領域の概要

平成 23 年度～平成 27 年度に科学研究費助成事業(科学研究費補助金)の新学術領域研究(研究領域提案型)として実施された、領域名「先端加速器 LHC が切り拓くテラスケールの素粒子物理学～真空と時空への新たな挑戦」(領域番号 2303、領域略称「テラスケール物理」)の研究成果について報告する。

研究組織

本領域は総括班と 10 件の計画研究で構成されており、さらに平成 24 年度～平成 25 年度に 8 件、平成 26 年度～平成 27 年度に 5 件の公募研究を採択した。以下、研究組織の概要について表 2 及び表 3 に示す。各計画研究の組織の詳細についてはそれぞれの研究成果報告の部分に示す。領域代表者は浅井祥仁東京大学大学院理学系研究科教授がつとめた。

領域の研究組織

本領域は、LHC・アトラス実験でのテラスケール物理の研究（研究項目 A）を核に、宇宙、余剰次元、真空、超弦理論などの新しい展開を推進する研究（研究項目 B）の 2 つの研究項目で構成されている。

研究項目 A を推進するのが 6 つの計画研究(A01-06)である。
◎計画研究 A01(徳宿克夫(KEK))　　ヒッグス粒子の発見、次世代半導体検出器の開発
◎計画研究 A02(浅井祥仁(東京大)) 超対称性粒子や余剰次元などテラスケールでの新しい物理現象の探索、次世代加速器の基幹技術となる新しい超伝導技術の開発
◎計画研究 A03(藏重久弥(神戸大)) 標準理論の精密検証を通して、そのズレを探る、次世代の高放射線耐性、高速ミューオン検出器の開発
◎計画研究 A04(戸本誠(名古屋大)) トップクォークの詳細な研究、高速エレクトロニクスを用いた新しいトリガーシステムの開発
◎計画研究 A05(野尻美保子(KEK))　テラスケール物理の現象論的研究
◎計画研究 A06(駒宮幸男(東京大)) 次世代エネルギーフロンティア実験の準備研究、高性能カロリメータの開発研究

領域の概要

研究項目 B を推進するのが 4 つの計画研究(B01-04)である。
◎計画研究 B01(山口昌弘(東北大)) LHC 時代の新しい宇宙像
◎計画研究 B02(細谷裕(大阪大)) テラスケール物理がもたらす新しい時空像
◎計画研究 B03(渡利泰山(IPMU)) テラスケール物理から超弦理論への展開
◎計画研究 B04(久野純治(名古屋大)) テラスケール物理における世代構造の研究

領域の連携について

◎ 計画研究 A01,02 は、高い感度を有する直接探索による方法で、ヒッグス粒子や超対称性粒子などの標準理論を超えた新しい物理の直接発見を目指す。計画研究 A03,A04 は標準理論やトップクォークを精密に検証し、そのズレを探ることで新しい素粒子現象の発見を目指す。この方法は間接的であるが、特定のモデルに依存することなく、直接探索では見えないより高いエネルギースケールの物理を発見できる。このように直接・間接の二つの方法は相補的な研究で確実に新しい素粒子現象をとらえる。
◎ A01-A04 及び A06 各計画研究は、他の計画研究のバックグラウンドの理解や、検出器の効果の理解など共有すべきトピックスが多数ある。実験が行われている CERN に長期滞在している各計画研究の研究者が、毎月定期的に会合をもって、最新の検出器の状況や、解析の現状を共有している。(図中緑部の下側横の繋がり)
◎ 次世代のエネルギーフロンティア実験での超伝導加速器や検出器の基幹技術を、ただ開発するのではなく、LHC・アトラス実験での現場での実験経験にもとづいて開発を進めるところが本領域の大きな特徴である。成果や経験のフィードバックを絶えず行うために、各研究計画の中で情報を共有し、物理研究と基幹技術開発を平行に行う。(図中、緑部と肌色部を共有する様に計画研究を構成した。)
◎ 計画研究 A05 が、実験と理論を結びつける現象論的な研究である。テラスケールでの現象論的研究は、研究項目 A 及び B の両方と情報を常時交換しながら研究を進めている。
◎ 計画研究 A06 は、LHC でのテラスケール物理の成果を次世代実験に結びつける準備研究を行う。ヒッグスの発見からその背後のヒッグス・ポテンシャル解明への道筋を研究する。これと同時に次世代カロリメータ開発を行う。以上の 5 つで次期技術の主要なものをカバーする.
◎ 研究項目 B の成果は、宇宙、重力、真空・時空の融合と本領域の外に広がりを持つ。当該分野のみならず、関連分野へと広がっていく。
◎ 計画研究 B02, B03 は時空構造や超弦理論研究であり、top-down 型の研究を通して、テラスケールの物理を探る。
◎ 研究項目 B の各計画研究は、互いに協力しながら、関係する外国の研究者や国内の研究者を招待しミニワークショップを開催し、お互いの連携を深めている。このミニワークショップなど

には、研究項目 A の研究者も参加して最新の実験成果を発表すると同時に、新しい理論的な成果を取り込んで研究を進めている。(図中緑の上部の横の連携)
◎ 次世代の実験の基幹技術開発は、当該分野の発展に大きな寄与をするばかりでなく、超伝導、放射線耐性検出器などスピンオフが期待される。

交付決定額

本領域に配分された交付額を表 1 に示す。

表 1. 交付決定額（配分額）　（金額単位：円）

年度	直接経費	間接経費	合計
平成 23 年度	178,000,000	53,400,000	231,400,000
平成 24 年度	215,600,000	64,680,000	280,280,000
平成 25 年度	217,100,000	65,130,000	282,230,000
平成 26 年度	222,600,000	66,780,000	289,380,000
平成 27 年度	214,400,000	64,320,000	278,720,000
総計	1,047,700,000	314,310,000	1,362,010,000

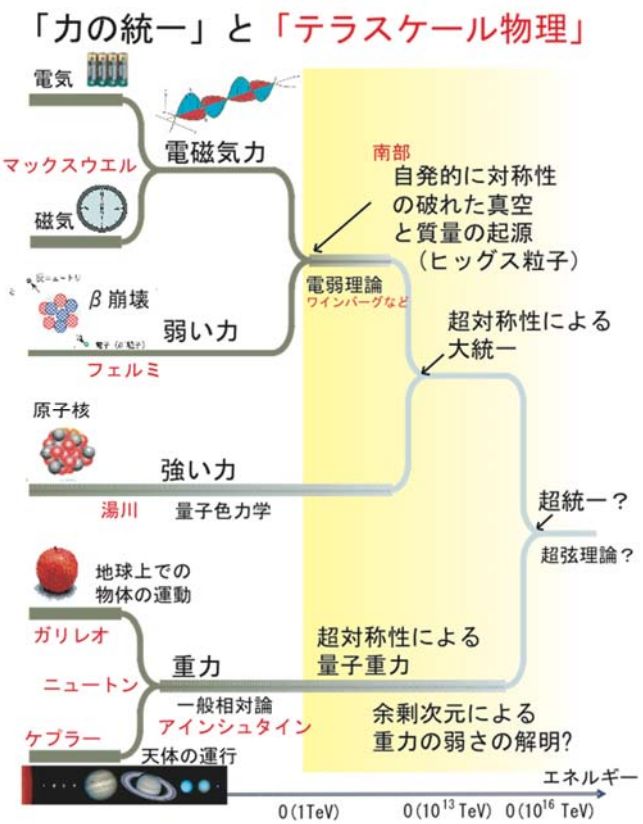
表 3. 公募研究課題一覧

研究項目	研究課題名	研究期間	代表者氏名	所属機関・部局・職
公募研究	世界最高輝度 X 線を用いた真空の構造の研究	平成 26 年度～平成 27 年度	難波 俊雄	東京大学･素粒子物理国際研究センター・助教
公募研究	テラスケール余剰次元模型の性質についての現象論的研究	平成 26 年度～平成 27 年度	柿崎 充	富山大学･大学院理工学教育部理学領域・助教
公募研究	吸収層を用いる画期的ハドロンカロリメータの開発	平成 26 年度～平成 27 年度	竹下 徹	信州大学・理学部・教授
公募研究	標準ヒッグス結合のズレからテラスケールへ	平成 26 年度～平成 27 年度	津村 浩二	京都大学・大学院理学研究科・助教
公募研究	ミューオン異常磁気能率のアノマリーを説明する新物理の現象論的研究	平成 26 年度～平成 27 年度	戸部 和弘	名古屋大学･大学院理学研究科・准教授
公募研究	微細加工技術を用いた ATLAS ミューオン前方検出器の開発	平成 26 年度～平成 27 年度	越智 敦彦	神戸大学･大学院理学研究科・准教授
公募研究	重力波で探る新たな時空像	平成 26 年度～平成 27 年度	早田 次郎	神戸大学･大学院理学研究科・教授
公募研究	sub-eV 弱結合中性ボゾン探索へ向けた原子起因四光波混合の定量化	平成 26 年度～平成 27 年度	本間 謙輔	広島大学・大学院理学研究科・助教
公募研究	ジルコニウム９６を用いたニュートリノを放出しない２重ベータ崩壊事象の探索実験	平成 24 年度～平成 25 年度	福田 善之	宮城教育大学・教育学部・教授
公募研究	精密測定実験に基づくテラスケール素粒子模型の研究	平成 24 年度～平成 25 年度	曹 基哲	お茶の水女子大学･大学院人間文化創成科学研究科･教授
公募研究	ＬＨＣ後に必須な超微細分割カロリメータの検出器要素の基礎的研究	平成 24 年度～平成 25 年度	小寺 克茂	信州大学・理学部・研究員
公募研究	ゲージボソン３点結合の精密測定による新物理探索とそれを可能にするトリガーの研究	平成 24 年度～平成 25 年度	石野 雅也	京都大学・大学院理学研究科・准教授
公募研究	テラスケール弦模型の定式化と加速器実験での検証	平成 24 年度～平成 25 年度	北澤 敬章	首都大学東京・理工学研究科・助教

研究成果の概要



研究領域の目的

（研究領域の全体像）
◎本領域の目的は、ヒッグス粒子や超対称性粒子などの確実な発見を目指す。
◎その発見を核に、素粒子・時空・真空の新しい融合領域の生成を目指す。素粒子をプローブとして時空や真空を探り、新たな宇宙観や自然観の創成を目指す

