations remaining directly at the focal point are performed by changing the field strength and rotation angles of the FD quadrupoles. This coarsely corrects for offset of the horizontal and vertical waist and energy dispersion at the focal point, and also for coupling. Following the tuning procedures described thus far typically yields a horizontal spot size of around 10 μm, close to the design value, and a vertical size of between 1 and 3 μm at the FFS focal point. At this stage, the focal point beam size measurements are performed using a carbon wirescanner (diameter $\sim$5 μm).

Monte Carlo style simulations of the complete tuning process, including the final spot size tuning described below, have been performed by multiple people independently using different simulation programs to verify the tuning process. The simulations have demonstrated that the FFS should be tuneable following the procedures that are outlined here. Descriptions of the simulation process which also further describe the various tuning steps can be seen in [21,22]. Similar simulation efforts have been performed for the ILC and CLIC colliders [23]. It is through these simulations that confidence in the ability of this FFS design to generate the desired beam conditions in future collider facilities is reached. Therefore, the ongoing efforts to use the data from ATF2 to validate these simulations are considered important.

Before final tuning, the vertical beam size is dominated by the linear aberrations of waist shift (the focal point displaced longitudinally), energy dispersion, and coupling of the particle's horizontal angle at the focal point to vertical position. We also expect, and observe, second-order coupling and chromatic coupling terms to be present. Tuning knobs devised to remove the expected sources of linear beam size aberrations are constructed using deliberate horizontal and vertical moves of the FFS sextupole magnets to construct orthonormal knobs. Four skew-sextupole magnets were added to control second-order terms and loosen the tolerances on higher-order field terms in the quadrupole magnets.

To perform the final tuning of the vertical spot size at the focal point from $\mathcal{O}(1\ \mu\mathrm{m})$ down to the design 37 nm, we use a unique beam size measurement device, referred to as a *Shintake Monitor* [24]. This is installed at the ATF2 focal point and is a highly improved version of the original, first used at FFTB [8]. It forms a vertically-orientated laser interference pattern at the electron beam focal point, which is scanned across the beam by altering the path length of one arm of the laser interferometer to scan the phase of the interference pattern. The beam size is inferred from the modulation of the resulting Compton scattered photon signal detected by a downstream CsI calorimeter-type photon detector. The *modulation depth* (M) of the signal is written as a function of the laser crossing angle and electron beam spot size:

$$M = C|\cos\theta|\exp[-2(k_y\sigma_y)^2],$$
$$k_y = \pi/d, d = \frac{\lambda}{2\sin(\theta/2)}, \quad (1)$$

where λ is the laser wavelength, θ is the laser crossing angle, and d represents the fringe pitch which determines the beam size range that can be measured. The correction factor C is included to express any contrast reduction of the laser fringe pattern due to mismatch of the laser overlap, distorted laser profile, etc. Multiple possible error sources inherent to the Shintake Monitor measurement process can also be included into this correction factor.

There are three possible collision modes for the Shintake Monitor (made available by adjusting the crossing angle between the interfering laser beams): 2° to 8° (continuously variable), 30°, and 174°. Mode switching is possible remotely and allows for continuously tuning the electron beam from a few micrometers down to a theoretical minimum of about 20 nm. An example modulation scan performed after beam tuning, in the 174° mode of operation, is shown in Fig. 3.

The results from three separate attempts to tune the beam in the ATF2 FFS beam line are summarized in Fig. 4. The entries in the histograms have unity C correction factors and represent an upper limit on the achieved vertical beam size [25]. As shown by these results, we demonstrate a capability for repeated tuning of the vertical beam size to around 70 nm and below using iterations of the tuning techniques described above. This should be compared with a calculated beam size of 450 nm without the use of sextupoles for local chromaticity correction. Rescaled to the nominal ILC beam energy of 250 GeV, these results correspond to a vertical beam size of about 5 nm (below the

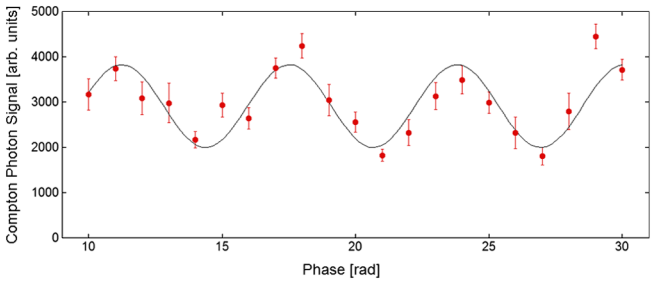

FIG. 3 (color online). Vertical beam size measurement (14th March 2013). Compton photon signals are measured as a function of the Shintake Monitor fringe phase with a crossing angle of 174°. The phase between the maxima of 2π corresponds to 266 nm. The beam size is 64.4 nm from the modulation depth ($M = 0.314$) without any systematic error correction applied.

baseline ILC design criteria). This confirms the practical operability of this optics design and the associated tuning procedure.

Studies are ongoing to identify the systematic effects contributing to the remaining ~30 nm of reduction required to reach the betatron limited beam size given by the optics design of 37 nm. We single out our two major contributing systematic effects here: wakefields and jitter effects in the Shintake Monitor. The beam is especially sensitive to wakefields (an order of magnitude more than expected at ILC) due to the long bunch lengths at ATF2 (6–10 mm) and considerably lower beam energy. We express the wakefield contribution to the measured beam size as $\sigma_y^2 = \sigma_y(0)^2 + w^2 q^2$, where $\sigma_y(0)$ is the zero-charge (no wakefield effect) beam size, w the wakefield contribution, and q the bunch charge in nC. We have measured wakefield contributions of between 100–140 nm nC^{-1} [18]. To minimize the effect on the beam size we operated at the lowest possible charges: between 80 and 200 pC. Work is ongoing to identify the wakefield sources and engineer solutions to mitigate them [26]. The beam size calculation is subject to systematic errors associated with the Shintake Monitor measurement and the complex interplay between these systematic effects and the beam tuning procedure. Error sources considered include those arising from phase jitter between the Shintake Monitor fringe pattern and the electron beam. This can be due to position jitter of the incident electron beam as well as spatial and temporal jitter sources within the laser system itself. Vertical jitter (statistical errors, background fluctuation, and laser timing errors, etc.) and horizontal jitter (where the signal is attenuated by varying power levels in the laser fringe) are present, with the latter responsible for degradation of the modulation depth. For a full treatment of Shintake Monitor error sources, see [25]. The relative phase jitter between the fringe pattern and the electron beam has been estimated by comparing measurements and simulations: this could account for about 10 nm in the beam sizes measured in 174° mode.

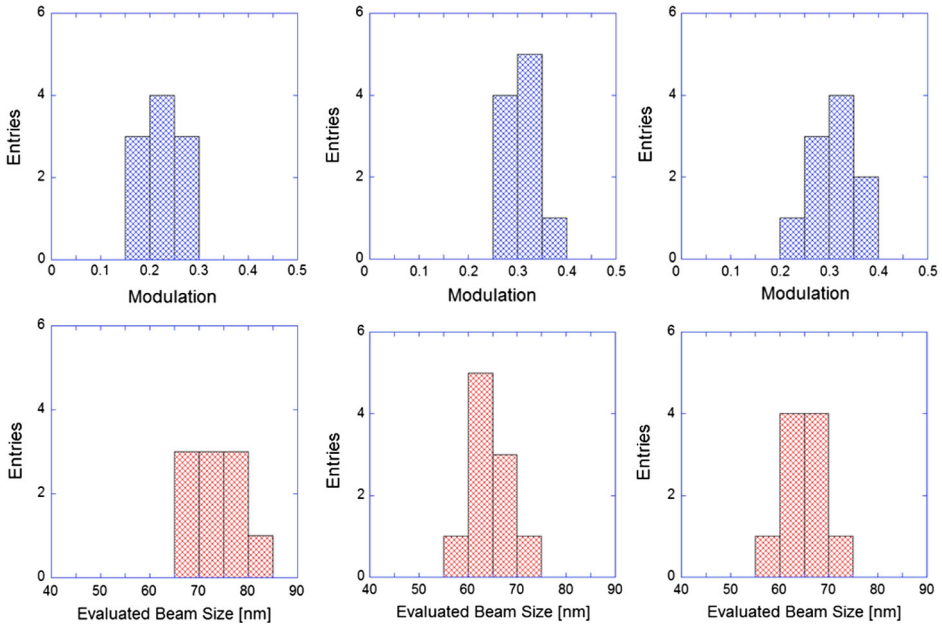

FIG. 4 (color online). Ten consecutive beam size measurements for each of the run periods: December 21, 2012 (left), March 8, 2013 (center), March 14, 2013 (right). The measured modulation depths shown on the top row are: 0.23 ± 0.05, 0.31 ± 0.04, and 0.30 ± 0.04 which correspond to beam sizes of: 73.2 ± 5.2, 64.9 ± 3.5, and 65.2 ± 4.0 nm, respectively (these represent upper limits: no systematic error correction applied). The measured beam charges for these data taking periods were < 200, 100–130 and 80–100 pC, respectively.

The authors would like to acknowledge and thank the tireless work of the administration staff, engineers, and operations contract personnel of ATF2 who have made the construction and operation of the ATF2 facility possible. We also acknowledge and thank KEK management and support staff for their support of this international project. Work also supported in part by Department of Energy Contract No. DE-AC02-76SF00515 and US National Science Foundation Grant No. NSF-PHY 0935296 and Spanish Research Project No. FPA2010-21456-C02-01. We also acknowledge the support of the Agence Nationale de la Recherche of the French Ministry of Research (Programme Blanc, Project No. ATF2-IN2P3-KEK, Contract No. ANR-06-BLAN-0027).

ABSTRACT: Calorimeters with a high granularity are a fundamental requirement of the Particle Flow paradigm. This paper focuses on the prototype of a hadron calorimeter with analog readout, consisting of thirty-eight scintillator layers alternating with steel absorber planes. The scintillator plates are finely segmented into tiles individually read out via Silicon Photomultipliers. The presented results are based on data collected with pion beams in the energy range from 8 GeV to 100 GeV. The fine segmentation of the sensitive layers and the high sampling frequency allow for an excellent reconstruction of the spatial development of hadronic showers. A comparison between data and Monte Carlo simulations is presented, concerning both the longitudinal and lateral development of hadronic showers and the global response of the calorimeter. The performance of several GEANT4 physics lists with respect to these observables is evaluated.

1. Introduction

The next generation of lepton colliders, such as the International Linear Collider (ILC) [1], will require unprecedented detector performances in order to fully exploit the physics potential. A clean separation between the hadronic decays of the W and Z bosons sets the goal for the jet energy resolution. Ideally, the di-jet mass resolution should be comparable to the decay widths of the weak vector bosons. This requires a jet energy resolution σ_E/E_j of the order of 3-4% at the Z peak, which translates approximately into $\sigma_E/E_j \sim 30\%/\sqrt{E_j/\mathrm{GeV}}$. Within the ILC community, Particle Flow calorimetry has been identified as the most promising way to achieve this level of precision [2, 3, 4], as successfully tested on Monte Carlo simulations. For instance, the Pandora Particle Flow algorithm, which has been developed in the context of the detector optimization studies for the ILC, has demonstrated the feasibility of jet energy resolutions of $\sigma_E/E_j \lesssim 3.8\%$ for $40-400\,\mathrm{GeV}$ jets [4].

The key factor in Particle Flow calorimetry is the single particle separability within a jet, which requires a high granularity of the calorimeters. The CALICE collaboration is performing studies of several designs of highly granular calorimeters, with sensitive layers finely segmented into cells, which are individually read out. The stability over a large number of channels of new readout technologies has been demonstrated and reliable procedures of cell equalization and calibration have been established. Furthermore, the high spatial resolution allowed by the fine granularity provides valuable input to the validation of the shower models used for Monte Carlo simulations. Such studies are of broader interest, which goes beyond the support of simulation studies of Particle Flow algorithms. Uncertainties in the shower modeling still contribute significantly to energy scale uncertainties in high energy physics experiments, for instance at the Large Hadron Collider detectors [5].