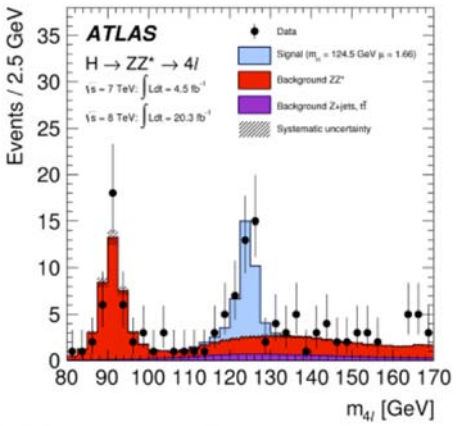
（領域の研究目的）
1）先端加速器 LHC でのアトラス実験で、『テラスケール(TeV=10^{12}電子ボルトのエネルギースケール)』 の物理を直接研究することができる。**本領域の一つ目の研究目的は、このテラスケールに期待されているヒッグス粒子や超対称性粒子などの確実な発見**である。ヒッグス粒子や超対称性粒子の発見は、「物質」や「力」などの研究ばかりでなく、その容れ物である「真空」や「時空」の研究へと発展するものであり、本領域はこれらの発見をさらに推し進めて標準理論を超えた新しいパラダイムの構築を目指す。このため、**物理研究のみならず、最先端検出器の開発や新しい加速器技術の開発を通してエネルギーフロンティア**の更なる改善を図る。
2）これら**テラスケールでの実験的成果を核に、宇宙、時空の謎などの研究を、新しいパラダイムの中で大きく展開させ新しい研究領域を創造する**ことが第二の目的である。

右図にテラスケールの物理の成果が大きな成果につながるものであることを示す。素粒子研究は「統一」の歴史そのものである。ヒッグス粒子の発見で、電磁気力と弱い力を統一し、質量の起源を解明することが出来る。超対称性粒子の発見は、強い力を含めた３つの力の大統一の証拠となる。超対称性や余剰次元は重力をも統一する（超統一）。

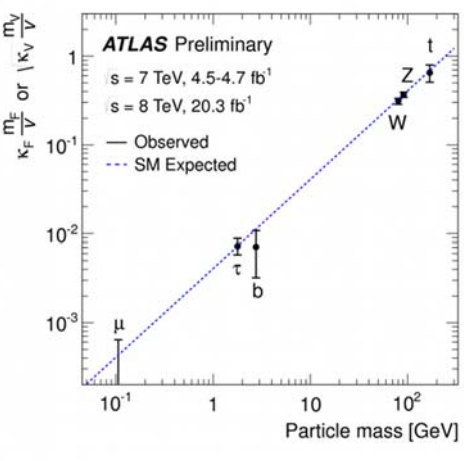
この様なテラスケールでの新しい物理の

領域の概要

発見は、素粒子物理学に大きく貢献するのみならず、宇宙の進化の解明など、科学全般への計り知れない貢献をもたらすものである。素粒子研究や宇宙研究の我が国の学術水準は、多くのノーベル物理学賞が示す様に高いものであるが、この成果により更に向上することができる。



また時間や空間は、我々の日常生活に密接に結びついた概念であり、超対称性の発見や余剰次元の研究を通して新しい「自然観」を創造することが期待される。



研究領域の成果

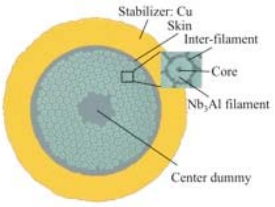
---

(1) **ヒッグス粒子発見**

本領域の一番大きな成果は、ヒッグス粒子の発見（右図は不変質量分布:ヒッグス粒子が ZZ を経由して 4 つのレプトンに崩壊した場合）と、質量の起源の解明(右下図)にある。測定されたヒッグス粒子の質量は、125.09±0.24GeV であり、すでに 0.2%の精度で決まった。ヒッグス粒子とゲージ粒子の結合のみならず、フェルミ粒子との結合が測定され、ヒッグス粒子がゲージ粒子とフェルミ粒子の質量の起源であることが分かった。また、第 2 世代の結合が弱いことも分かり、世代の理解をすすめることができた。今後はより測定精度を高め、質量起源の全貌を解明する為に、より詳細な研究が必要である。

(2) **超対称性など標準理論を超える新しい素粒子現象に対する厳しい制限と新現象の可能性の示唆**

新現象を確実に捉えるため、標準理論反応過程の精密検証と新現象の直接探索の両輪で研究を推進した。



◎**超対称性粒子に対して厳しい制限（グルイーノに対して、約 1.5TeV より重い）が得られた。**従来考えられていた超対称性理論のモデルやパラメーターに対する厳しい制約が得られ,ヒッグス粒子の質量とあいまって、ナチュラルネス（自然さ）を考え直す大きな成果となった。また暗黒物質に対する制限も厳しいものが得られた。

(3) **ヒッグス粒子の発見は、真空が相転移しヒッグス場が凝縮した特殊な状態にあることの実験的な証拠**

ヒッグス粒子の詳細な研究を通して、真空がどのような構造を持っているのかを調べ、宇宙の相

転移に関する知見が得られた。この質量は、この宇宙の状態が安定でなく、準安定な状態である可能性が指摘され、宇宙進化の重要な情報が得られた。
ヒッグスの 3 点結合測定に関し、次世代の ILC での精度がもたらす成果について新しい知見が得られた。CMB などの情報とあいまってインフレーションのモデルを絞ることができる。
125GeV のヒッグス粒子の存在と、超対称性などの新しい素粒子現象が 1 TeV より軽い領域にないことから、宇宙初期像や素粒子世代の研究に大きな影響を与えた。特に、ヒッグス粒子の質量スケールの自然さを問い直す新しい展開があった。(人間原理など)

(4) **LHC 高輝度実験・次世代エネルギーフロンティア実験の基盤技術の確立**

LHC 実験での経験から、高性能・耐放射線検出器、高速トリガーシステム、超伝導加速器技術に新たな知見が得られ、それを基に次世代の基盤技術の開発を行っている。より強い磁場を発生させることができる Nb_3Al 線材(右上図：ラザフォード線断面図、右下写真：試作した Nb_3Al 磁石)を開発し、放射線や機械的な強度耐性などを調べ設計に反映された。これらの技術は、次世代実験の鍵となる技術であり、J-PARC など広い応用への道筋ができた。

◎ビームのエミッタンスの向上にむけてビームサイズの精密測定技術を開発し、ATF で測定に用いられている。
半導体検出器、ミューオン検出器、高速トリガーシステム、カロリメータの主要な技術開発を行っている。例えば、n–in-p 型 pixel 検出器の開発、ミューオントリガーチェンバー、高速トラックトリガーシステム、High Level Trigger、カロリメータなどであり、ルミノシティーを１０倍に増強した HL-LHC や、次世代実験 ILC の検出器の基幹技術である。特に HL-LHC の検出器のグランドデザインとなる基幹技術の開発に成功した。これらは、LHC に限らず、エネルギーフロンティア実験全体に大きな貢献ができ、多くの応用が行われた。

以下各研究項目別の成果の概要を報告する。詳細については次章以降に述べる。

研究項目 A01 計画研究（ヒッグス粒子の発見による素粒子の質量起源の解明）

ヒッグス粒子を発見した。統計を増やして各崩壊モードの解析を行い、ヒッグス粒子が標準模型の予測する性質を持つことを確認した。標準模型を超えたヒッグス粒子の探索では兆候は確認されていない。

2012 年 7 月に、ヒッグス粒子と考えられる新粒子を発見でき、その後に収集したデータにより、この新粒子がヒッグス粒子であり、標準理論の予測する性質と合致していることが判明した。ヒ

ッグスの発見、スピン・パリティの解析に続き、全データを使った各崩壊モードでの解析と、超対称性粒子等で予想される他のヒッグス粒子の探索が進み、ほぼすべての解析が終了し論文として発表した。W,Z 及びγへの崩壊は確立し、フェルミ粒子への崩壊に関してはτへの崩壊が 4.5σで観測できている。一方でμへの崩壊はτと同レベルでは観測されないことは確定できており、この粒子が二つのレプトン（二つの世代）を区別することを実験的に示した。ボトムへの崩壊や、トップクォークとの随伴生成の探索も進めている。これらのモードでは、標準理論のヒッグスと無矛盾であることを示すことができている。これらの測定結果から、この粒子が標準理論のヒッグスとよく合っていることを示せた。もう一つの LHC 実験である CMS 実験との共同解析も進み、0.2%精度の質量測定を達成した。結合定数に関する共同研究も進んでいる。発見したヒッグス粒子に加えて、新たな荷電及び中性ヒッグス粒子の探索も行った。残念ながら新しい粒子の兆候は得られていない。

次世代型シリコンピクセル検出器の開発を進めた。試作後、本実験で想定される放射線量を照射した。その後の性能評価を国内外の加速器施設におけるビームラインを用いて行い、十分な性能を確認した。

大面積の検出器を作る上でコストを下げられる n-in-p 型のシリコンセンサーの開発を進めた。センサーを試作後、放射線照射をした上で、国内外の加速器施設を使ったビームテストを行って、ピクセルの構造のどの部分が放射線損傷に弱いかを洗い出し、その改良を進め、弱点の克服にほぼ目処がついた。

研究項目 A02 計画研究（超対称性の発見と大統一理論の実験的検証）

生成･崩壊の事象トポロジー分類により､超対称性粒子探索を組織的に進めることを目標とした。発見には至らず、各チャンネルに厳しい制限を課した。一方、超対称性の存在を示唆する事象も確認した。

重心系エネルギー 13, 8, 7 TeV の陽子陽子衝突を用いて超対称性粒子の探索を進めた。Z/W+jets、ttbar+jets などの背景事象の高精度な見積り手法の開発も進め、第 3 世代スクォーク（超対称性クォークパートナー）質量下限 0.84TeV (於 13TeV)、グルイーノ、第 1,2 世代スクォーク質量下限 1.9TeV(於 8TeV)、電弱生成ゲージ粒子パートナー質量下限 0.4TeV（於 8TeV）などの厳しい制限を課した。一方で、複数ジェット＋消失エネルギー＋Z を要求するチャンネルでは 3σの超過事象数があることを確認。また 13TeV 衝突におけるグルイーノ・スクォーク対生成の 0 レプトン探索チャンネルでは、超対称性事象の可能性がある事象も複数確認されており、高エネルギー・高統計での追解析が急がれる。