Since 2006 several beam tests of the CALICE prototypes have been conducted at the Deutsches Elektronen-Synchrotron (DESY), at the European Organization for Nuclear Research (CERN) and at the Fermi National Accelerator Laboratory (FNAL). This paper focuses on data collected at CERN in 2007, when the experimental set-up consisted of a silicon-tungsten electromagnetic sampling calorimeter (SiW-ECAL) [6], a scintillator-steel hadron sampling calorimeter with analog readout (AHCAL) [7] and a scintillator-steel tail catcher and muon tracker (TCMT) [8].

The analyzed data were collected when the prototypes were exposed to pion beams in the energy range from 8 GeV to 100 GeV, provided by the CERN SPS H6 beam line. The overall response of the calorimeter and the lateral and longitudinal profiles of hadronic showers are compared to the predictions made by several Monte Carlo simulations, which make use of different GEANT4 physics lists (Sec. 4).

The study is completed by an update on the validation of the calibration of the AHCAL performed with electromagnetic showers, already described in a previous publication [9]. This study uses data collected both at FNAL and CERN, exposing the prototypes to electron and positron beams in the energy range from 1 GeV to 50 GeV.

2. Experimental Setup

During the beam tests at CERN the detectors were exposed to muon, positron and pion beams.

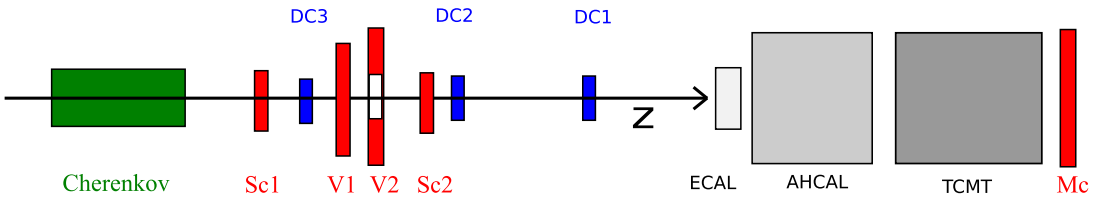

Figure 1. *Schematic layout (not to scale) of the CALICE experimental setup at CERN, with calorimeters and beam instrumentation. Sc1 and Sc2 are the scintillators for the beam trigger, V1 is the multiplicity counter, V2 is the veto trigger and Mc is the scintillator for the muon trigger.*

The SiW-ECAL and the AHCAL were mounted on a movable stage, providing the possibility to translate and rotate the calorimeters with respect to the beam. However, the studies discussed in the following only make use of data collected with the beam incident in the center of the calorimeters, along their center line.

A schematic overview of the experimental setup is shown in Fig. 1. Three sets of wire chambers were operated upstream of the detectors in order to measure the beam coordinates. The coincidence signal of two upstream $10 \times 10\,\mathrm{cm}^2$ scintillator counters (Sc1 and Sc2 in Fig. 1) triggered the readout of the detector (*beam trigger*). One scintillator (V1 in Fig. 1) with an area of $20 \times 20\,\mathrm{cm}^2$ and analog readout tagged multi-particle events (*multiplicity counter*). A $100 \times 100\,\mathrm{cm}^2$ scintillator with a $20 \times 20\,\mathrm{cm}^2$ hole in the center (V2 in Fig. 1) rejected beam halo events (*veto trigger)*. Muons were identified by a downstream $100 \times 100\,\mathrm{cm}^2$ scintillator (Mc in Fig. 1). A Cherenkov counter was also operated in threshold mode to discriminate between electrons and negative pions or between positive pions and protons.

2.1 The SiW-ECAL

The SiW-ECAL is divided into three stacks, each composed of 10 modules of alternating tungsten and silicon layers. Each stack has tungsten layers with different thicknesses: 1.4 mm (0.4 radiation lengths X_0) per layer in the first stack, 2.8 mm or $0.8\,X_0$ in the second and 4.2 mm or $1.2\,X_0$ in the third one. The silicon layers are segmented into PIN diodes of $1 \times 1\,\mathrm{cm}^2$, for a total number of about 9700 read-out cells.

The overall thickness of the prototype is about 20 cm, corresponding to $24.6\,X_0$ or 0.9 nuclear interaction lengths λ_I. The lateral size of the SiW-ECAL is $18 \times 18\,\mathrm{cm}^2$.

2.2 The AHCAL

The AHCAL is a sampling structure of 38 modules, each consisting of a $\sim$2 cm thick steel absorber plate and a sensitive layer instrumented with 0.5 cm thick scintillator tiles. The total depth of the prototype is 1.2 m, translating into about $5.3\,\lambda_\mathrm{I}$, while the lateral dimensions are approximately $1 \times 1\,\mathrm{m}^2$. Each sensitive layer is composed of scintillator tiles of different sizes (Fig. 2, left). The $30 \times 30\,\mathrm{cm}^2$ core has a granularity of $3 \times 3\,\mathrm{cm}^2$, while the outer region is equipped with tiles of increasing sizes ($6 \times 6\,\mathrm{cm}^2$ and $12 \times 12\,\mathrm{cm}^2$). In the last 8 layers the highly granular core is replaced by $6 \times 6\,\mathrm{cm}^2$ tiles. The scintillation light from each tile is read out individually by a Silicon PhotoMultiplier (SiPM) [10, 11], coupled to the scintillator via a WaveLength Shifting fiber (WLS). The SiPMs employed in the AHCAL have a photosensitive surface of $1.1\,\mathrm{mm}^2$, which is

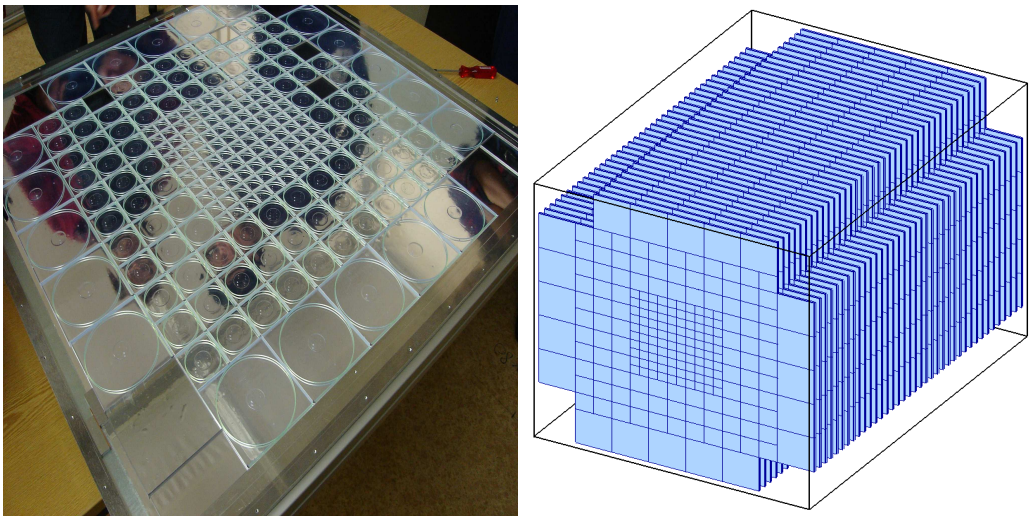

Figure 2. *Left: Segmentation of a sensitive layer of the AHCAL. The size of the scintillator tiles increases towards the outer region. Right: schematic view of the active layers of the AHCAL.*

divided into 1156 pixels. These pixels are individually equipped with a quenching resistor and mounted on a common substrate, in such a way that the charge signal is proportional to the number of pixels fired.

The readout system of the SiPMs is operated in two different modes, called *calibration* and *physics* modes. For calibration purposes single photons need to be resolved in the SiPM spectrum, since the distance between two consecutive peaks in the spectrum determines the gain of the SiPM. Therefore, a short shaping time of the signal (40 ns) and a high amplification are needed. In contrast, during physics runs large signals are produced and the amplification needs to be reduced by approximately a factor 10 to minimize saturation effects. Furthermore, a longer shaping time of about 180 ns is used to provide sufficient latency for the beam trigger decision.

The response of the SiPMs is measured both in physics and calibration modes, in order to determine the gain and saturation level of the SiPMs and the electronics intercalibration between the two operation modes. The response is monitored using LEDs with tunable intensities.

Temperature sensors placed inside the detector in correspondence to each module monitor temperature changes with an accuracy better than 0.6 °C .

2.3 The TCMT

The TCMT is positioned downstream with respect to the AHCAL in order to absorb the tails of the showers leaking out of the AHCAL. The TCMT has a lateral size of $109 \times 109\,\mathrm{cm}^2$ and is 142 cm in depth, corresponding to $5.8\,\lambda_\mathrm{I}$. It consists of two sections, a *fine* one and a *coarse* one. Each section has 8 sensitive layers, alternating with steel absorbers. The absorber plates are 2 cm thick in the fine section and 10 cm thick in the coarse section. The sensitive layers are 0.5 cm thick and are segmented into 5 cm wide and 1 m long scintillator strips, with alternating horizontal and vertical orientation in adjacent layers. The scintillation light is collected by WLS fibers and detected by SiPMs, as for the AHCAL prototype.

3. Calibration

As typical of semiconductor devices, SiPMs are sensitive to temperature and bias voltage changes that affect most of their performance parameters [7]. Moreover, SiPMs show saturation effects, due to the finite number of pixels and the finite pixel recovery time. One of the main technical aims of the AHCAL prototype is to show that these effects can be handled over a large number of channels.

The calibration chain is described in [9]. It proceeds through the following steps:

- inter-cell equalization of the response;
- calibration of the SiPM signal and correction for the non-linear response;
- conversion of the calibrated signal to the GeV scale.

The equalization of the response of the 7608 AHCAL cells is performed using the reference signal from muons [12]. Muons represent the best approximation of the behavior of a Minimum Ionizing Particle (MIP). The signal measured in a cell expressed in ADC counts can be converted to MIPs, using as unit the Most Probable Value (MPV) of the response to the muon beam.

In order to calibrate the SiPM signals, the gain is measured periodically during data taking using the LED system. A correction is also applied to account for the non-linear response of the SiPMs, based on the specific response curve of each SiPM, measured during dedicated laboratory tests. Since the SiPM properties depend on the temperature and the voltage, a given set of calibration constants is only valid for measurements at the same operation conditions and needs to be extrapolated to the operating conditions to account for possible changes, such as temperature fluctuations [13].

Finally, the conversion of the signal to the GeV scale is derived from the response of the detector to electromagnetic showers (Sec. 6).

4. Monte Carlo Simulations

The Monte Carlo simulations for the CALICE prototypes are carried out in the framework of GEANT4 [14]. The version 9.4 patch 3 of GEANT4 is used as default in the following, apart from explicit comparisons with previous versions. The geometries of the calorimeters are simulated within GEANT4 using Mokka [15, 16]. The detectors upstream of the calorimeters are simulated as well. The origin of the simulated particles is located upstream of the full system, such that any interactions with the Cherenkov counter, the scintillator-triggers, the tracking chambers and the air volumes in between are taken into account. Sensitive and passive materials, gaps and support structures are also considered in detail. The simulated AHCAL active layers have a uniform granularity of $1 \times 1\,\mathrm{cm}^2$ cell size. The realistic geometry of the AHCAL is obtained during the digitization procedure, as described below.

4.1 Digitization

The simulated events are processed further in the so-called digitization step, which models the response of the detector and its electronics. This allows the same treatment for data and Monte

Carlo in the subsequent analysis steps, such as calibration and reconstruction. This procedure takes into account several factors:

- the detector granularity. The signal amplitude of the $1 \times 1\,\mathrm{cm}^2$ virtual cells simulated is summed up to obtain the real geometry with 3×3, 6×6 and $12 \times 12\,\mathrm{cm}^2$ cells.
- the light sharing between neighboring tiles (known also as *cross-talk*). A 2.5% light sharing from each tile edge is used in simulations [9].
- non-linearity effects of the SiPMs, based on their specific saturation curves.
- Poissonian fluctuations of the photo-electron statistics.
- the noise contribution. The noise is overlaid on the simulation, using real noise measured in dedicated triggers without beam.

Shielding effects in the scintillator material saturate the scintillation process at high ionization densities. This causes a non-linearity of the light yield, which has been simulated in Monte Carlo according to the Birks Law [17].

The read out electronics have a defined time window. Late energy depositions, for instance from neutrons, might escape this time window. In order to reproduce this effect, a time cut of 150 ns is applied in simulations.

The effects of gaps between the calorimeter tiles, as well as the non-uniform response of the tiles have been studied in Monte Carlo events in [18], showing that these type of effects do not have a significant influence on the measurement of hadron showers.

4.2 Physics Lists

The interactions of hadrons with matter cannot be modeled from first principles alone; several phenomenological models, working with different approximations, exist. An overview of the different models is given in [19]. The main features are summarized here:

- **String Parton Models**. These models are employed to simulate the interaction of medium or high energy hadrons with nuclei. As a first stage the interaction of the particles with at least one nucleon of the nucleus is modeled using a string excitation model. Two different approaches are available in GEANT4: the Fritiof (**FTF**) and the Quark Gluon String (**QGS**) model. In the FTF approach the diffractive scattering of the primary particle with the nucleons is realized only via momentum exchange. In the QGS model the hadron-nucleon interaction is mediated via pomerons. The products of an interaction between the primary particle and the nucleus are one or several excited strings and a nucleus in an excited state. The fragmentation of the excited strings into hadrons is handled by a longitudinal string fragmentation model, with differences between FTF and QGS. The interaction of secondaries with the excited nucleus is handled by a shower model or by a precompound model (see below). In the latter case the string parton models get the suffix "P" (FTFP and QGSP). The de-excitation of the excited nucleus is further simulated by nuclear fragmentation, precompound and nuclear de-excitation models.

- **Parameterized Models**. Low Energy Parametrized (**LEP**) and High Energy Parametrized (**HEP**) models are based on fits to experimental data, with little theoretical guidance. They do not conserve energy, momentum, charge or other quantum numbers on an event-by-event basis, but instead seek to conserve these quantities on average. The approach of GEANT4 is to limit the use of these models and replace them by more sophisticated ones where possible.

- **Cascade Models**. The Bertini cascade **BERT** and the binary cascade **BIC** models are employed at medium and low energies, where the quark-substructure of individual nuclei can be neglected. The BERT model describes a nucleus as a sphere with constant nucleon density. Incident hadrons collide with protons and neutrons in the target nucleus and produce secondaries which in turn collide with other nucleons generating a so-called intra-nuclear cascade. At the end of the cascade the excited nucleus is represented as a sum of particle-hole states which is then decayed by pre-equilibrium, nucleus explosion, fission and evaporation models. The BIC model considers the nucleus as a sum of discrete nucleons, at defined positions and with defined momenta. The propagation through the nucleus of the incident hadron and the secondaries produced are modeled by a cascading series of two-particle collisions. Secondaries are created during the decay of resonances formed during the collisions. The decay of the excited nucleus is handled by the precompound model.

- **Precompound Model**. The precompound model generates the final state for hadron inelastic scattering. It describes the emission of protons, neutrons, and light ions before the equilibrium of a nuclear system is reached. The final products are passed to de-excitation models.

- **`CHIPS` Model**. The Chiral Invariant Phase Space (`CHIPS`) model is a nuclear fragmentation model acting at the quark level. The model is based on the concept of a quasmon, which is an excited intermediate state of massless quarks that are asymptotically free, formed from the quarks of the projectile hadron and of the target nucleon. The quasmons decay via internal quark fusion or by double quark exchange with neighboring quasmons. This model is still at an experimental phase and several parameters are still being optimized.

Several "physics lists" are available in GEANT4, which combine different models in different energy ranges, with a random choice of which model is used for overlapping energy regions. A summary of the physics lists considered in this paper and of their composition at different energies is given in Fig. 3.

5. Event Selection

This paper presents electron (or positron[1]) and negative pion data collected with the experimental set-up described in Sec. 2. While performing measurements with an electron beam, the SiW-ECAL is moved out of the beam line. Though the beam is highly enriched with the nominal particle, some contamination is present and the recorded event samples need to be purified for analysis. The selection applied is summarized in the following and has been tested on Monte Carlo

[1]In the following, by "electron beam" we refer to either an electron or positron beam, since no distinction between the two beam particles is relevant for the performed studies.

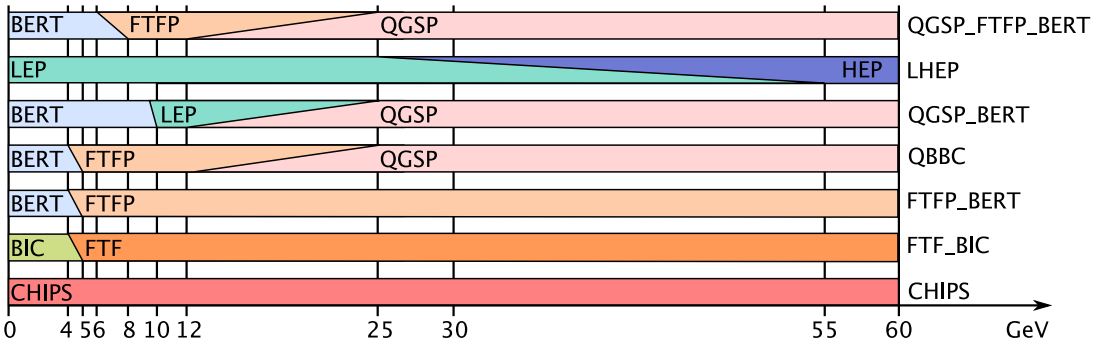

Figure 3. *Models applied at different energies in several physics lists for the simulation of pions in* GEANT4*, version 9.4 patch3.*

simulations, comparing the selection efficiencies for simulated muons, electrons and pions. Some of the selection criteria use information from the AHCAL itself. Applying the same requirements to simulated events confirms that no bias is introduced in the energy distributions. More details on the event selection are given in [20].

Beam events are selected requiring the beam trigger. Events where particles generate a beam trigger signal but fail to reach the calorimeters are rejected by requiring a minimum energy deposition of 4 MIPs in the $3 \times 3\,\mathrm{cm}^2$ cells of the first five layers of the AHCAL. Signals of less than 0.5 MIPs in single cells are rejected in all calorimeters to reduce the noise contribution. This requirement has been tested on events collected without incoming beam, since they have a topology similar to that given by spurious trigger events (i.e. only noise). About 96% of the beam-off events are rejected. Some events contain additional particles in the beam halo or particles that initiate a shower before reaching the AHCAL. These events are excluded by requiring no signal from the veto trigger and less than 15 hits in the $6 \times 6\,\mathrm{cm}^2$ cells of the first five layers of the AHCAL. In order to exclude events with more than one particle depositing energy in the AHCAL at the same time, only events with a multiplicity counter amplitude of less than 1.4 MIPs are kept. This selection yields a multi-particle contamination of less than 0.1%, which has been evaluated using the estimated distribution of the signal from double particle events in the multiplicity counter. Such a distribution has been simulated from the known distribution of noise, measured during triggers without beam, and the signal from single particle events. The signal from single particles has been obtained fitting the distribution of the measured amplitude in the multiplicity counter in a low amplitude region, where no significant contribution from double particle events is expected.

In order to improve the purity of the electron data, a signal is required in the Cherenkov detector. In addition, the center of gravity of the energy deposits in the beam direction is required to be in the front part of the AHCAL (less than 360 mm beyond the front face of the AHCAL). At least one cluster of neighboring hits with a total energy of 18 MIPs or higher has to be found in the AHCAL and an energy of less than 5 MIPs has to be deposited in the last 10 layers of the AHCAL.

For minimizing the electron contamination in pion data, events with a signal in the Cherenkov detector are rejected. The contamination from muons is suppressed by requiring the identification in the AHCAL of the position where the pion shower is initiated by the first hard interaction, since muons generally do not produce showers. The position of the first hard interaction is identified

using a cluster-based algorithm, based on the three-dimensional distribution of hits [21]. Seed hits with visible energies of more than 1.65 MIPs are sorted by their z-positions in ascending order. Starting with the first seed hit according to this ordering, each seed hit and all neighboring hits are assigned to a cluster. As long as one or more of the cells added to a cluster meet the seed hit requirement, the clustering continues and all hits adjacent to these cells are assigned to the same cluster. The cluster closest to the point the pion enters the calorimeter consisting of at least 4 hits and having a minimum energy of 16 MIPs is identified as the beginning of the shower. The end of the cluster axis pointing in the direction of the incoming hadron is used as location of the first inelastic scattering. According to Monte Carlo simulations this procedure allows rejection of muons with an efficiency of more than 80%. Since muons can produce shower-like clusters along the track due to Bremsstrahlung, the muon contamination is further reduced by requiring additionally more than 60 hits in the AHCAL, yielding a muon rejection efficiency of more than 95%.

In order to minimize the systematic uncertainties arising from combining the information from different detectors, pion events for which the shower starting point is found in the SiW-ECAL are rejected. The algorithm used to identify the beginning of the hadronic shower in the SiW-ECAL is described in [22]. The beginning of the shower is found by imposing thresholds on the energy measured in the different layers and on the number of hits deposited. This requirement further minimizes the contamination from electrons, which start to shower in the SiW-ECAL.

6. Calibration Validation

Although the AHCAL is designed to measure hadrons, during beam tests it has also been exposed to electron beams. The study of the electromagnetic response serves to prove the understanding of the detector and to validate the calibration procedure, since electromagnetic showers can be precisely modeled. Additionally, the AHCAL is a non-compensating calorimeter and the energy response to hadrons may be non-linear. In contrast, apart from saturation effects, the response to electromagnetic showers is linear and allows for the determination of the conversion of the calibrated signal to the energy scale in units of GeV (referred to as electromagnetic energy scale).

The study of the electromagnetic response of the AHCAL is described in detail in [9]. Electron data of energies between 10 GeV and 50 GeV are compared to Monte Carlo simulations and the systematic uncertainties associated to the different steps of the calibration procedure are estimated.

Overall, the studies in [9] validate the simulation of electromagnetic showers at a level sufficient for the present analysis of the hadronic response. A residual disagreement of the order of 2 mm is found between data and simulation, when comparing the radial development.

In order to confirm that the results in [9] are up-to-date with the most recent calibration and reconstruction software tools and to extend them over a broader energy range, the measurement of the energy response to electromagnetic showers is repeated here. This new study focuses on the determination of the electromagnetic energy scale, since it is applied in the following to pion data. The validation of the simulation of electromagnetic showers for the observables discussed in [9] is not repeated. The data set has been extended with respect to [9] to lower energies down to 1 GeV, using data collected at FNAL exposing the AHCAL to electron beams, with an experimental set-up similar to the one employed at CERN (Sec. 2).

	u [MIP/GeV]	v [MIP]
Data	42.4 ± 0.3	-1.1 ± 0.9
MC	42.8 ± 0.1	-6.6 ± 0.5

Table 1. *Measured parameters of the linear fit to the electromagnetic response, as defined in Eq. 6.1, for data and Monte Carlo. The errors reported are the fit uncertainties.*

The expected linear response to electrons is described by the following equation:

$$\langle E^{\mathrm{e}}_{\mathrm{rec}} \rangle = p_{\mathrm{beam}} \cdot u + v, \tag{6.1}$$

where $\langle E^{\mathrm{e}}_{\mathrm{rec}} \rangle$ is the mean calibrated response to electrons expressed in MIPs, p_{beam} is the beam momentum, and the parameters u and v are obtained from a linear fit to the dependence of $\langle E^{\mathrm{e}}_{\mathrm{rec}} \rangle$ on p_{beam}. The factor u represents the calibration to the GeV scale of the electromagnetic response. The offset v accounts for the combined effect of the 0.5 MIPs threshold applied to all events (Sec. 5) and of the residual noise above the threshold. The residuals to the fit are shown in Fig. 4 (left). The linearity is better than about 2% at all energies. The errors taken into account in the fit and shown in the figure are both the statistical and the systematic uncertainties. The systematic uncertainty includes a calibration scale uncertainty of 1.6% and the SiPMs saturation uncertainty, which ranges between 0.5% at 1 GeV and 3% at 50 GeV.