長寿命粒子、高質量共鳴ピーク、その他特異な終状態など、超対称性以外の新粒子・現象の発見を目標とした。発見には至らず、各チャンネルに厳しい制限を課した。一方で、統計的有意な超過も確認した。

検出器中で崩壊する比較的長寿命の未知粒子、高質量領域の共鳴質量ピーク、その他特異な終状態など、超対称性以外の新粒子・現象の探索が行われ、多くのチャンネルに厳しい制限を課した。高質量領域では崩壊後のボソンが 2 本の近接したジェットに崩壊し、既存の手法では検出効率が下がる問題があったが、近接ジェットを再構成する新手法を開発し、8TeV 衝突で 2 ボソン共鳴の超過を 2.5σで確認した。高エネルギー・高統計での追解析が急がれる。

LHC 高輝度アップグレードに向けた磁石の開発、並びに次世代加速器用高磁場超電導磁石・線材の開発を目標にした。新開発の耐放射線線材を開発。線材を組み込んだ、2m 長モデル機の試作に成功し、冷却励磁試験を実施した。10T を超える高磁場磁石を製作し、励磁試験によりケーブル性能を評価した。

加速器開発: LHC 高輝度アップグレードに向けたビーム分離用大口径双極超電導磁石の開発を行い、電磁設計・機械構造設計などの基礎開発を進めた。2m 長モデル機を試作し、1.9K における冷却励磁試験を行った。同時に耐放射線性に優れた有機絶縁構造材料の開発を進めた。放射線照射による試験、並びに 2m 長モデル機に搭載し性能評価を行った。次世代高エネルギー加速器(FCC)計画に向けた、高磁場超電導磁石及び線材の開発も行った。10T を超える高磁場下でも臨界電流密度が安定する機械特性に優れた Nb3Al 線材に着目し研究開発を進めた。こちらはラザフォードケーブル（撚線）の試作に成功し、性能評価を行った。

研究項目 A03 計画研究（素粒子標準模型の精密検証で探るテラスケール物理現象）

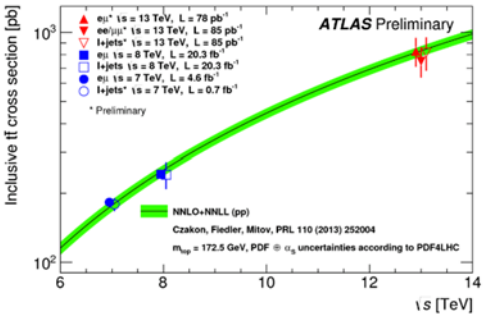
弱ボゾン生成，ジェット生成などから LHC エネルギー領域での標準模型を精密検証し，同時に新物理探索のバックグランド理解を高めることを目標とした。パートン密度の新制限など標準模型の理解を深め，弱ボゾン融合生成や 4 レプトン崩壊など，ヒッグス粒子の測定感度を上げる測定ができた。

複数の弱ボゾン生成を通して標準模型の特徴的構造である弱ボゾンの 3 点・4 点ゲージ結合を精密測定し，また生成断面積の異常から新物理を探ることを目標とした。高精度の測定により，異常ゲージ結合に対し上限値を 1 桁以上更新した。また，新物理に感度の高い弱ボゾン同士の散乱を初めて観測した。

W/Z および WW,WZ,ZZ,2 光子生成断面積測定では最高で約 10%の精度で行い、理論予想値と矛盾しない結果を得た。これらの測定結果から、異常 3 点ゲージ結合カップリングとして、Tevatron/LEP の測定より 1 桁以上小さい上限値を得た。また，ヒッグス粒子生成と関連の深い Z

領域の概要

粒子の 4 レプトン崩壊，ベクトルボゾン融合過程などの散乱断面積を精密に測定した。
b-tagging の改良により、高 Pt を持つ Z 粒子の b 崩壊過程や、Bc+ 稀崩壊過程の測定を行った。ジェット生成反応の異なる重心系エネルギーでの断面積測定を行い、QCD Next Leading Order プロセスの計算結果との比較などによって、PDF 決定につなげた。



次世代の高ルミノシティーLHC 実験に対応した，事象を効率よく選別できるミューオントリガー検出器とトリガー回路の開発を目標とした。次のアップグレード用に放電を抑制したミューオントリガー検出器，トリガー論理と回路を開発した。より高ルミノシティー用の放射線耐性を持つ回路も開発した。

ミューオン検出器開発： LHC フェーズ 1 アップグレードで計画されている ATLAS ミューオンスモールウィールでの Micromegas 検出器も開発を中心に行った。電極の構造・製造方法の開発を行い、アノードに高抵抗電極を用いることで、中性子による大きな電離損失事象に起因する放電を大幅に押さえられることがわかった。これを受けて，スモールウィールのプロトタイプの製作を行った。

トリガー開発： スモールウィール検出器を用いたトリガーのためのアルゴリズム及びプロセッサーの開発を行った。LHC フェーズ 2 アップグレードで計画されている高ルミノシティー運転におけるミューオントリガーのために、ドリフトチューブを用いたアルゴリズムについて検討を行い、トリガーレートを削減できることを明らかにした。また、そのための高精度 TDC など放射線耐性をもつフロントエンド回路の開発を行った。

研究項目 A04 計画研究 （トップクォークを用いた新しい素粒子現象の探索）

重心系エネルギー 7、8、13TeV の陽子陽子衝突によるトップクォークの生成と崩壊を詳細に検証し（右図）、テラスケールに至るまで、摂動 QCD がトップクォーク対生成を良く記述する有効理論であることを立証した。また、高速飛跡再構成トリガーを新たに開発するなど、トリガーシステムを改良した。

トップクォーク物理： 重心系エネルギー13TeV、8TeV, 7TeV の陽子陽子衝突による t クォーク対の生成断面積を、2 レプトン終状態事象（両方の t クォークの崩壊粒子に電子または μ 粒子が含まれる）を用いて精密に測定し、摂動 QCD がトップクォーク生成を良く記述する有効理論であることを立証した。

t クォークの崩壊による荷電レプトンと b クォークの角度差から、t→Wb 崩壊中の W 粒子の 3 種類の偏極度（FL, F0, FR）を測定した。F0 = 0.687±0.005, FR = 0.0017±0.0001（FL = 1 − F0

– FR）の結果は、V-A 型の弱い相互作用によってｔクォークが崩壊する時の偏極度と無矛盾であることを示した。

重心系エネルギー7TeV の陽子陽子衝突による t クォーク対の生成断面積をτ had-レプトン事象（片方にハドロン崩壊をするτ粒子、もう一方に電子またはμ粒子が含まれる）、全ハドロン事象（両方ともハドロンに崩壊する）を用いて測定し、標準模型と無矛盾であることを示した。

トリガー開発：　将来の高輝度 LHC 実験に向け、これまではトリガーに用いる必要のなかった精密飛跡検出器によるμ粒子トリガー回路の開発を行った。TDC 回路の基礎設計を終えた。

Run2 での導入を目指し、高速飛跡再構成トリガー(FTK)回路の開発と製作を行った。本計画研究によって開発する回路が ATLAS 実験の量産要請を満たすことを確認し、本研究によって構築したテストスタンドを用いて量産時の諸問題に対するフィードバックを行った結果、回路製作の量産を完遂させた。

ｔクォーク対生成事象の取得に重要なμ粒子トリガーや電子トリガーの運動量閾値を 25GeV 程度の低い値に抑えつつ、トリガーレートを低く維持するアルゴリズムの開発に成功した。

研究項目 A05 計画研究（テラスケール物理の理論的研究）

QCD の理論特性を利用して新物理の探索感度を上げる研究をおこない、テラスケール物理探索の背景事象をより正しく理解することを目標とした。ジェットの構造や制動輻射に関する研究を行い, クォーク・グルーオン識別の向上や、ISR の性質を利用した背景事象の低減方法を明らかにした。標準模型の分布のズレから新粒子の断面積、崩壊パターン、スピン、質量を測定する新しい解析方法を考案することを目的とした。新物理の信号である高エネルギーのトップジェットから偏極を導き出す方法を明らかにするとともに、ISR の分布からスピンを明らかにする方法などを研究した。テラスケールでの新物理を新しいパラダイム（時空、宇宙など）に転換する研究を行い、この実験的検証にむけた現象論研究を目的とした。バリオン数生成、暗黒物質、ニュートリノ質量の生成機構とヒッグス粒子が関係する模型を網羅的に検討して、拡張模型を制限する方法を明らかにした。

検出手法の研究：　QCD の知見を用い a) QCD の高次過程の特性を利用して新粒子を発見する手法の考案 b)ジェットの種となるパートンがクォークかグルーオンかによって異なることを用いた、新粒子探索における S/N 向上方法の提案と理論的不定性の解明 c) Boost された top quark や重たいゲージ粒子から生成されるジェットの内部構造をもちいた scalar top や heavy boson の探索可能性の検討等を行った。

暗黒物質探索：　暗黒物質を含む模型について総合的に検討を行い、超対称模型、バリオン数生成と暗黒物質を関係づける模型、フェルミオンと暗黒物質のある系など、LHC での検証が可能である領域を明らかにした。

新物理の理論的検討：　ヒッグス粒子の発見に伴い、その性質の精密測定によって、新しい物

理の構造の手がかりを得ることが可能なのではないか期待された。Radion と Higgs の混合のあ Randall-Sundrum 模型, 超対称模型、Minimal composite Higgs 模型などについて、Higgs の生成、分岐比等の研究によって、広いパラメータ領域で新物理を明らかにできることを示した。また、兼村はヒッグスセクターの取り得る構造を輻射補正も含めて研究し ILC 実験や LHC 実験でその性質が明らかにできることを示した。また、電弱対称性の破れの背後の物理、標準理論で説明できない諸現象（暗黒物質、バリオン数生成、ニュートリノ質量）とヒッグス物理の関係を研究し、LHC Run2 等の将来実験を用いて検証可能である場合を明らかにした。