The same procedure is applied to Monte Carlo, yielding the results summarized in Tab. 1, which are compatible with the results obtained previously in [9]. The factor u agrees with the results obtained for data within the fit uncertainties, while the offset v disagrees by about 5 standard deviations (5 MIPs or $\sim$100 MeV). This remaining discrepancy is attributed to an imperfect implementation of noise, light-sharing and threshold effects. An imperfect modeling of the beam line and of the energy lost in the upstream material could also contribute. Since in electromagnetic showers the signal cells below threshold concentrate on the edges, an inaccurate simulation of the lateral extension of electromagnetic showers, as observed in [9], could also contribute to this effect.

The difference between the simulated response and the measured response is shown in Fig. 4 (right). The discrepancy in v is visible at low energies, while at high energies the Monte Carlo slightly underestimates the SiPMs saturation.

The electromagnetic analysis allows the conclusion that the detector calibration and simulation are sufficiently understood, in order to carry on studies based on hadronic data. The calibration to the GeV scale obtained for electromagnetic data is applied in the following to pion data and to the digitized Monte Carlo.

6.1 Systematic Uncertainties

The results shown in the following focus on the response of the calorimeter to hadrons. The systematic uncertainty on the calibration scale of 1.6%, quoted above for the electromagnetic study, affects the hadronic analysis in the same way. This uncertainty is relevant for the study of the hadronic energy response discussed in Sec. 7. The saturation uncertainty, which ranges between 0.5% at 1 GeV and 3% at 50 GeV for elecromagnetic showers, is expected to have a reduced impact on hadronic showers, due to the lower energy density. This is discussed in [9], where it is shown that electromagnetic showers have more hits with high energy deposition that pion showers,

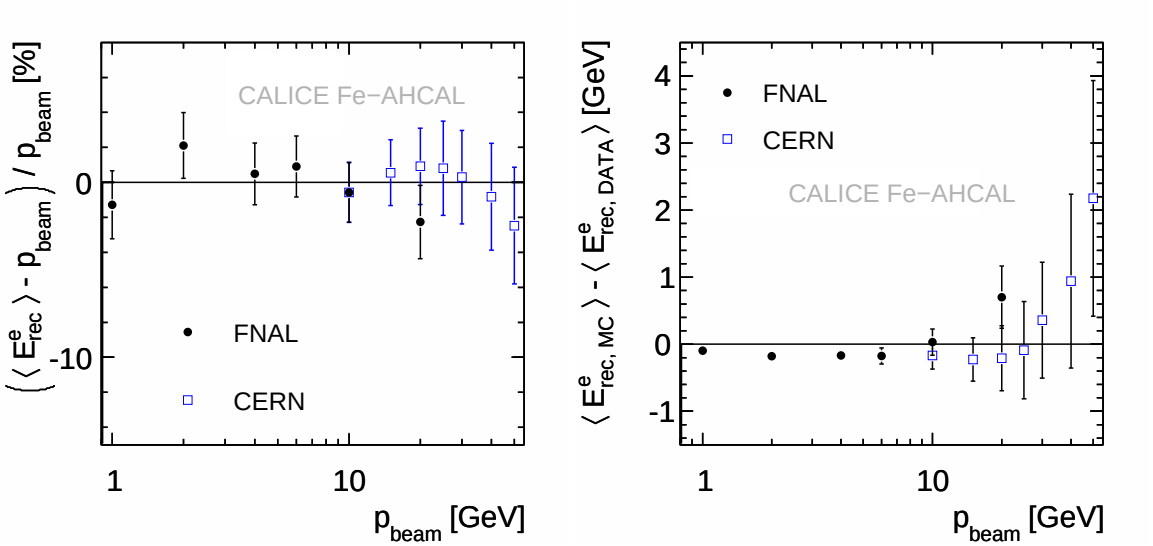

Figure 4. *Left: Residuals from linearity for electromagnetic data collected at FNAL (circles) and CERN (squares). Right: Difference between the simulated and the measured electromagnetic response. The error bars take into account both the statistical and the systematic uncertainties, as described in the text.*

even when the beam energy is only half that of the pion. Therefore, this source of uncertainty is neglected during the measurement of the hadronic energy response.

The measurement of the pion interaction length is dominated by the fit uncertainty, as discussed in Sec. 8.

The individual response of each layer is relevant for the longitudinal shower profiles discussed in Sec. 9. For this study a dedicated evaluation of the systematics has been performed, as described in Sec. 9. A similiar procedure has been performed for radial profiles (Sec. 10), yielding negligible uncertainties.

Systematic uncertainties are assumed to affect in a negligible way the observables concerning average global quantities of the calorimeter, such as the center of gravity and the standard deviation of longitudinal profiles (Sec. 9) , the mean energy-weighted shower radius and the standard deviation of radial energy distributions (Sec. 10). As a cross-check, the uncertainties obtained for longitudinal profiles have been propagated to the measurement of the longitudinal center of gravity of showers, obtaining uncertainties lower than 1%, and to the standard deviation of the longitudinal profiles, yielding uncertainties lower than 0.5%. Such a level of accuracy does not affect comparisons between data and Monte Carlo, which involve larger effects.

7. Energy Response

The calibrated response to pion showers in units of MIPs is converted to the GeV scale according to the following equation:

$$E_{\mathrm{rec}}\,[\mathrm{GeV}] = (E_{\mathrm{ECAL1}} + E_{\mathrm{ECAL2}} \cdot 2 + E_{\mathrm{ECAL3}} \cdot 3) \cdot 0.002953 + (E_{\mathrm{AHCAL}} - v)/u, \tag{7.1}$$

where E_{ECAL1} is the energy in MIPs measured in the first section of the SiW-ECAL. E_{ECAL2}, E_{ECAL3} are defined analogously. E_{AHCAL} is the energy in MIPs measured in the AHCAL. The factors 2 and 3 account for the different sampling structure in the three sections of the SiW-ECAL, with different absorber thicknesses. The factor 0.002953 is obtained from simulations. It has been evaluated using simulated muons, since the selection criteria require pions to start showering in the AHCAL and so to traverse the SiW-ECAL losing energy only by ionization, similarly to muons. The parameters u and v have been defined in Sec. 6 and refer to the electromagnetic energy scale. Additional corrections to account for the different response to electromagnetic and hadronic showers need to be applied, if one is interested in the absolute scale of the hadronic response. This topic is discussed in [23] and is not relevant for this paper, which only concerns comparisons between the measured and the simulated response to pions.

In addition to the requirements discussed in Sec. 5, only events for which the hadronic shower starts in the first five AHCAL layers are considered for the studies presented in this section. This requirement minimizes the leakage of the showers out of the AHCAL and reduces the energy collected by the TCMT. This additional selection can be applied since this paper focuses on the validation of Monte Carlo models, rather than on the estimate of the energy resolution. Studies of leakage for non-contained showers have been performed in [24, 8].

The total energy distribution for pion runs at different energies is shown in Fig. 5 (top). Figure 5 (lower left) presents the response to 10 GeV pions for data and for digitized Monte Carlo simulations based on the FTFP_BERT physics list. The shape of the response as well as the position of the peak are rather well simulated by the Monte Carlo. At higher energies, as exemplified by an 80 GeV run in Fig. 5 (lower right), the agreement gets worse. This is due to a worse simulation of the energy response and to an imperfect description of the shower length by the Monte Carlo, which results in a different impact of leakage in data and Monte Carlo. The longitudinal development of showers is described in Sec. 9.

In order to quantify the agreement between data and Monte Carlo models, their mean response as function of beam momentum is compared in Fig. 6. The average energy response $\langle E_{\mathrm{rec}} \rangle$ for the different beam energies is given by the arithmetic mean of the energy distributions, after subtraction of the average contribution of the noise above the 0.5 MIPs threshold. The QGSP_BERT, the QGSP_FTFP_BERT and the QBBC physics lists agree within 4% with data at 8 GeV, where the Bertini model is employed. At higher energies the disagreement with data increases, by about 7-10% at 100 GeV. The difference between QGSP_FTFP_BERT and QBBC at low energies, where they apply the same model, is attributed to the different treatment of the inelastic scattering of secondary protons and neutrons at very low energies, which is described using the Bertini model in QGSP_FTFP_BERT, while QBBC uses the BIC model. The Fritiof-based physics lists underestimate the response compared to the data at 8 GeV by up to 2-3%, while they agree with data in the range 10-30 GeV. At higher energies, between 40 GeV and 100 GeV, they overestimate data, though the deviations are below 6%. The performance of the FTFP_BERT physics list for previous versions of GEANT4 is shown in Fig. 6 (top, right). The performance has significantly improved from the version 9.2 to the version 9.3. In the most recent version the response has slightly increased with respect to the version 9.3, worsening the agreement with data at high energies. CHIPS overestimates data at all energies, by up to 10% at 80 GeV. At low energies, below 20 GeV the description of the energy response improves and the disagreement reduces to 2%. The LHEP physics list, based

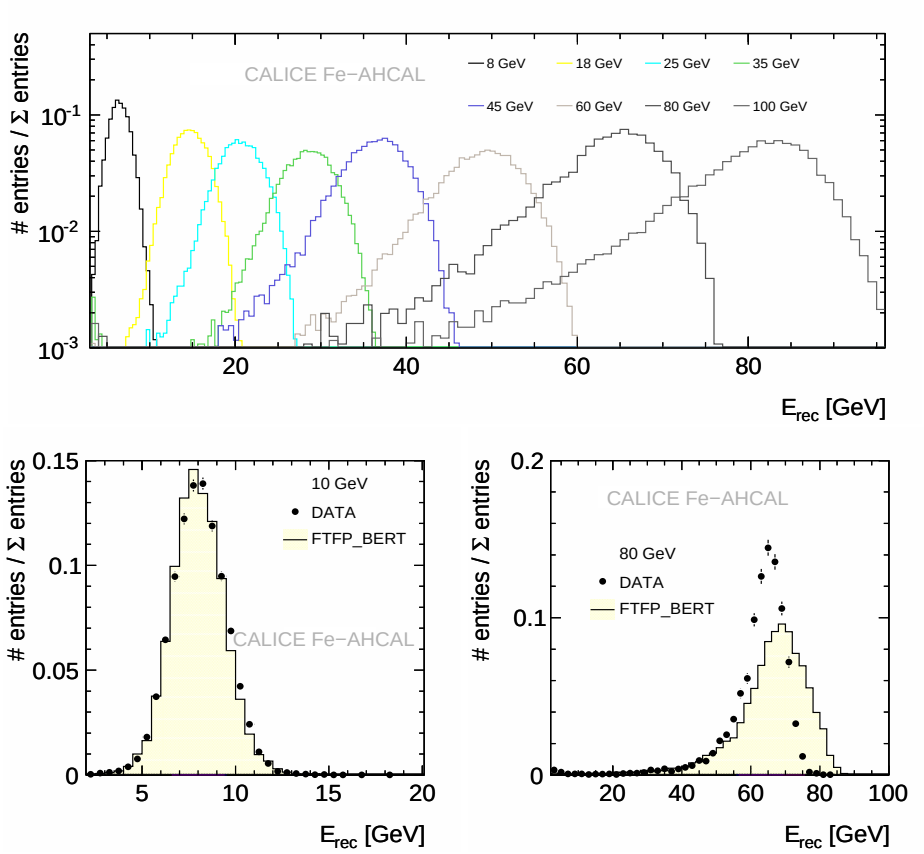

Figure 5. *Top: Total energy distribution for selected pion events at different energies. Bottom, left (right): Response to 10 GeV (80 GeV) pions for data (points) and for digitized Monte Carlo simulations using the FTFP_BERT physics list.*

on parameterized models, largely underestimates the response by up to 8-10% at 8-10 GeV. At high energies above 40 GeV the disagreement between data and Monte Carlo reduces to about 3%.

8. Pion Interaction Length

As long as a pion traversing a material does not interact strongly with a nucleus, it loses energy mainly by ionization. The probability P_I of having an inelastic hadron-nucleus interaction before a distance x is given by:

$$P_I = 1 - e^{-x/\lambda_\pi}, \tag{8.1}$$

where λ_π is the pion interaction length.

The position of the first hard interaction of the primary beam particle is approximated by the reconstructed layer where the shower starts. The measured distribution of the shower starting point follows the exponential behavior expected from Eq. 8.1, as shown in Fig. 7 (left) for 45 GeV pion showers.

From this distribution it is possible to derive the effective interaction length of a pion λ_π in the AHCAL. The interaction length is obtained fitting an exponential to the distribution. The first

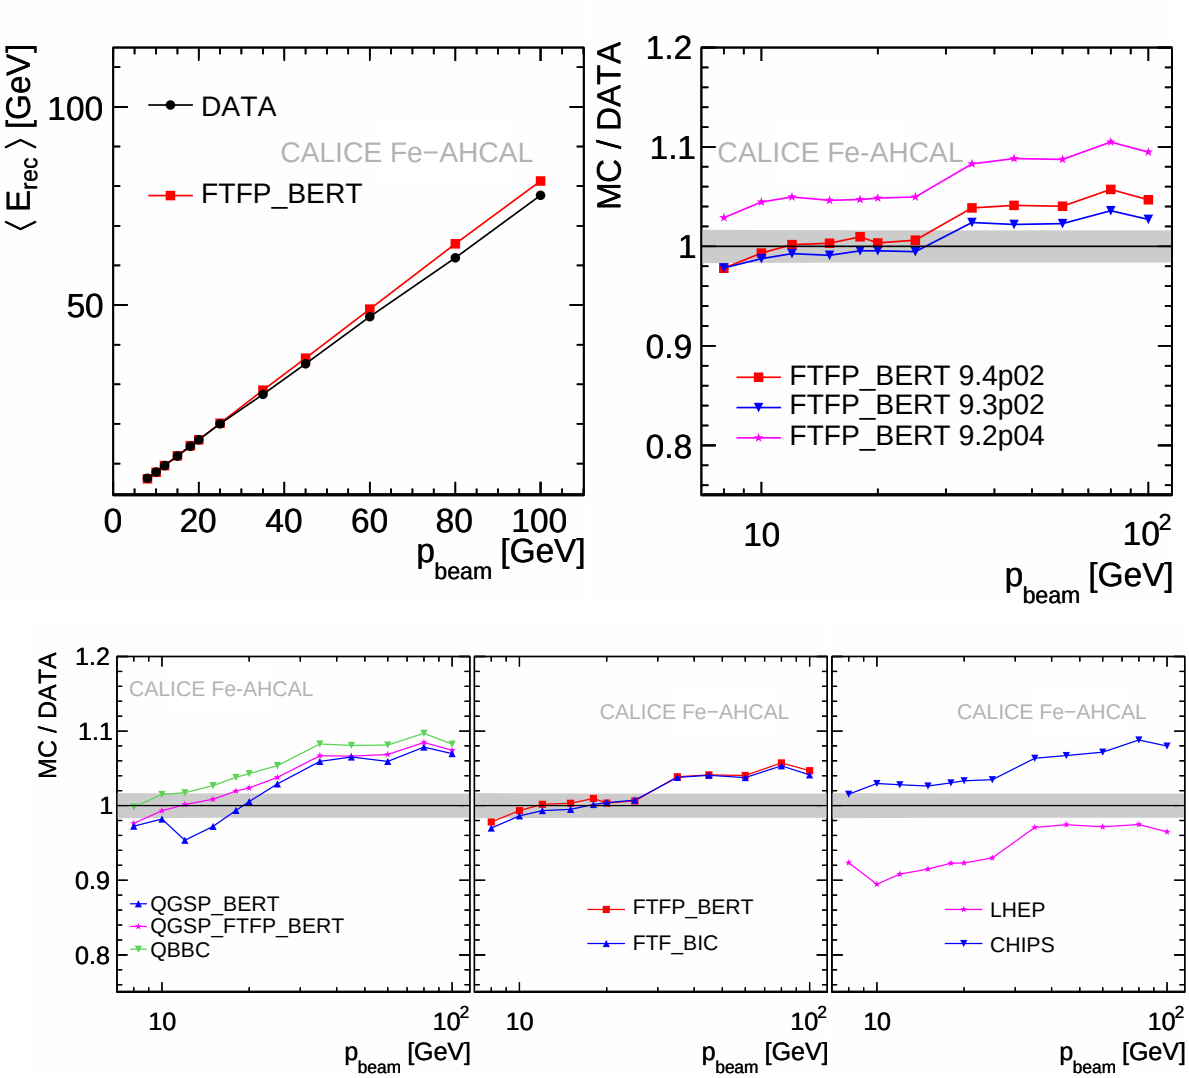

Figure 6. *Summary of the energy response to pions. Top, left: For data and for the FTFP_BERT physics list. Top, right: Ratio between Monte Carlo and data using the FTFP_BERT physics list with different versions of* GEANT4*. Bottom: Ratio between Monte Carlo and data for several physics list. The gray band in the ratios represents the uncertainty on data (statistical plus a systematic calibration uncertainty of 1.6%).*

layers are excluded from the fit, since the uncertainty of the algorithm used to determine the layer of the first hard interaction is larger there, due to the contamination from showers that start to develop in the last layers of the SiW-ECAL. The last layers are also not considered when performing the fit, since the fluctuations are higher due to the lower statistics and the algorithm used to identify the shower starting point has not been optimized for the coarser granularity of the last layers of the AHCAL. Hence, the fit is performed in the range from 120 mm to 800 mm of the longitudinal z coordinate.

The extracted values of the interaction length for data and Monte Carlo are shown in Fig. 8. No energy dependence of the interaction length is observed in data. The measurements yield an average of $\lambda_\pi = (26.8 \pm 0.46)$ cm. The error includes the statistical error, determined from the

standard deviation of the measurements performed at different energies, and the systematic error. The only source of systematics taken into account is the fit uncertainty due to choice of the fit range. Such an uncertainty has been determined by comparing the fit results for two different z ranges, namely [120, 800] mm and [90, 900] mm. The λ_π value obtained is in good agreement with the expectations from the material composition of the detector, which yield a λ_π of approximately 28 cm (from [7]: 4.28 λ_π for an AHCAL thickness of 120.26 cm, which yield a λ_π of 28.1 cm). This serves as a cross-check of the detector modeling used for Monte Carlo simulations, which assumes the material composition of the detector described in [7], and of the algorithm developed for the identification of the shower starting point, used in the event selection.

All Monte Carlo models except `CHIPS` and `LHEP` use the same cross-sections for hadron-nucleus interactions, which is reflected in a general agreement between the models themselves within fit uncertainties. The `QGSP_FTFP_BERT` and the Fritiof-based physics lists agree with data at approximately the 4% level at all energies, while `QBBC` agrees with data within 6%. The `QGSP_BERT` physics list is consistent with data within 4% for energies greater than 10 GeV, while at 10 GeV and 8 GeV the disagreement with data increases by up to ∼9%. `CHIPS` shows a behavior similar to the other models, with a good agreement with data, better than 4% at all energies. Only `LHEP` has an energy-dependent trend and systematically underestimates data by up to 14% at 100 GeV.

9. Longitudinal Development

Thanks to the fine longitudinal segmentation of the AHCAL into 38 layers, the longitudinal profile of hadronic showers can be investigated with an excellent accuracy. In particular, the fluctuations

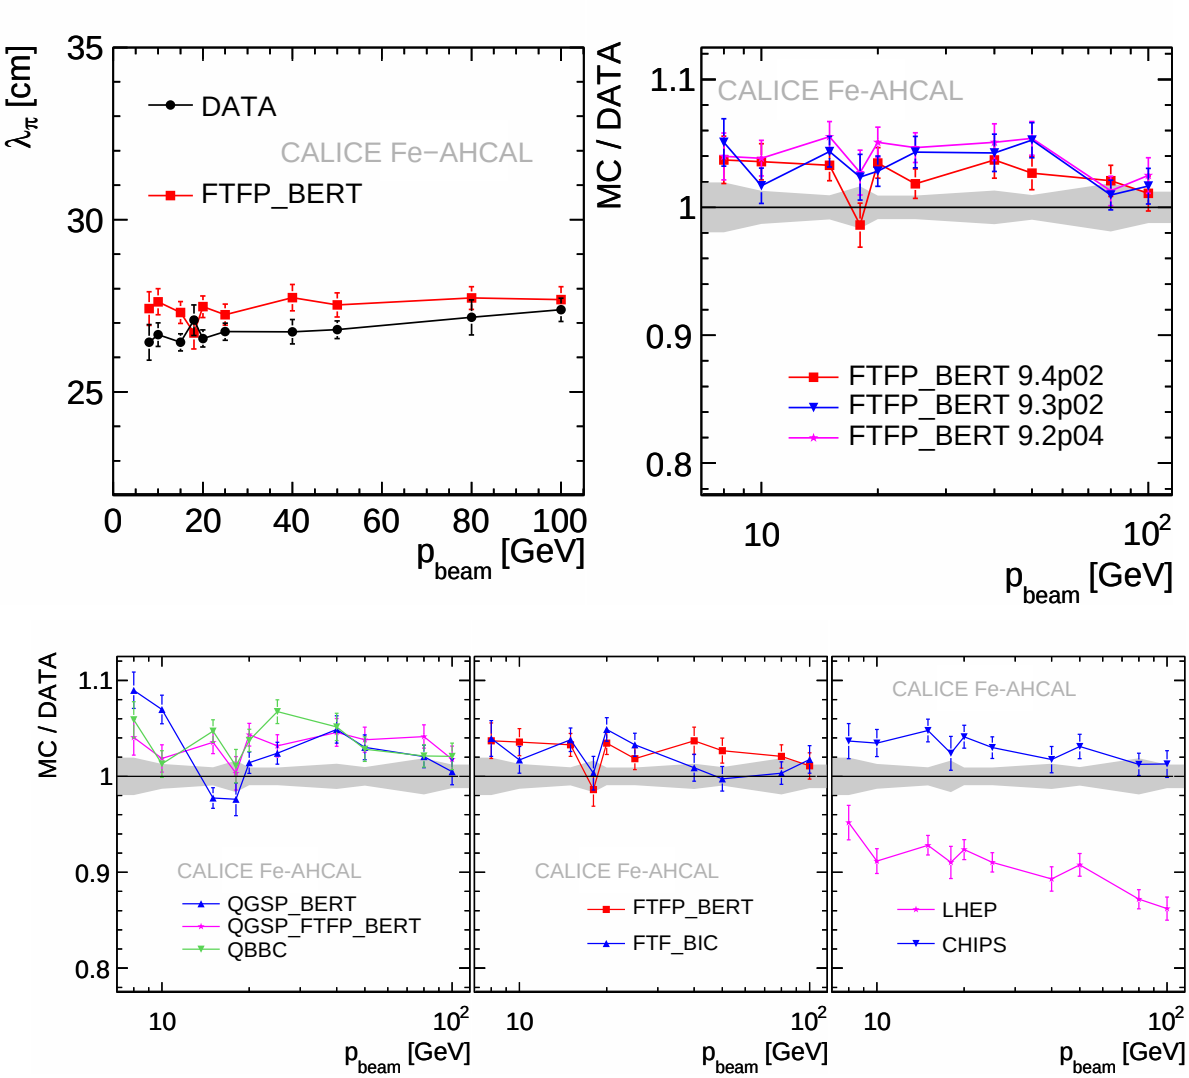

Figure 8. *Summary of the measurement of the interaction length of pions in the AHCAL. Top, left: For data and for the FTFP_BERT physics list. Top, right: Ratio between Monte Carlo and data using the FTFP_BERT physics list with different versions of* GEANT4. *Bottom: Ratio between Monte Carlo and data for several physics lists. The gray band in the ratios represents the uncertainty on data (statistical plus systematic fit uncertainty). The error bands take into account both the statistical uncertainty and the systematic uncertainty due to the choice of the fit range.*

in the shower starting point, which are large since they are due to the statistical behavior of one single particle, can be separated from the intrinsic longitudinal shower development. This is shown in Fig. 7 (right), where the shower profile relative to the calorimeter front face and the shower profile relative to the measured shower starting point are compared. The latter is shorter, since only the effective length of the hadronic shower is taken into account, excluding the path of the primary beam particle before the first hard interaction. In addition, the layer-to-layer fluctuations due to calibration uncertainties are smeared out into a smoother distribution, as different showers extend over different regions of the calorimeter. In the following, the results are therefore discussed

for profiles relative to the measured shower starting point, shown in Fig. 9. However, the trend of the agreement with data of the physics lists considered is independent from the definition of the profiles. The unit chosen to express the longitudinal development of showers is the nuclear interaction length λ_{I}. For the AHCAL it has been estimated to correspond to 231.1 mm.