研究項目 A06 計画研究（LHC の発見が導く次世代エネルギーフロンティアの発展）

ILC での実用に向けたジェットエネルギー高精度測定用の稠密な電磁カロリメータを開発。素子の放射線耐性を、中性子を用いて精査した。ドイツで電子ビームを用いたプロトタイプの性能評価に成功した。
KEK の試験加速器 ATF2 において、電子ビームサイズを極限に抑え、鉛直方向世界最小サイズ 41nm の測定に成功した。フィードバックを用いたビームジッター抑制を英国や KEK と共同で行い成功した。
LHC で新粒子の事象候補があった。これらを ILC の実験で精査し物理の方向を見極める方法を開発した。

ILC ビーム収束系開発： local chromatic 補正と言うビームオプティクスを確立した。KEK の試験加速器 ATF2 において、世界で最小の縦方向ビームサイズ σy=41nm を達成した。2 バンチのビームを ATF でつくり 1 バンチ目の測定でフィードバックをかけ 2 バンチ目のビームジッターを減らすことに成功。

ILC のシリコン電磁カロリメータの詳細設計において安価でかつ性能を落とさないための素子のスペックを研究した。また、素子の放射線耐性を神戸大学の中性子ビームを用いて精査。十分な耐性があることを検証。ドイツ DESY においてプロトタイプのビームテストに成功。

τ の再構成は、重いヒッグスの CP 混合の決定に重要である。ILC での衝突点の位置、荷電粒子の軌道、π^0 からの光子の電磁カロリメータでのシャワー測定を用いて、いかなる τ 崩壊も再構成できることを証明。

研究項目 B01 計画研究（LHC 時代の新しい宇宙像）

実験結果に基づきテラスケールの素粒子模型を構築し、宇宙進化史への影響を明らかにすることを目標とした。ヒッグス粒子の質量を説明する超対称模型を複数構築し、暗黒物質の性質を中心

に宇宙進化史への影響を明らかにした。
標準模型を超える物理がもたらす宇宙進化への影響を明らかにすることを目標とした。超対称 Peccei-Quinn 模型の宇宙進化史について、宇宙初期の熱的プラズマの影響がアクシオンの超対称対の振る舞いに大きな影響を与えることを見つけることができた。
LHC 実験が示唆する物理に基づき、インフレーションに関する理解を進めることを目標とした。ヒッグス場がインフレーションを引き起こす可能性を追求し、運動項が重要となるインフレーション模型において実現できることを示した。

ヒッグス発見が超対称標準模型に与える示唆を研究：ヒッグス粒子質量を説明するには、超対称粒子が重いか、超対称標準模型を拡張する必要がある。①ゲージ一重項を加えた模型について詳細に研究し、Peccei-Quinn 対称性を持つ模型を構成、ヒッグスセクターの量子補正や混合によりヒッグス質量を実現できることを示し、暗黒物質の性質など宇宙論的影響を考察した。②超対称粒子の質量スケールが 10TeV にある可能性の重要性を指摘し、特に Wino 暗黒物質の場合、直接探査実験による検証可能性や、LHC における発見可能性を議論した。

超対称 Peccei-Quinn 模型に基づく宇宙論の研究： 超対称化された Peccei-Quinn 模型に基づく宇宙進化について、宇宙初期の熱的プラズマがアクシオンやその超対称対の運動に与える影響を考察し、特にアクシーノ場についてはプラズマとの相互作用がその運動に大きな影響を与え得ることを明らかにした。

ヒッグスインフレーション：運動項のヒッグス場自身への依存性を用いることでヒッグス粒子がインフレーションを引き起こす running kinetic inflation を提唱した。

研究項目 B02 計画研究（テラスケール物理がもたらす新しい時空像）

５次元時空ゲージヒッグス統合理論の構成を目標とした。期間中に達成した。低エネルギー実験や LHC 実験と無矛盾な SO(5)xU(1)統合理論を構成した。
14 TeV LHC 実験で検証できる予言を導くことを目標とした。ヒッグス粒子と標準模型粒子の結合は、標準模型とほぼ同じであるが、6TeV-10TeV 領域に、幅の大きい Z'(KK 粒子)が現れる事を予言した。ヒッグス粒子の自己相互作用も標準模型からずれるが、この検証は LHC では難しい。
ヒッグス場をもとにした新しい宇宙論の構築を目標とした。ヒッグスインフレーション理論を精密化した。ヒッグス場をもとにプランクスケールの物理が探れることを明らかにした。目標は概ね達成した。

ゲージヒッグス統合理論： ヒッグス場の正体を明らかにし、新しい時空像を探った。ヒッグス場が５次元目のゲージ場であるとする SO(5)xU(1)ゲージヒッグス統合理論が、低エネルギーや LHC での実験結果と整合すること、５次元目があるにもかかわらず高次の量子補正が有限になること、6TeV-10TeV 領域に、幅の大きい Z'(KK 粒子)が現れることを示した。今後の LHC 実験で

５次元目が探索できることを示した。一般にゲージヒッグス統合のシナリオでは、高次元でのゲージ不変性により紫外発散が相殺し、ヒッグス粒子の質量の安定性や崩壊幅の有限性が保証され、超対称性理論にとって代わる理論的枠組みになることを示した。

また、ヒッグス場と重力との結合の結果、ヒッグス場によるインフレーションが可能となり、繰り込み群の解析から、プランクスケールまで標準理論を適用でき、超弦理論と結びつくことも示した。

研究項目 B03 計画研究（テラスケール物理の超弦理論への展開）

超弦理論のコンパクト化の文脈で初期宇宙、フレーバー構造を探求し、シナリオを絞りこむことを企図した。フレーバー、統一理論については、超弦理論で詰め切れるところまで達した。
超対称性と例外系代数がある時空の量子像の開拓。F-理論コンパクト化のモジュラー群の同定、弦理論双対性対応の対応関係の精密化などの成果が挙がった。
ハドロン高エネルギー散乱の非摂動的側面を扱う理論手法の開発においては、ハドロン内のパートンの（縦方向だけでない）３次元情報を捕まえる理論的枠組みを確立した。

A: 超弦理論の解の統計学。当科研費補助事業期間中、７本の連作論文(総計３７７ページ)において、超弦理論の解の統計を研究するための物理理論、数学的道具の開発を行い、実際の統計の結果をした。その結果、１）標準模型の U(1) ゲージ場を得るためには、「統一理論の低エネルギー有効理論として標準模型を得ること」がもっとも統計的に典型的であること、２）素粒子の世代数は統計的にガウス分布に従うこと、分散は O(1)、３）R-パリティの自発的破れの有効理論となる解は、超弦理論においては非常に稀であること、などがあげられる。

ハドロンの高エネルギー散乱を解析する理論的枠組みの構築。パートン同志の散乱であり大運動量移行が含まれる場合には、量子色力学を用いた理論計算が可能である。より一般のハドロン散乱過程で非摂動的な情報を扱える理論的枠組みを、AdS/CFT 対応を用いることによって目指す。2014 年の西尾・渡利の論文は Brower et.al.の 2006 年の論文で導入された理論を拡張し、ハドロン２体→２体の非弾性散乱を扱えるようにした。

この成果は、より一般のハドロンの ２体→N 体 の非弾性散乱を扱える理論を構築する上でのささやかな前進であると見ることができる。一方、この ２体→２体 非弾性、の理論の段階で、すでに ep → ep gamma(exclusive) の散乱過程の部分過程として含まれる、gamma (off shell) + p → gamma (on shell) + p に適用することができる。そして、この部分過程は、一般化されたパートン分布関数 (GPD) というハドロンの非摂動的情報によって決定されることが知られている。このことを利用して、上記論文では、AdS/CFT 対応 (holographic) 原理を用いた一般化パートン分布関数の模型をも導いた。

研究項目 B04 計画研究（テラスケールにおける世代構造の研究）

テラスケール物理における世代構造をフレーバーの物理から制限を与え、それにより LHC 実験で模型の選別を行うことを目的とした。LHC 実験では明確な新物理の発見はなかったが、超対称模型、拡張ヒッグス模型などに対して、LHC 実験とフレーバーの物理から期待される新物理の可能性を明らかにした。

新しい素粒子像の構築を目的とした LHC 実験とフレーバーの物理から期待される新物理を外挿し、超対称大統一模型の現象論、超対称性の破れの起源、ニュートリノ質量起源の可能性を明らかにした。

宇宙の物質・反物質の非対称性の解明を目指した。拡張ヒッグス模型における電弱バリオン数生成の可能性を明らかにし、その検証の方法を明らかにした。世代対称性を課した超対称大統一模型においてレプトジェネシスが宇宙のバリオン数を説明できることを明らかにした。

中性子 EDM： クォークの EDM、カラーEDM の中性子 EDM への寄与を QCD 和則、次元 6 までの CP 対称性を破る相互作用のウィルソン係数のくりこみ群の方程式の導出など、中性子の EDM の系統的な評価のための研究を行った。超対称模型、拡張ヒッグス模型などの標準模型を超える理論の EDM を評価し、模型に制限を与えるとともに、将来実験での検証の可能性の議論をした。

レプトンフレーバー研究： 超対称性シーソー模型におけるレプトンフレーバーを破る過程の研究を行った。ヒッグス質量をインプットとして，$\mu \to e\gamma$ や $\tau \to \mu\gamma$ などに対しどのような予言が得られるかを明らかにした。

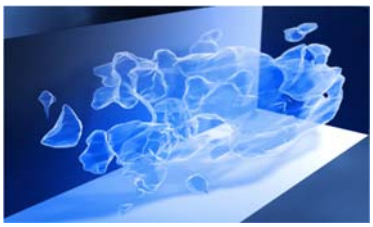
拡張ヒッグス模型で電弱バリオン数生成を評価、現在のバリオン数を説明できる理論が電子、中性子の電気双極子能率の測定、ヒッグス粒子精密測定、新粒子探索により検証可能であることを示した。超対称性の破れが 100TeV 程度の超対称標準模型は発見されたヒッグス粒子の質量 125GeV を説明しうるが、この模型は超対称大統一模型に拡張した時、ゲージ結合定数の統一が改善すること、カラーヒッグス交換による陽子崩壊の問題が解消することを示した。超対称大統一模型の予言する X ボゾン交換による陽子崩壊に対する高次の量子補正を電弱スケールから大統一スケールまでの間の全てにおいて系統的に評価し、予言の信頼性を高めた。