Fig. 9 shows the longitudinal shower profiles for pions of 8 GeV, 18 GeV and 80 GeV, in data and Monte Carlo. The shown distributions are average distributions over all selected events. The profiles are normalized to unity. The normalization allows the decoupling of the pure description of the spatial development of showers from the energy response already discussed above. The three energy points have been chosen in order to partially disentangle the different contributions from low, medium and high energy models (Fig. 3). The energy contribution from electrons, positrons, pions and protons produced during the showers can be determined for the simulated events and is also shown in the graphs. The technique used for this decomposition is described in [25]. This additional information helps to understand which physics processes contribute most in which phase of the shower development. In the first layers electrons and positrons contribute about equally to hadrons to the energy deposition. In the region around the shower maximum the deposition of electromagnetic energy dominates while in the tails the energy depositions by hadrons and electrons are again about equal.

The uncertainty on the measurement of the profiles has been evaluated creating 6 profiles, for showers starting in 6 different layers of the AHCAL, namely the first 6 layers. Due to the exponential distribution of the measured layer of the first hard interaction (Fig. 7), the 6 profiles considered dominate the final measurement of the longitudinal shower profiles, which has been performed without any selection on the shower starting point. The first (second, ...) bin of the profiles for showers starting in the first layer of the AHCAL, corresponds to the first (second, ...) layer of the AHCAL. The first (second, ...) bin of the profiles for showers starting in the second layer of the AHCAL, corresponds to the second (third, ...) layer of the AHCAL. An analogous correspondence between the bins of the profiles and the AHCAL layers is true for the remaining profiles measured for showers starting in layers 3-6 of the AHCAL. The variance var_j of the energy desposited in the bin j of the profiles has been evaluated as the variance between the 6 measurements. Some bins in the tails are not covered by all the 6 measurements. For instance, showers starting in the second layer of the AHCAL extend over at most 37 AHCAL layers and give no contribution to the bin 38 of the shower profiles.

The development of showers does not depend on the measured layer of the first interaction and with an ideal calorimeter the 6 considered profiles would not differ. The measured variance is an inclusive measurement of the uncertainties associated to the energy measurement, such as bad calibrations and saturation effects. Thanks to the high statistics of several 10^4 events used to create the profiles, the variance is dominated by systematic uncertainties, while statistical fluctuations are expected to be negligible.

For the final measurement of the longitudinal shower profiles no selection on the measured layer of the first hard interaction has been applied and n_j different profiles are averaged to calculate the average energy deposition in the j-th layer, namely 37 for the first layer, 36 for the second, and so on for the remaining layers. The final uncertainty to be associated to the energy measurement in

the layer j is given by:

$$\sigma_{E_j} = \sqrt{\frac{var_j}{n_j}}. \tag{9.1}$$

This uncertainty is shown with a grey area in Fig. 9.

The position of the shower maximum is in general quite well reproduced by Monte Carlo models. In the first part of the showers QGSP_BERT, QGSP_FTFP_BERT and QBBC agree with data at the 5-10% level at 8 GeV and 18 GeV. The same is true for the Fritiof-based physics lists and for CHIPS. Larger deviations are present in the tails of the showers, but they remain within systematic uncertainties. At 80 GeV the energy deposition in the shower maximum is generally underestimated by Monte Carlo simulations, with discrepancies up to 20%. At 80 GeV CHIPS shows a moderate tendency to prefer compact showers, overestimating the energy deposition in the first part of the shower and underestimating the tail. A similar trend is exhibited by LHEP at 8 GeV and 18 GeV, though with a more pronounced disagreement with data, up to 50% at 8 GeV.

The energy dependence of the center of gravity and of the standard deviation of the longitudinal shower profiles are shown in Fig. 10 and Fig. 11, respectively. The center of gravity is defined as the energy weighted mean of the hit longitudinal coordinate along the shower axis:

$$\langle z \rangle = \frac{\sum_i E_i \cdot z_i}{\sum_i E_i}, \tag{9.2}$$

while the standard deviation is defined as:

$$\sqrt{\langle z^2 \rangle - \langle z \rangle^2} = \sqrt{\frac{\sum_i E_i \cdot (z_i - \langle z \rangle)^2}{\sum_i E_i}}, \tag{9.3}$$

where z_i is the longitudinal coordinate of the cell i and E_i is the energy measured in that cell.

The center of gravity is located between 0.8 and 1.6 interaction lengths and exhibits the expected logarithmic increase with energy. The standard deviation only mildly increases with energy from about 0.825 to about 0.925 λ_I.

All physics lists except LHEP show a similar energy-dependent behavior in the description of the center of gravity $\langle z \rangle$ of showers. The ratio Monte Carlo over data decreases with energy. Overall the best behavior is shown by the physics lists based on the Fritiof model, which agree with data at about the 4% level. The LHEP parameterized models show also for this observable the worst agreement with data. The disagreement is up to 15% at 8 GeV. A similar message is given by the standard deviation $\sqrt{\langle z^2 \rangle - \langle z \rangle^2}$.

The changes in FTFP_BERT with different GEANT4 versions are significant for both longitudinal observables and the agreement with data changes by a few percent for different versions. The ratio Monte Carlo over data for the center of gravity $\langle z \rangle$ gets generally worse when comparing versions 9.3 and 9.4, apart from the intermediate energy points between 30 GeV and 50 GeV, where the agreement is comparable. Both versions of the physics list show an improvement with respect to the older version 9.2. The agreement with data for the standard deviation $\sqrt{\langle z^2 \rangle - \langle z \rangle^2}$ improves in the version 9.3 of GEANT4, with respect to the older version. The most recent version has a worse performance than the version 9.3 at energies greater than 20 GeV, but is still significantly better than version 9.2.

10. Radial Development

An accurate modeling of the transverse shower profile is particularly important for a successful development of particle flow algorithms, since it affects the degree of overlap between showers and therefore the efficiency in disentangling single particles within jets. Using the AHCAL, it is possible to reconstruct the radial development of showers with high precision, thanks to the fine lateral segmentation of the sensitive layers.

For each cell of the AHCAL, the radial distance to the incoming particle trajectory is determined as:

$$r_i = \sqrt{(x_i - x_0)^2 + (y_i - y_0)^2}, \tag{10.1}$$

where (x_i, y_i) are the coordinates of the center of the cell i and (x_0, y_0) is the position of the energy weighted shower center:

$$x_0 = \frac{\sum_i E_i \cdot x_i}{\sum_i E_i} \text{ and } y_0 = \frac{\sum_i E_i \cdot y_i}{\sum_i E_i}, \tag{10.2}$$

E_i being the energy measured in the cell i.

For this study, all physical AHCAL cells are subdivided into virtual cells of $1 \times 1\,\text{cm}^2$ [21]. The energy deposited in the physical cells is equally distributed over the virtual cells covering its area. The dimension of the smallest AHCAL tiles, i.e. $3 \times 3\,\text{cm}^2$, is chosen as natural bin width for the radial shower profiles, which show the average energy deposited in the AHCAL as a function of the coordinate r. The radial shower profiles are shown in Fig. 12, for the same set of beam energies and physics lists considered for the longitudinal profiles.

All physics lists show a similar behavior and tend to underestimate the radial extent of showers, showing a relatively higher energy deposition in the core of the showers. The disagreement is more pronounced at high energies. `QGSP_BERT`, `QGSP_FTFP_BERT` and `QBBC` agree better with data at low energies, in particular `QGSP_BERT`, which is consistent with data within 5-10%. `CHIPS` has the best behavior at 80 GeV, describing the data at the 5-10% level. The ratios between data and Monte Carlo generally show a discontinuity at about 300-350 mm, corresponding to the transition between the tiles with a granularity of $6 \times 6\,\text{cm}^2$ and the outer tiles with a granularity of $12 \times 12\,\text{cm}^2$ in the active layers.

As expected, the contributions from electrons, pions and protons show that the electromagnetic component of the showers is concentrated in the core, while in the tails the energy is mostly deposited by protons.

The mean energy-weighted shower radius and the standard deviation of the radial energy distribution are compared for all physics lists and all energies in Fig. 13 and Fig. 14, respectively. As for the longitudinal observables, the mean is defined as:

$$\langle r \rangle = \frac{\Sigma E_i \cdot r_i}{\Sigma E_i}, \tag{10.3}$$

and the standard deviation as:

$$\sqrt{\langle r^2 \rangle - \langle r \rangle^2}, \quad \langle r^2 \rangle = \frac{\Sigma E_i \cdot r_i^2}{\Sigma E_i}, \tag{10.4}$$

where r_i is defined in Eq. 10.1.

The energy-weighted shower radius ranges between 90 mm and 60 mm and exhibits the expected exponential decrease with energy [26]. The standard deviation only mildly decreases with energy from about 80 mm to about 70 mm.

Monte Carlo models underestimate the radial extent of showers, both in terms of radius and of standard deviation. The majority of simulations exhibit an energy-dependent behavior and the disagreement with data increases with energy. QGSP_BERT reproduces the mean radius of showers at 8-10 GeV, but disagrees with data by up to about 12% at high energies. Similar results are achieved by QGSP_FTFP_BERT and QBBC, though they give a worse agreement with data at low energies. FTF_BIC underestimates the mean shower radius by about 3% at 8 GeV and by up to $\sim$12% at high energies. A similar behaviour is shown by FTFP_BERT, though the disagreement between data and Monte Carlo is about 2% worse at all energies. Above 10 GeV, the best results are achieved by CHIPS, which shows the least energy dependence and underestimates the mean radial shower expansion by 2-4%. At lower energies the performance degrades and the disagreement increases by up to 5% at 8 GeV. LHEP shows a dramatic disagreement with data at all energies.

Similar trends are observed for the standard deviation of the radial energy distributions, though the agreement with data improves for all physics lists with respect to the mean radius of showers (Fig. 14).

The study of the evolution of FTFP_BERT with different GEANT4 versions (Fig. 13 and 14) shows that in the version 9.4 the simulation of the radial shower development went back to the performance achieved for the version 9.2. The intermediate version 9.3 is the closest to the data. This conclusion concerns both the observables considered.

It should be underlined that the residual discrepancies in radial profiles observed in electromagnetic showers [9], discussed above, do not prevent conclusions from being drawn concerning these radial observables and the results shown remain an important input to the process of validation of Monte Carlo models. The absolute uncertainties in the description of electromagnetic radial profiles are of the order of 2 mm, while the deviations observed in hadronic showers are of the order of 10 mm.