公募研究

平成 24 年～平成 25 年に 5 件、平成 26 年～平成 27 年に 8 件の公募研究を採択した。
LHC 実験の高度化にむけた検出器開発に関するもの、LHC の実験結果の現象論的予測を研究計画 A05 とは別の角度から与えるもの、LHC の結果を受けて弦理論、重力波の理論など更に高エ

ネルギーの素粒子論との整合性を問う研究などが行われた。また、LHC の結果を受け、将来の国際リニアコライダー（ILC）を建設した際に用いられる検出器の開発、低・中エネルギー実験で探る真空構造など、LHC の物理に間接的に関係する研究も行われ、それぞれ一定の成果を収め、学術論文の形で研究結果を公開している。

領域の貢献



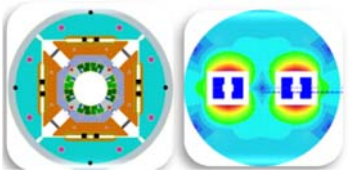
当該学問分野及び関連学問分野への貢献度

「ヒッグス粒子発見のインパクト」

本領域最大の成果であるヒッグス粒子の発見は当該素粒子分野に限らず、周辺分野まで含めその影響は極めて大きい。その重要性から発見翌年のノーベル物理学賞受賞へとつながった。ヒッグス粒子の発見、その後の性質測定により様々なことが分かって来ている。ヒッグス粒子の性質測定により、真空にはヒッグス場の凝縮状態が満ちており、これにより力を伝える粒子（ゲージ粒子）のみならず、物質粒子も質量を得ていることが判明した。ヒッグス場は素粒子の世代を明確に区別しており、大きな未解決問題である世代問題に足がかりができた。また、この真空の場の変化（相転移）により、初期宇宙が進化してきたことを初めて実験的に立証できた。今後の宇宙理論はヒッグス場の存在・測定された性質を前提に相転移前の宇宙の解明を目指して発展してゆく。またヒッグス粒子が軽かった(125GeV)ことは、標準模型を超える物理がテラ電子ボルトスケールに潜んでいることを示す。LHC 実験の長期計画、ILC 実験など、次世代の高エネルギー素粒子分野を牽引する加速器計画に対しても、具体的な強い方向付けを与えた。

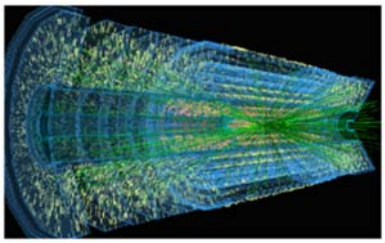
「新粒子事象の兆候」

本領域最終年に 13TeV 衝突エネルギーで得られた幾つかの超過事象チャンネルから、宇宙・素粒子分野に大きな議論が巻き起こっている。高統計データにより存在が確認されれば、素粒子実験分野の将来計画を一気に具現化するインパクトをもつ。超対称性



領域の概要

粒子探索チャンネルで見られた超過事象は、宇宙暗黒物質など未解決問題の解明にも大きく寄与することが期待される。



「標準模型を超える物理の探索・標準模型の精密検証」

上述のように新物理の兆候は見られるが、一方で数多くの新物理探索チャンネルにおいて、新物理、特に従来考えられていた超対称性理論のモデルパラメータへの厳しい制限を得て、今後の探索領域を強く限定する成果を得た。特に、超対称性粒子探索など大きな消失エネルギーを用いるチャンネルからの制限より、宇宙暗黒物質の候補に対して強い制限を与える結果となり、非加速器実験による直接探索分野と相補的な暗黒物質研究が期待される。また、軽いヒッグス粒子の存在と新粒子未発見の事実は、これからの新たな物理模型構築の基本方針を大きく変更する成果となった。同時に精密測定による標準模型の精密検証、高統計データを用いた高次の標準模型過程が検証され、テラスケールにおける標準模型の有効領域が確認された。

「LHC 高輝度・次世代加速器開発による基盤技術の確立」

本領域では次世代加速器に向け、放射線耐性に優れ、高い磁場精度を保つ、超伝導素材開発が行われた。また、10T 以上の高電磁力線下での機械特性に優れた超伝導新素材の開発が行われた。これらの新たな超伝導加速器技術の知識・経験は我が国の加速器技術立国としての立場を不動のものにする影響力を持つ。

「次世代検出器開発」半導体検出器、ミューオン検出器等、アトラス実験の主要な構成検出器の高度化が進められた。これは次世代実験 ILC、その他の様々な実験で使われる検出器の基本設計に直接影響を及ぼす。

研究計画に参画した若手研究者の成長の状況

国際的に活躍する若手研究者の育成

若手研究者を最先端で競争の厳しい素粒子研究に従事させることで育成を行ってきた。実験が行われている CERN には、世界中から優秀な研究者が集まっている。若手研究者は、そのような環境である CERN に長期滞在し、諸外国の第一線の研究者と議論を重ね切磋琢磨することで、国際的に活躍する優秀な研究者に成長することができる。本領域の若手研究者はヒッグス粒子発見において、3 つの主要なチャンネルで解析責任者として現場を率いて発見という大きな成果をあげる活躍をした。そのほか多くの若手研究者(20 名以上)が解析や検出器の責任者として活躍をしてきた。

実験・理論の融合を通した若手研究者の育成

本領域の展開するテラスケール物理は、最先端の素粒子研究であると同時に、領域として実験・理論を融合した研究を推進してきた。若手研究者には研究会や勉強会を開催する(合計 11 回)などして実験と理論の両方の視点から研究を進める、他では得がたい研究環境を提供することを行ってきた。

博士研究員の雇用と育成

本領域の特徴として理論研究の博士研究員(17 名)を多く採用した。LHC・アトラス実験の Run1 の成果が出続けるなか、理論的に取り組むべき研究テーマは次々と生まれる。このような研究環境は単に若手研究者を引きつける魅力ある環境としてだけでなく若手研究者を優秀な研究者に育成する環境でもある。彼らの約 9 割はアカデミックな分野で教員(准教授 1 名, 講師 1 名, 助教 3 名)や研究員(10 名)として活躍している。また、実験の博士研究員 7 名は若手研究者として上述した成果をあげて、7 名全員がアカデミックな分野で教員(准教授 1 名, 助教 2 名)や研究員(4 名)として活躍している。

大学院生の育成

本領域では研究協力者として多くの大学院生を CERN という現場に中・長期に滞在させた。最先端の素粒子研究に従事することで、研究を直に学ぶ、経験することで将来のキャリアについて考える機会を与えてきた。修士号を取得した学生は 131 名で 57 名が進学、博士号を取得した学生は 70 名でそのうち 49 名はアカデミックの分野で活躍している。

最後に本領域に関わった若手研究者の動向をまとめる。非常勤の研究職であった研究者の約半数は常勤の職に就き、博士号を取得した多くの大学院生が非常勤の研究者として研究人生をスター

トさせていることが分かる。また、修士号のみを取得した大学院生は民間企業、官公庁などで活躍している。

本領域に関わった時点 → H28 年 4 月 1 日の時点	人数
研究職(常勤) → 研究職(常勤)（昇格など）	4
研究職(非常勤) → 研究職(常勤)	21
研究職(非常勤) → 研究職(非常勤)	19
研究職(非常勤) → その他(企業など)	2
大学院生 → 研究職(常勤)	5
大学院生 → 研究職(非常勤)	44
大学院生 → その他(企業など)	95

ABSTRACT

A search for the Standard Model Higgs boson in proton–proton collisions with the ATLAS detector at the LHC is presented. The datasets used correspond to integrated luminosities of approximately 4.8 fb^{-1} collected at $\sqrt{s} = 7$ TeV in 2011 and 5.8 fb^{-1} at $\sqrt{s} = 8$ TeV in 2012. Individual searches in the channels $H \to ZZ^{(*)} \to 4\ell$, $H \to \gamma\gamma$ and $H \to WW^{(*)} \to e\nu\mu\nu$ in the 8 TeV data are combined with previously published results of searches for $H \to ZZ^{(*)}$, $WW^{(*)}$, $b\bar{b}$ and $\tau^+\tau^-$ in the 7 TeV data and results from improved analyses of the $H \to ZZ^{(*)} \to 4\ell$ and $H \to \gamma\gamma$ channels in the 7 TeV data. Clear evidence for the production of a neutral boson with a measured mass of 126.0 ± 0.4 (stat) ± 0.4 (sys) GeV is presented. This observation, which has a significance of 5.9 standard deviations, corresponding to a background fluctuation probability of 1.7×10^{-9}, is compatible with the production and decay of the Standard Model Higgs boson.

1. Introduction

The Standard Model (SM) of particle physics [1–4] has been tested by many experiments over the last four decades and has been shown to successfully describe high energy particle interactions. However, the mechanism that breaks electroweak symmetry in the SM has not been verified experimentally. This mechanism [5–10], which gives mass to massive elementary particles, implies the existence of a scalar particle, the SM Higgs boson. The search for the Higgs boson, the only elementary particle in the SM that has not yet been observed, is one of the highlights of the Large Hadron Collider [11] (LHC) physics programme.

Indirect limits on the SM Higgs boson mass of $m_H < 158$ GeV at 95% confidence level (CL) have been set using global fits to precision electroweak results [12]. Direct searches at LEP [13], the Tevatron [14–16] and the LHC [17,18] have previously excluded, at 95% CL, a SM Higgs boson with mass below 600 GeV, apart from some mass regions between 116 GeV and 127 GeV.

Both the ATLAS and CMS Collaborations reported excesses of events in their 2011 datasets of proton–proton (pp) collisions at centre-of-mass energy $\sqrt{s} = 7$ TeV at the LHC, which were compatible with SM Higgs boson production and decay in the mass region 124–126 GeV, with significances of 2.9 and 3.1 standard deviations (σ), respectively [17,18]. The CDF and DØ experiments at the Tevatron have also recently reported a broad excess in the mass region 120–135 GeV; using the existing LHC constraints, the observed local significances for $m_H = 125$ GeV are 2.7σ for CDF [14], 1.1σ for DØ [15] and 2.8σ for their combination [16].

The previous ATLAS searches in 4.6–4.8 fb^{-1} of data at $\sqrt{s} = 7$ TeV are combined here with new searches for $H \to ZZ^{(*)} \to 4\ell$,[1] $H \to \gamma\gamma$ and $H \to WW^{(*)} \to e\nu\mu\nu$ in the 5.8–5.9 fb^{-1} of pp collision data taken at $\sqrt{s} = 8$ TeV between April and June 2012.