11. Conclusions

The response of the CALICE analog hadron calorimeter to pions is measured for energies between 8 GeV and 100 GeV, using data collected at CERN in 2007. The high sampling frequency together with the fine segmentation of the sensitive layers of this detector allows the investigation of the properties of hadronic showers and the validation of Monte Carlo models with an unprecedented spacial accuracy.

The paper covers the measurement of several properties of hadronic showers, such as the global energy response and the longitudinal and radial development of showers. The physics lists based on the Fritiof model yield overall the best simulation of the energy response, with a particularly good agreement with data at energies between 10 GeV and 30 GeV. A good simulation of the energy response at low energies is achieved also by the physics lists based on the quark-gluon string model, such as QGSP_BERT and QGSP_FTFP_BERT, which agree with data at the 2-4% level. At high energies these physics lists overestimate the energy response by up to 10%. A similar trend is exhibited by the CHIPS physics list, while the LHEP physics list underestimates the

deposited energy at all energies by up to 10%. This list has generally the worst performance also with respect to the other observables considered.

The best description of the longitudinal development of showers is achieved by the physics lists based on the Fritiof model and by CHIPS. The physics lists based on the quark-gluon string model agree with data at about the 6-8% level.

Previous publications show limitations in the understanding of the radial development of electromagnetic showers [9]. However, the results published in [22] show that despite these limitations the ability to model the hadronic shower separation is not degraded. Moreover, the discrepancies at the electromagnetic level are one order of magnitude smaller than the average radial extension of hadronic showers and do not prevent conclusions from being drawn concerning radial observables of hadronic showers. Hadronic data indicate broader showers than expected from simulation. The best performing list is CHIPS, which shows an almost energy-independent behavior and underestimates the shower mean radial expansion by less than about 2-5% at all energies. All the other physics lists with the exception of LHEP exhibit a disagreement with data increasing at high energies. The LHEP physics list shows a moderate energy-dependence, but largely disagrees with data by up to 15%. More detailed studies are needed, in order to improve the description of radial shower profiles.

FTFP_BERT and CHIPS are overall the physics lists that best agree with the observables presented. CHIPS is a very recent list, which is still under development. FTFP_BERT is an older list and the presented time evolution reflects changes in both the Bertini and the Fritiof models and their combination. Most observables fluctuate by $\pm$2-6% depending on the GEANT4 version considered and remain in acceptable agreement with data. The considered radial observables present more significant changes of the order of 10% and show a better agreement with data for an older version of the physics list.

In the last decade the LHC experiments have also performed comparison studies of their test-beam data to GEANT4 v9.3.p01 models. The beam energies available in the LHC beam tests were either below 9 GeV or above 20 GeV. They concluded in [27, 28] that the physics list QGSP_BERT was the closest to their pion test-beam data. The agreement was within 2-3%, with QGSP_BERT response higher in data than in simulations. During the ATLAS test beam the lateral spread of pion showers has also been quantified. Simulated showers were found significantly narrower than in data, with a disagreement of about 15% for QGSP_BERT [29]. Since these tests several improvements have been implemented in the simulation. The results presented in this paper have extended the comparison to more recent versions of GEANT4 over a similar energy range.

Acknowledgements

We gratefully acknowledge the DESY and CERN managements for their support and hospitality, and their accelerator staff for the reliable and efficient beam operation. We would like to thank the HEP group of the University of Tsukuba for the loan of drift chambers for the DESY test beam. ABSTRACT: The energy resolution of a highly granular 1 m^3 analogue scintillator-steel hadronic calorimeter is studied using charged pions with energies from 10 GeV to 80 GeV at the CERN SPS. The energy resolution for single hadrons is determined to be approximately $58\%/\sqrt{E/\mathrm{GeV}}$. This resolution is improved to approximately $45\%/\sqrt{E/\mathrm{GeV}}$ with software compensation techniques. These techniques take advantage of the event-by-event information about the substructure of hadronic showers which is provided by the imaging capabilities of the calorimeter. The energy reconstruction is improved either with corrections based on the local energy density or by applying a single correction factor to the event energy sum derived from a global measure of the shower energy density. The application of the compensation algorithms to GEANT4 simulations yield resolution improvements comparable to those observed for real data.

KEYWORDS: hadronic calorimetry; imaging calorimetry; software compensation.

1. Introduction

The physics goals of future high-energy lepton colliders such as the ILC [1] or CLIC [2] put stringent requirements on the detector systems. For example, the efficient event-by-event separation of heavy bosons in hadronic final states requires a jet energy resolution of better than 4% [1]. This is achievable with Particle Flow Algorithms (PFA) combined with highly granular calorimeters [3, 4, 5]. The CALICE collaboration has constructed and extensively studied highly granular electromagnetic and hadronic calorimeter prototypes to evaluate detector technologies for future linear collider experiments. These calorimeters have been successfully operated in various test beam experiments in different configurations at DESY, CERN and Fermilab from 2006 until 2012. The unprecedented granularity of the CALICE calorimeter prototypes allows the structure of hadronic showers to be studied with high spatial resolution, in order to validate different simulation

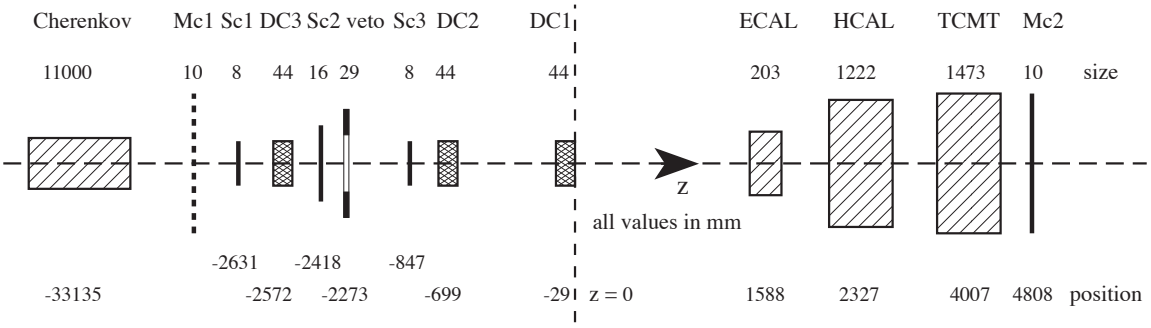

Figure 1. Top view of the CALICE test beam apparatus in the CERN SPS H6 beam line including calorimeters, trigger components (scintillator triggers SC1, SC2, and SC3; large area muon trigger counters Mc1, which was installed only during calibration runs, and Mc2; and the beam halo veto), and the tracking drift chambers DC1, DC2, and DC3. The beam enters from the left. Dimensions are in millimetres. Figure is not to scale. Positions are given at detector centre.

models (for one example of such studies see [6]) and to test particle flow algorithms, as demonstrated in [7]. The high granularity also offers the possibility for advanced energy reconstruction methods, the subject of this paper.

We present a study of the hadronic energy resolution of the CALICE analogue scintillator-steel hadronic calorimeter (AHCAL) [8] using data taken at the CERN SPS in 2007 with positive and negative pion beams in the energy range from 10 to 80 GeV. Two software compensation techniques, which weight energy depositions based on information about the local energy density within the shower obtained from the highly granular readout, are discussed in detail. Both techniques achieve an improvement of the hadronic energy resolution by approximately 20% for single hadrons in the energy range from 10 to 80 GeV, with a reduction of the stochastic term from $\sim 58\%/\sqrt{E/\mathrm{GeV}}$ to $\sim 45\%/\sqrt{E/\mathrm{GeV}}$.

In Section 2 we briefly describe the test beam setup, discuss the event selection and describe the energy reconstruction, calibration and the determination of the energy resolution in the AHCAL. The software compensation techniques are presented in Section 3, and Section 4 summarises the results obtained from data and compares them to simulations.

2. Energy reconstruction in the AHCAL

2.1 Test beam setup

The complete CALICE setup in the H6 beam line at the CERN SPS for the 2007 beam period, illustrated in Figure 1, consisted of a silicon-tungsten electromagnetic sampling calorimeter (ECAL) [9], the AHCAL, and a scintillator-steel tail catcher and muon tracker (TCMT) [10]. The test beam setup was also equipped with various trigger and beam monitoring devices.

The ECAL [9] has a total depth of 24 radiation lengths (approximately 1 nuclear interaction length λ_I) and consists of 30 active silicon layers arranged in three longitudinal sections with different absorber thicknesses. In this study, the ECAL was used for event selection and early shower

detection. Since the present study focuses on the AHCAL, events with a primary inelastic interaction in the ECAL are rejected, as discussed below.

The AHCAL [8] consists of small 5 mm thick plastic scintillator tiles with embedded wavelength-shifting fiber and individual readout by silicon photomultipliers (SiPMs). The tiles are assembled in 38 layers with lateral dimensions of 900×900 mm^2, separated by 21 mm of steel. The absorber material in each layer is made of 17 mm thick absorber plates and two 2 mm thick cover plates of the cassettes that house the scintillator cells. The size of the scintillator tiles ranges from 30×30 mm^2 in the central region and 60×60 mm^2 in the outer region to 120×120 mm^2 along the perimeter of each layer. In the last eight layers only 60×60 mm^2 and 120×120 mm^2 tiles are used. In total, the CALICE AHCAL has 7608 scintillator cells and a thickness of 5.3 λ_I (4.3 λ_π). To be able to correct off-line for variations in response of the photon sensors caused by the substantial temperature variations in the experimental hall, the temperature of the AHCAL inside the readout cassettes is monitored in each layer by five sensors installed equally spaced from bottom to top in the centre of the detector.

The TCMT [10] consists of 16 readout layers assembled from 5 mm thick, 50 mm wide and 1000 mm long scintillator strips with embedded wavelength-shifting fibers read out at one end by SiPMs. Each of the scintillator layers has 20 strips for a total of 320 strips in the TCMT. The scintillator is sandwiched between steel absorber plates. The TCMT has two sections with different sampling fractions, one fine section with 21 mm thick absorbers for the first nine layers (where the absorber plate for the first layer is the back plate of the AHCAL), and a coarse section with 104 mm thick absorbers. Two mm of the absorber thickness in each layer is provided by the cover sheets of the scintillator strip cassettes. In this study the information from the TCMT is used for muon separation and to measure energy leaking out the back of the AHCAL, which is of particular importance at higher energies. The total depth of the CALICE calorimeter setup amounts to approximately 12 λ_I, with a total of 17 648 readout channels.

In addition to the calorimeters themselves, the setup includes auxiliary detectors for triggering, tracking and particle identification as shown in Figure 1. The scintillation counters Sc1, Sc2 and Sc3 provide the beam trigger, where a coincidence between at least two out of the three is required. In addition, Sc2 has an analogue readout to tag multi-particle events. The large area veto counter is used to reject beam halo events and a large area scintillator counter Mc2 downstream of the TCMT provides muon tagging for particles penetrating the full calorimeter setup. For dedicated muon runs, an additional large area scintillation counter, Mc1, is installed upstream of the calorimeters. Three drift chambers DC1, DC2 and DC3 determine the position of the incoming beam particles. Particle identification is provided by a threshold Čerenkov counter upstream of the calorimeters, which discriminates between electrons and pions or between pions and protons in negatively or positively charged beams, respectively, by appropriately chosen gas pressures.

2.2 Event selection

The response of the individual calorimeter cells is calibrated with muons, using the visible signal of a minimum-ionising particle (MIP) as the cell-to-cell calibration scale. This signal corresponds to 13 detected photo-electrons in typical cells. After this cell-to-cell calibration, the most probable energy loss of a MIP is used as the base unit of the energy measurement. To reject noise, only cells

particle type	beam energy [GeV]	all pions	selected pions
π^-	10	440208	84706
π^-	15	127554	24997
π^-	18	52880	10492

π^+	80	272441	52442

Table 1. Summary of the data samples. The total number of pions is the number of events classified as pions, after rejection of empty, noisy and double particle events, and the application of muon rejection and particle identification cuts. The number of selected pions are the events with an identified shower start in the first five layers of the AHCAL, which are used in the present analysis. For most energies, several run periods at different temperatures are combined to maximise statistics.

with a visible energy above a threshold of 0.5 MIP are used in the analysis, referred to as hits in the following.