The data were recorded with instantaneous luminosities up to 6.8×10^{33} cm^{-2} s^{-1}; they are therefore affected by multiple pp collisions occurring in the same or neighbouring bunch crossings (pile-up). In the 7 TeV data, the average number of interactions per bunch crossing was approximately 10; the average increased to approximately 20 in the 8 TeV data. The reconstruction, identification and isolation criteria used for electrons and photons in the 8 TeV data are improved, making the $H \to ZZ^{(*)} \to 4\ell$ and $H \to \gamma\gamma$ searches more robust against the increased pile-up. These analyses were re-optimised with simulation and frozen before looking at the 8 TeV data.

In the $H \to WW^{(*)} \to \ell\nu\ell\nu$ channel, the increased pile-up deteriorates the event missing transverse momentum, $E_{\mathrm{T}}^{\mathrm{miss}}$, resolution, which results in significantly larger Drell–Yan background in the same-flavour final states. Since the $e\mu$ channel provides most of the sensitivity of the search, only this final state is used in the analysis of the 8 TeV data. The kinematic region in which a SM Higgs boson with a mass between 110 GeV and 140 GeV is

searched for was kept blinded during the analysis optimisation, until satisfactory agreement was found between the observed and predicted numbers of events in control samples dominated by the principal backgrounds.

This Letter is organised as follows. The ATLAS detector is briefly described in Section 2. The simulation samples and the signal predictions are presented in Section 3. The analyses of the $H \to ZZ^{(*)} \to 4\ell$, $H \to \gamma\gamma$ and $H \to WW^{(*)} \to e\nu\mu\nu$ channels are described in Sections 4–6, respectively. The statistical procedure used to analyse the results is summarised in Section 7. The systematic uncertainties which are correlated between datasets and search channels are described in Section 8. The results of the combination of all channels are reported in Section 9, while Section 10 provides the conclusions.

2. The ATLAS detector

The ATLAS detector [19–21] is a multipurpose particle physics apparatus with forward-backward symmetric cylindrical geometry. The inner tracking detector (ID) consists of a silicon pixel detector, a silicon microstrip detector (SCT), and a straw-tube transition radiation tracker (TRT). The ID is surrounded by a thin superconducting solenoid which provides a 2 T magnetic field, and by high-granularity liquid-argon (LAr) sampling electromagnetic calorimetry. The electromagnetic calorimeter is divided into a central barrel (pseudorapidity[2] $|\eta| < 1.475$) and end-cap regions on either end of the detector ($1.375 < |\eta| < 2.5$ for the outer wheel and $2.5 < |\eta| < 3.2$ for the inner wheel). In the region matched to the ID ($|\eta| < 2.5$), it is radially segmented into three layers. The first layer has a fine segmentation in η to facilitate e/γ separation from π^0 and to improve the resolution of the shower position and direction measurements. In the region $|\eta| < 1.8$, the electromagnetic calorimeter is preceded by a presampler detector to correct for upstream energy losses. An iron-scintillator/tile calorimeter gives hadronic coverage in the central rapidity range ($|\eta| < 1.7$), while a LAr hadronic end-cap calorimeter provides coverage over $1.5 < |\eta| < 3.2$. The forward regions ($3.2 < |\eta| < 4.9$) are instrumented with LAr calorimeters for both electromagnetic and hadronic measurements. The muon spectrometer (MS) surrounds the calorimeters and consists of three large air-core superconducting magnets providing a toroidal field, each with eight coils, a system of precision tracking chambers, and fast detectors for triggering. The combination of all these systems provides charged particle measurements together with efficient and precise lepton and photon measurements in the pseudorapidity range $|\eta| < 2.5$. Jets and $E_{\mathrm{T}}^{\mathrm{miss}}$ are reconstructed using energy deposits over the full coverage of the calorimeters, $|\eta| < 4.9$.

3. Signal and background simulation samples

The SM Higgs boson production processes considered in this analysis are the dominant gluon fusion ($gg \to H$, denoted ggF), vector-boson fusion ($qq' \to qq'H$, denoted VBF) and Higgs-strahlung ($qq' \to WH, ZH$, denoted WH/ZH). The small contribution from the associated production with a $t\bar{t}$ pair ($q\bar{q}/gg \to t\bar{t}H$, denoted $t\bar{t}H$) is taken into account only in the $H \to \gamma\gamma$ analysis.

For the ggF process, the signal cross section is computed at up to next-to-next-to-leading order (NNLO) in QCD [22–28]. Next-to-leading order (NLO) electroweak (EW) corrections are applied [29,30], as well as QCD soft-gluon re-summations at up to next-to-next-to-leading logarithm (NNLL) [31]. These calculations, which are described in Refs. [32–35], assume factorisation between QCD and EW corrections. The transverse momentum, p_{T}, spectrum of the Higgs boson in the ggF process follows the HqT calculation [36], which includes QCD corrections at NLO and QCD soft-gluon re-summations up to NNLL; the effects of finite quark masses are also taken into account [37].

For the VBF process, full QCD and EW corrections up to NLO [38–41] and approximate NNLO QCD corrections [42] are used to calculate the cross section. Cross sections of the associated WH/ZH processes (VH) are calculated including QCD corrections up to NNLO [43–45] and EW corrections up to NLO [46]. The cross sections for the $t\bar{t}H$ process are estimated up to NLO QCD [47–51].

The total cross sections for SM Higgs boson production at the LHC with $m_H = 125$ GeV are predicted to be 17.5 pb for $\sqrt{s} = 7$ TeV and 22.3 pb for $\sqrt{s} = 8$ TeV [52,53].

The branching ratios of the SM Higgs boson as a function of m_H, as well as their uncertainties, are calculated using the HDECAY [54] and PROPHECY4F [55,56] programs and are taken from Refs. [52,53]. The interference in the $H \to ZZ^{(*)} \to 4\ell$ final states with identical leptons is taken into account [55,56,53].

The event generators used to model signal and background processes in samples of Monte Carlo (MC) simulated events are listed in Table 1. The normalisations of the generated samples are obtained from the state of the art calculations described above. Several different programs are used to generate the hard-scattering processes. To generate parton showers and their hadronisation, and to simulate the underlying event [66–68], PYTHIA6 [69] (for 7 TeV samples and 8 TeV samples produced with MadGraph [70,71] or AcerMC) or PYTHIA8 [72] (for other 8 TeV samples) are used. Alternatively, HERWIG [73] or SHERPA [74] are used to generate and hadronise parton showers, with the HERWIG underlying event simulation performed using JIMMY [75]. When PYTHIA6 or HERWIG are used, TAUOLA [76] and PHOTOS [77] are employed to describe tau lepton decays and additional photon radiation from charged leptons, respectively.

The following parton distribution function (PDF) sets are used: CT10 [78] for the POWHEG, MC@NLO, gg2WW and gg2ZZ samples; CTEQ6L1 [79] for the PYTHIA8, ALPGEN, AcerMC, MadGraph, HERWIG and SHERPA samples; and MRSTMCal [80] for the PYTHIA6 samples.

Acceptances and efficiencies are obtained mostly from full simulations of the ATLAS detector [81] using GEANT4 [82]. These simulations include a realistic modelling of the pile-up conditions observed in the data. Corrections obtained from measurements in

Table 1
Event generators used to model the signal and background processes. "PYTHIA" indicates that PYTHIA6 and PYTHIA8 are used for simulations of $\sqrt{s} = 7$ TeV and $\sqrt{s} = 8$ TeV data, respectively.

Process	Generator
ggF, VBF	POWHEG [57,58] + PYTHIA
WH, ZH, $t\bar{t}H$	PYTHIA
W + jets, Z/γ^* + jets	ALPGEN [59] + HERWIG
$t\bar{t}$, tW, tb	MC@NLO [60] + HERWIG
tqb	AcerMC [61] + PYTHIA
$q\bar{q} \to WW$	MC@NLO + HERWIG
$gg \to WW$	gg2WW [62] + HERWIG
$q\bar{q} \to ZZ$	POWHEG [63] + PYTHIA
$gg \to ZZ$	gg2ZZ [64] + HERWIG
WZ	MadGraph + PYTHIA, HERWIG
$W\gamma$ + jets	ALPGEN + HERWIG
$W\gamma^*$ [65]	MadGraph + PYTHIA
$q\bar{q}/gg \to \gamma\gamma$	SHERPA

[2] ATLAS uses a right-handed coordinate system with its origin at the nominal interaction point (IP) in the centre of the detector, and the z-axis along the beam line. The x-axis points from the IP to the centre of the LHC ring, and the y-axis points upwards. Cylindrical coordinates (r, ϕ) are used in the transverse plane, ϕ being the azimuthal angle around the beam line. Observables labelled "transverse" are projected into the x–y plane. The pseudorapidity is defined in terms of the polar angle θ as $\eta = -\ln\tan(\theta/2)$.

data are applied to account for small differences between data and simulation (e.g. large samples of W, Z and J/ψ decays are used to derive scale factors for lepton reconstruction and identification efficiencies).

4. $H \to ZZ^{(*)} \to 4\ell$ channel

The search for the SM Higgs boson through the decay $H \to ZZ^{(*)} \to 4\ell$, where $\ell = e$ or μ, provides good sensitivity over a wide mass range (110–600 GeV), largely due to the excellent momentum resolution of the ATLAS detector. This analysis searches for Higgs boson candidates by selecting two pairs of isolated leptons, each of which is comprised of two leptons with the same flavour and opposite charge. The expected cross section times branching ratio for the process $H \to ZZ^{(*)} \to 4\ell$ with $m_H = 125$ GeV is 2.2 fb for $\sqrt{s} = 7$ TeV and 2.8 fb for $\sqrt{s} = 8$ TeV.

The largest background comes from continuum $(Z^{(*)}/\gamma^*)(Z^{(*)}/\gamma^*)$ production, referred to hereafter as $ZZ^{(*)}$. For low masses there are also important background contributions from Z + jets and $t\bar{t}$ production, where charged lepton candidates arise either from decays of hadrons with b- or c-quark content or from mis-identification of jets.

The 7 TeV data have been re-analysed and combined with the 8 TeV data. The analysis is improved in several aspects with respect to Ref. [83] to enhance the sensitivity to a low-mass Higgs boson. In particular, the kinematic selections are revised, and the 8 TeV data analysis benefits from improvements in the electron reconstruction and identification. The expected signal significances for a Higgs boson with $m_H = 125$ GeV are 1.6σ for the 7 TeV data (to be compared with 1.25σ in Ref. [83]) and 2.1σ for the 8 TeV data.

4.1. Event selection

The data are selected using single-lepton or dilepton triggers. For the single-muon trigger, the p_{T} threshold is 18 GeV for the 7 TeV data and 24 GeV for the 8 TeV data, while for the single-electron trigger the transverse energy, E_{T}, threshold varies from 20 GeV to 22 GeV for the 7 TeV data and is 24 GeV for the 8 TeV data. For the dielectron triggers, the thresholds are 12 GeV for both electrons. For the dimuon triggers, the thresholds for the 7 TeV data are 10 GeV for each muon, while for the 8 TeV data the thresholds are 13 GeV. An additional asymmetric dimuon trigger is used in the 8 TeV data with thresholds 18 GeV and 8 GeV for the leading and sub-leading muon, respectively.

Muon candidates are formed by matching reconstructed ID tracks with either a complete track or a track-segment reconstructed in the MS [84]. The muon acceptance is extended with respect to Ref. [83] using tracks reconstructed in the forward region of the MS ($2.5 < |\eta| < 2.7$), which is outside the ID coverage. If both an ID and a complete MS track are present, the two independent momentum measurements are combined; otherwise the information of the ID or the MS is used alone. Electron candidates must have a well-reconstructed ID track pointing to an electromagnetic calorimeter cluster and the cluster should satisfy a set of identification criteria [85] that require the longitudinal and transverse shower profiles to be consistent with those expected for electromagnetic showers. Tracks associated with electromagnetic clusters are fitted using a Gaussian-Sum Filter [86], which allows for bremsstrahlung energy losses to be taken into account.

Each electron (muon) must satisfy $p_{\mathrm{T}} > 7$ GeV ($p_{\mathrm{T}} > 6$ GeV) and be measured in the pseudorapidity range $|\eta| < 2.47$ ($|\eta| < 2.7$). All possible quadruplet combinations with same-flavour opposite-charge lepton pairs are then formed. The most energetic lepton in the quadruplet must satisfy $p_{\mathrm{T}} > 20$ GeV, and the second (third) lepton in p_{T} order must satisfy $p_{\mathrm{T}} > 15$ GeV ($p_{\mathrm{T}} > 10$ GeV). At least one of the leptons must satisfy the single-lepton trigger or one pair must satisfy the dilepton trigger requirements. The leptons are required to be separated from each other by $\Delta R = \sqrt{(\Delta\eta)^2 + (\Delta\phi)^2} > 0.1$ if they are of the same flavour and by $\Delta R > 0.2$ otherwise. The longitudinal impact parameters of the leptons along the beam axis are required to be within 10 mm of the reconstructed primary vertex. The primary vertex used for the event is defined as the reconstructed vertex with the highest $\sum p_{\mathrm{T}}^2$ of associated tracks and is required to have at least three tracks with $p_{\mathrm{T}} > 0.4$ GeV. To reject cosmic rays, muon tracks are required to have a transverse impact parameter, defined as the distance of closest approach to the primary vertex in the transverse plane, of less than 1 mm.

The same-flavour and opposite-charge lepton pair with an invariant mass closest to the Z boson mass (m_Z) in the quadruplet is referred to as the leading lepton pair. Its invariant mass, denoted by m_{12}, is required to be between 50 GeV and 106 GeV. The remaining same-flavour, opposite-charge lepton pair is the sub-leading lepton pair. Its invariant mass, m_{34}, is required to be in the range $m_{\mathrm{min}} < m_{34} < 115$ GeV, where the value of m_{min} depends on the reconstructed four-lepton invariant mass, $m_{4\ell}$. The value of m_{min} varies monotonically from 17.5 GeV at $m_{4\ell} = 120$ GeV to 50 GeV at $m_{4\ell} = 190$ GeV [87] and is constant above this value. All possible lepton pairs in the quadruplet that have the same flavour and opposite charge must satisfy $m_{\ell\ell} > 5$ GeV in order to reject backgrounds involving the production and decay of J/ψ mesons. If two or more quadruplets satisfy the above selection, the one with the highest value of m_{34} is selected. Four different analysis sub-channels, $4e$, $2e2\mu$, $2\mu2e$ and 4μ, arranged by the flavour of the leading lepton pair, are defined.

Non-prompt leptons from heavy flavour decays, electrons from photon conversions and jets mis-identified as electrons have broader transverse impact parameter distributions than prompt leptons from Z boson decays and/or are non-isolated. Thus, the Z + jets and $t\bar{t}$ background contributions are reduced by applying a cut on the transverse impact parameter significance, defined as the transverse impact parameter divided by its uncertainty, d_0/σ_{d_0}. This is required to be less than 3.5 (6.5) for muons (electrons). The electron impact parameter is affected by bremsstrahlung and thus has a broader distribution.

In addition, leptons must satisfy isolation requirements based on tracking and calorimetric information. The normalised track isolation discriminant is defined as the sum of the transverse momenta of tracks inside a cone of size $\Delta R = 0.2$ around the lepton direction, excluding the lepton track, divided by the lepton p_{T}. The tracks considered in the sum are those compatible with the lepton vertex and have $p_{\mathrm{T}} > 0.4$ GeV ($p_{\mathrm{T}} > 1$ GeV) in the case of electron (muon) candidates. Each lepton is required to have a normalised track isolation smaller than 0.15. The normalised calorimetric isolation for electrons is computed as the sum of the E_{T} of positive-energy topological clusters [88] with a reconstructed barycentre falling within a cone of size $\Delta R = 0.2$ around the candidate electron cluster, divided by the electron E_{T}. The algorithm for topological clustering suppresses noise by keeping cells with a significant energy deposit and their neighbours. The summed energy of the cells assigned to the electron cluster is excluded, while a correction is applied to account for the electron energy deposited outside the cluster. The ambient energy deposition in the event from pile-up and the underlying event is accounted for using a calculation of the median transverse energy density from low-p_{T} jets [89,90]. The normalised calorimetric isolation for electrons is required to be less than 0.20. The normalised calorimetric isolation discriminant for muons is defined by the ratio to the p_{T} of the muon of the E_{T} sum of the calorimeter cells inside a cone of size

$\Delta R = 0.2$ around the muon direction minus the energy deposited by the muon. Muons are required to have a normalised calorimetric isolation less than 0.30 (0.15 for muons without an associated ID track). For both the track- and calorimeter-based isolation, any contributions arising from other leptons of the quadruplet are subtracted.

The combined signal reconstruction and selection efficiencies for a SM Higgs with $m_H = 125$ GeV for the 7 TeV (8 TeV) data are 37% (36%) for the 4μ channel, 20% (22%) for the $2e2\mu/2\mu2e$ channels and 15% (20%) for the $4e$ channel.

The 4ℓ invariant mass resolution is improved by applying a Z-mass constrained kinematic fit to the leading lepton pair for $m_{4\ell} < 190$ GeV and to both lepton pairs for higher masses. The expected width of the reconstructed mass distribution is dominated by the experimental resolution for $m_H < 350$ GeV, and by the natural width of the Higgs boson for higher masses (30 GeV at $m_H = 400$ GeV). The typical mass resolutions for $m_H = 125$ GeV are 1.7 GeV, 1.7 GeV/2.2 GeV and 2.3 GeV for the 4μ, $2e2\mu/2\mu2e$ and $4e$ sub-channels, respectively.

4.2. Background estimation

The expected background yield and composition are estimated using the MC simulation normalised to the theoretical cross section for $ZZ^{(*)}$ production and by methods using control regions from data for the $Z+$jets and $t\bar{t}$ processes. Since the background composition depends on the flavour of the sub-leading lepton pair, different approaches are taken for the $\ell\ell + \mu\mu$ and the $\ell\ell + ee$ final states. The transfer factors needed to extrapolate the background yields from the control regions defined below to the signal region are obtained from the MC simulation. The MC description of the selection efficiencies for the different background components has been verified with data.

The reducible $\ell\ell + \mu\mu$ background is dominated by $t\bar{t}$ and $Z+$jets (mostly $Zb\bar{b}$) events. A control region is defined by removing the isolation requirement on the leptons in the sub-leading pair, and by requiring that at least one of the sub-leading muons fails the transverse impact parameter significance selection. These modifications remove $ZZ^{(*)}$ contributions, and allow both the $t\bar{t}$ and $Z+$jets backgrounds to be estimated simultaneously using a fit to the m_{12} distribution. The $t\bar{t}$ background contribution is cross-checked by selecting a control sample of events with an opposite charge $e\mu$ pair with an invariant mass between 50 GeV and 106 GeV, accompanied by an opposite-charge muon pair. Events with a Z candidate decaying to a pair of electrons or muons in the aforementioned mass range are excluded. Isolation and transverse impact parameter significance requirements are applied only to the leptons of the $e\mu$ pair.

In order to estimate the reducible $\ell\ell + ee$ background, a control region is formed by relaxing the selection criteria for the electrons of the sub-leading pair. The different sources of electron background are then separated into categories consisting of non-prompt leptons from heavy flavour decays, electrons from photon conversions and jets mis-identified as electrons, using appropriate discriminating variables [91]. This method allows the sum of the $Z+$jets and $t\bar{t}$ background contributions to be estimated. As a cross-check, the same method is also applied to a similar control region containing same-charge sub-leading electron pairs. An additional cross-check of the $\ell\ell + ee$ background estimation is performed by using a control region with same-charge sub-leading electron pairs, where the three highest p_{T} leptons satisfy all the analysis criteria whereas the selection cuts are relaxed for the remaining electrons. All the cross-checks yield consistent results.

The data-driven background estimates are summarised in Table 2. The distribution of m_{34}, for events selected by the analysis except that the isolation and transverse impact parameter requirements for the sub-leading lepton pair are removed, is presented in Fig. 1.

Table 2
Summary of the estimated numbers of $Z+$jets and $t\bar{t}$ background events, for the $\sqrt{s} = 7$ TeV and $\sqrt{s} = 8$ TeV data in the entire phase-space of the analysis after the kinematic selections described in the text. The backgrounds are combined for the $2\mu2e$ and $4e$ channels, as discussed in the text. The first uncertainty is statistical, while the second is systematic.