The data samples for the present analysis are selected from π^- and π^+ data in the energy range of 10 to 80 GeV and 30 to 80 GeV respectively, as summarised in Table 1. To maximise statistics, data from several run periods taken at different temperatures are combined for most energies, with corrections for the temperature dependence of the response of the photon sensors applied during event reconstruction [11]. The event selection procedure purifies the pion sample by rejecting admixtures of muons, electrons, and protons. To identify muons, information from the ECAL, AHCAL and TCMT is used, requiring small energy deposits consistent with a minimum-ionising particle in all three detectors. Optimal separation of muons and hadrons is achieved by using beam energy-dependent constraints on the energy sum in the TCMT versus the combined energy sum of the ECAL and AHCAL. For beam energies of 30 GeV and 35 GeV a muon contamination at the level of 30% and 15% before muon rejection is observed, respectively. For all other energies the muon content does not exceed 7%. After the event selection, the muon content is below 0.5% at all energies, estimated using the muon identification efficiency of 98% at 10 GeV and 99.5% at 30 GeV and above, which is determined from muon data and simulations. Protons and kaons are removed from the π^+ samples by requiring a positive pion identification in the Čerenkov counter. Even before selection, the kaon content is below 3% at all energies. The proton content of the beam is very small below 30 GeV since a tertiary beam is used at these energies, and varies between

approximately 15% and 30% at higher energies. Since the positive identification of π^+ is based on the detection of Čherenkov photons the proton and kaon contamination of the positive pion sample is negligible. Electrons are removed from the π^- sample both by the Čerenkov counter and by selecting events with no inelastic interaction in the ECAL, as discussed below.

Since the goal of the present analysis is the study of the performance of the AHCAL, pion showers that develop predominantly in the AHCAL are selected. This is achieved by requiring that the position of the primary inelastic interaction is located in the first five layers of the hadron calorimeter. This excludes events with sizeable energy deposit in the ECAL while keeping energy leakage into the TCMT to a minimum. The location of the primary inelastic interaction is determined by detecting the change from a minimum-ionising particle track to multiple secondary particles, evidenced by increased energy deposition and number of hits over several consecutive layers [7]. Simulation studies indicate that the difference between the reconstructed and the true primary interaction layer does not exceed one layer for 78% of all events and does not exceed two layers for more than 90% of all events in the energy range from 10 to 80 GeV.

2.3 Energy reconstruction and intrinsic energy resolution

To measure the energy deposited in the sub-detectors, a conversion from the visible signal in MIP units to the total energy in units of GeV is necessary. Since only hadrons with a shower start in the AHCAL are considered, the relevant conversion factor for the ECAL is determined using simulated muons to obtain the correlation between the visible energy and the true ionisation energy loss in the detector. This factor is validated with the measured response to muons obtained from a sample of muon data. The ratio of the visible signal in the active silicon to the total deposited energy in active and passive material is approximately 25% higher for minimum-ionising particles than for electromagnetic showers, resulting in a lower conversion factor than that for electrons presented in [12]. The total energy deposited in the AHCAL is obtained at the electromagnetic scale, using calibration factors determined for electron and positron data [13]. Since the AHCAL is a non-compensating calorimeter, the response to hadrons differs from that to electrons, requiring an additional scaling factor. This factor is determined by comparing the reconstructed energy for pions using the electromagnetic calibration factors with the known beam energy. In the present study, the energy dependence of this factor is ignored by taking a constant $\frac{e}{\pi} = 1.19$, corresponding to the average over the energy range studied. Since the first nine TCMT layers are essentially identical to the AHCAL layers in terms of absorber and active material, the same electromagnetic calibration factors and an identical $\frac{e}{\pi}$ ratio are assumed. For the last seven TCMT layers, the calibration factors are adjusted according to the increased absorber thickness.

For each event, the uncorrected reconstructed energy for hadrons, E_{unc}, is given by the sum of reconstructed energies in the three calorimeters,

$$E_{\text{unc}} = E_{\text{ECAL}}^{\text{track}} + \frac{e}{\pi} \cdot (E_{\text{HCAL}} + E_{\text{TCMT}}), \tag{2.1}$$

where $E_{\text{ECAL}}^{\text{track}}$ is the measured energy in the ECAL deposited by the particle track, and E_{HCAL} and E_{TCMT} are the energies measured in the AHCAL and in the TCMT, both given at the electromagnetic scale. The energy in each subdetector is given by the sum of all hits above a noise threshold of 0.5 MIP.

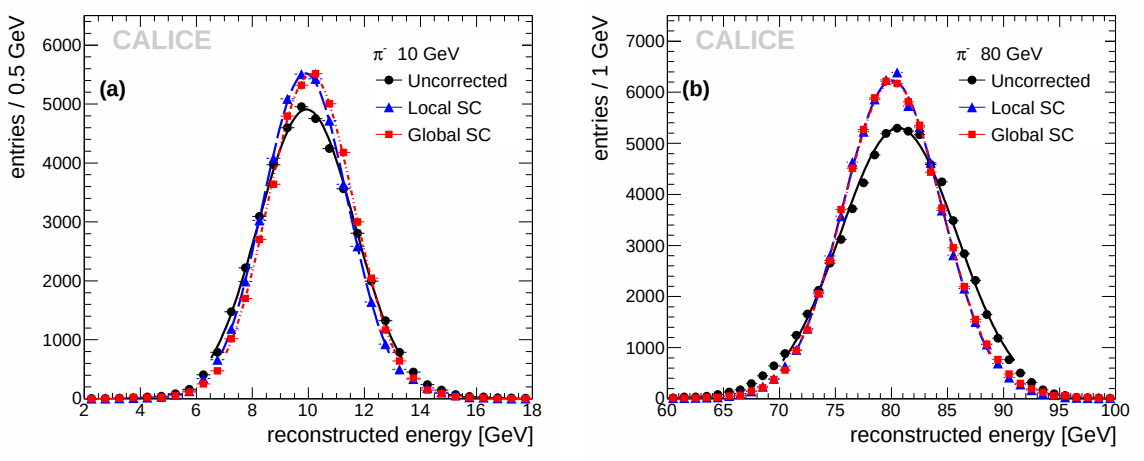

Figure 2. Reconstructed energy distributions for 10 GeV π^- (a) and 80 GeV π^- (b) without compensation (black circles) and after local software compensation (LC), shown by the blue triangles, and after global software compensation (GC), shown by the red squares. The curves show Gaussian fits to the distributions in the range of ± 2 standard deviations. Errors are statistical only.

The resulting reconstructed energy distributions are fit with a Gaussian in the interval of ± 2 standard deviations around the mean value, providing good fits for all energies. The differences compared to a fit over the full range are on the sub-percent level for the extracted mean and on the one percent level for the standard deviation and depend on the beam energy. Fitting over the full range reduces the fit quality for some energies in particular for the uncorrected data, leading to the choice of ± 2 standard deviations for best consistency between the different data points. In the following, the mean and standard deviation of this Gaussian fit at a given beam energy are referred to as the mean reconstructed energy E_{reco} and the resolution σ_{reco}, respectively.

Systematic uncertainties on the energy measurement in the AHCAL are discussed in detail in [13]. For the reconstruction of hadrons, the main uncertainty is due to the MIP to GeV conversion factor that is extracted from the electromagnetic calibration of the detector. The size of the uncertainty was studied thoroughly for the present data set, and is determined to be 0.9% by varying the calibration constants within the allowed limits. Other effects which contribute to the uncertainties for electromagnetic showers, such as the saturation behaviour of the photon sensor, are found to be negligible for hadrons even at the highest energies studied here.

Figure 2 shows the distribution of reconstructed energies for 10 GeV and 80 GeV pions, with the uncorrected reconstructed energy shown by black data points. At all energies, the distributions of the reconstructed energies follow a Gaussian distribution well, with typically more than 95% of all events in the fit range of ± 2 standard deviations. The software compensation methods also included in the figure are described in Sections 3.1 (local software compensation) and 3.2 (global software compensation).

Figure 3 shows the mean reconstructed energy versus beam energy, with the black points giving the uncorrected reconstructed energy. The measured responses to positive and negative pions agree well within the systematic uncertainties, which are shown by the green band. Relative

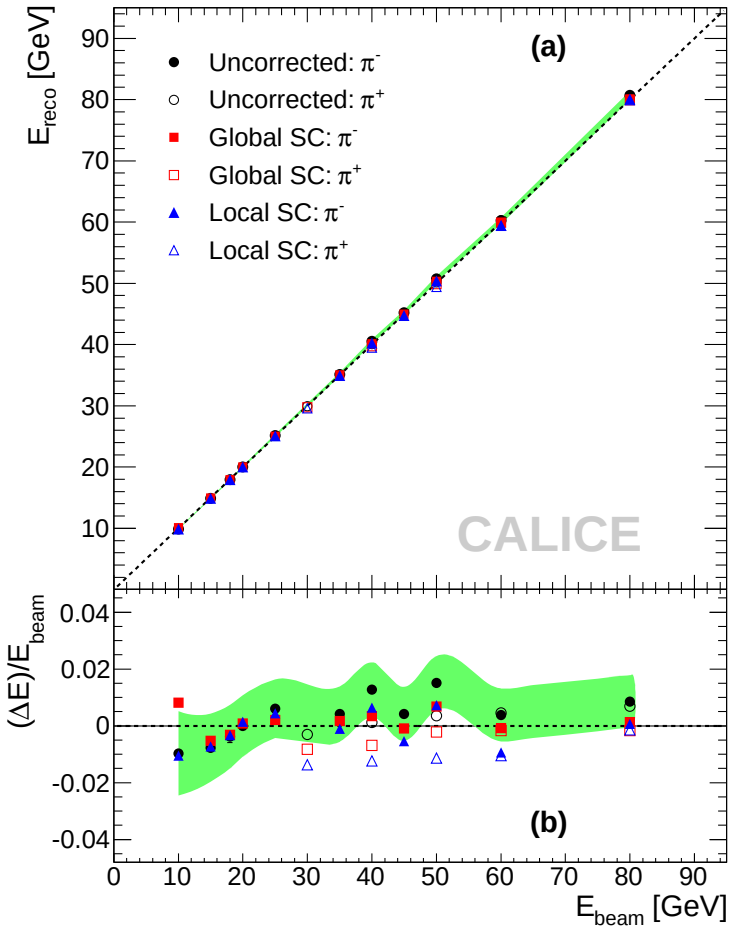

Figure 3. (a) Mean reconstructed energy for pions and (b) relative residuals to beam energy versus beam energy without compensation (black circles) and after local software compensation (LC), shown by the blue triangles, and after global software compensation (GC), shown by the red squares. Filled and open markers indicate π^- and π^+, respectively. Dotted lines correspond to $E_{\text{reco}} = E_{\text{beam}}$. Systematic uncertainties are indicated by the green band, which corresponds to the uncertainties for the uncorrected π^- data sample.

residuals to the beam energy are shown in the lower panel of Figure 3, where $\Delta E = E_{\text{reco}} - E_{\text{beam}}$. The linearity of the calorimeter response to hadrons showering predominantly in the AHCAL is within $\pm 2\%$ in the studied energy range.

The fractional energy resolution, $\sigma_{\text{reco}}/E_{\text{reco}}$, is shown in Figure 4. Again, the uncorrected resolution is indicated by black points. The measured resolution for π^- is in very good agreement with that obtained for π^+, with the differences smaller than the size of the markers for all energies where both π^- and π^+ results exist. The black solid curve shows the result of a fit to these points with the following function:

$$\frac{\sigma_{\text{reco}}}{E_{\text{reco}}} = \frac{a}{\sqrt{E_{\text{beam}}}} \oplus b \oplus \frac{c}{E_{\text{beam}}}, \tag{2.2}$$