Background	Estimated numbers of events	
	$\sqrt{s} = 7$ TeV	$\sqrt{s} = 8$ TeV
4μ		
$Z+$jets	$0.3 \pm 0.1 \pm 0.1$	$0.5 \pm 0.1 \pm 0.2$
$t\bar{t}$	$0.02 \pm 0.02 \pm 0.01$	$0.04 \pm 0.02 \pm 0.02$
$2e2\mu$		
$Z+$jets	$0.2 \pm 0.1 \pm 0.1$	$0.4 \pm 0.1 \pm 0.1$
$t\bar{t}$	$0.02 \pm 0.01 \pm 0.01$	$0.04 \pm 0.01 \pm 0.01$
$2\mu2e$		
$Z+$jets, $t\bar{t}$	$2.6 \pm 0.4 \pm 0.4$	$4.9 \pm 0.8 \pm 0.7$
$4e$		
$Z+$jets, $t\bar{t}$	$3.1 \pm 0.6 \pm 0.5$	$3.9 \pm 0.7 \pm 0.8$

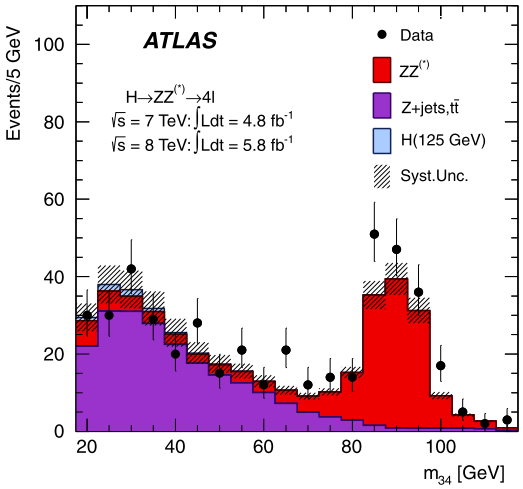

Fig. 1. Invariant mass distribution of the sub-leading lepton pair (m_{34}) for a sample defined by the presence of a Z boson candidate and an additional same-flavour electron or muon pair, for the combination of $\sqrt{s} = 7$ TeV and $\sqrt{s} = 8$ TeV data in the entire phase-space of the analysis after the kinematic selections described in the text. Isolation and transverse impact parameter significance requirements are applied to the leading lepton pair only. The MC is normalised to the data-driven background estimations. The relatively small contribution of a SM Higgs with $m_H = 125$ GeV in this sample is also shown.

4.3. Systematic uncertainties

The uncertainties on the integrated luminosities are determined to be 1.8% for the 7 TeV data and 3.6% for the 8 TeV data using the techniques described in Ref. [92].

The uncertainties on the lepton reconstruction and identification efficiencies and on the momentum scale and resolution are determined using samples of W, Z and J/ψ decays [85, 84]. The relative uncertainty on the signal acceptance due to the uncertainty on the muon reconstruction and identification efficiency is $\pm 0.7\%$ ($\pm 0.5\%/\pm 0.5\%$) for the 4μ ($2e2\mu/2\mu2e$) channel for $m_{4\ell} = 600$ GeV and increases to $\pm 0.9\%$ ($\pm 0.8\%/\pm 0.5\%$) for $m_{4\ell} = 115$ GeV. Similarly, the relative uncertainty on the signal acceptance due to the uncertainty on the electron reconstruction and identification efficiency is $\pm 2.6\%$ ($\pm 1.7\%/\pm 1.8\%$) for the $4e$ ($2e2\mu/2\mu2e$) channel for $m_{4\ell} = 600$ GeV and reaches $\pm 8.0\%$

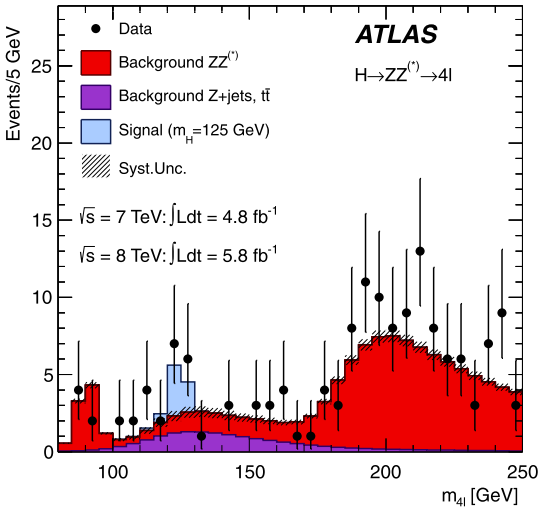

Fig. 2. The distribution of the four-lepton invariant mass, $m_{4\ell}$, for the selected candidates, compared to the background expectation in the 80–250 GeV mass range, for the combination of the $\sqrt{s} = 7$ TeV and $\sqrt{s} = 8$ TeV data. The signal expectation for a SM Higgs with $m_H = 125$ GeV is also shown.

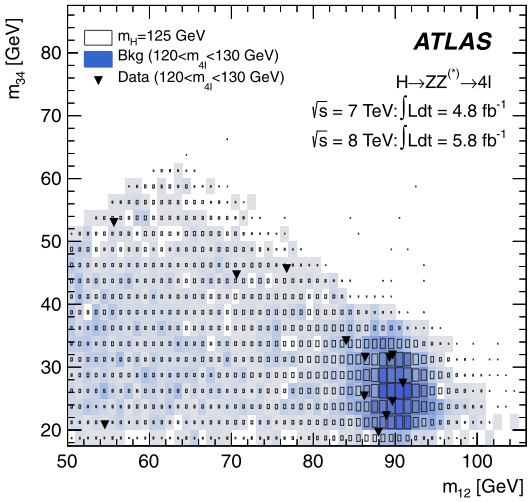

Fig. 3. Distribution of the m_{34} versus the m_{12} invariant mass, before the application of the Z-mass constrained kinematic fit, for the selected candidates in the $m_{4\ell}$ range 120–130 GeV. The expected distributions for a SM Higgs with $m_H = 125$ GeV (the sizes of the boxes indicate the relative density) and for the total background (the intensity of the shading indicates the relative density) are also shown.

Table 3
The numbers of expected signal ($m_H = 125$ GeV) and background events, together with the numbers of observed events in the data, in a window of size ±5 GeV around 125 GeV, for the combined $\sqrt{s} = 7$ TeV and $\sqrt{s} = 8$ TeV data.

	Signal	$ZZ^{(*)}$	$Z+$jets, $t\bar{t}$	Observed
4μ	2.09 ± 0.30	1.12 ± 0.05	0.13 ± 0.04	6
$2e2\mu/2\mu2e$	2.29 ± 0.33	0.80 ± 0.05	1.27 ± 0.19	5
$4e$	0.90 ± 0.14	0.44 ± 0.04	1.09 ± 0.20	2

(±2.3%/±7.6%) for $m_{4\ell} = 115$ GeV. The uncertainty on the electron energy scale results in an uncertainty of ±0.7% (±0.5%/±0.2%) on the mass scale of the $m_{4\ell}$ distribution for the $4e$ ($2e2\mu/2\mu2e$) channel. The impact of the uncertainties on the electron energy resolution and on the muon momentum resolution and scale are found to be negligible.

The theoretical uncertainties associated with the signal are described in detail in Section 8. For the SM $ZZ^{(*)}$ background, which is estimated from MC simulation, the uncertainty on the total yield due to the QCD scale uncertainty is ±5%, while the effect of the PDF and α_s uncertainties is ±4% (±8%) for processes initiated by quarks (gluons) [53]. In addition, the dependence of these uncertainties on the four-lepton invariant mass spectrum has been taken into account as discussed in Ref. [53]. Though a small excess of events is observed for $m_{4l} > 160$ GeV, the measured $ZZ^{(*)} \to 4\ell$ cross section [93] is consistent with the SM theoretical prediction. The impact of not using the theoretical constraints on the $ZZ^{(*)}$ yield on the search for a Higgs boson with $m_H < 2m_Z$ has been studied in Ref. [87] and has been found to be negligible. The impact of the interference between a Higgs signal and the non-resonant $gg \to ZZ^{(*)}$ background is small and becomes negligible for $m_H < 2m_Z$ [94].

4.4. Results

The expected distributions of $m_{4\ell}$ for the background and for a Higgs boson signal with $m_H = 125$ GeV are compared to the data in Fig. 2. The numbers of observed and expected events in a window of ±5 GeV around $m_H = 125$ GeV are presented for the combined 7 TeV and 8 TeV data in Table 3. The distribution of the m_{34} versus m_{12} invariant mass is shown in Fig. 3. The statistical interpretation of the excess of events near $m_{4\ell} = 125$ GeV in Fig. 2 is presented in Section 9.

5. $H \to \gamma\gamma$ channel

The search for the SM Higgs boson through the decay $H \to \gamma\gamma$ is performed in the mass range between 110 GeV and 150 GeV. The dominant background is SM diphoton production ($\gamma\gamma$); contributions also come from $\gamma +$ jet and jet + jet production with one or two jets mis-identified as photons (γj and jj) and from the Drell–Yan process. The 7 TeV data have been re-analysed and the results combined with those from the 8 TeV data. Among other changes to the analysis, a new category of events with two jets is introduced, which enhances the sensitivity to the VBF process. Higgs boson events produced by the VBF process have two forward jets, originating from the two scattered quarks, and tend to be devoid of jets in the central region. Overall, the sensitivity of the analysis has been improved by about 20% with respect to that described in Ref. [95].

5.1. Event selection

The data used in this channel are selected using a diphoton trigger [96], which requires two clusters formed from energy depositions in the electromagnetic calorimeter. An E_{T} threshold of 20 GeV is applied to each cluster for the 7 TeV data, while for the 8 TeV data the thresholds are increased to 35 GeV on the leading (the highest E_{T}) cluster and to 25 GeV on the sub-leading (the next-highest E_{T}) cluster. In addition, loose criteria are applied to the shapes of the clusters to match the expectations for electromagnetic showers initiated by photons. The efficiency of the trigger is greater than 99% for events passing the final event selection.

Events are required to contain at least one reconstructed vertex with at least two associated tracks with $p_{\mathrm{T}} > 0.4$ GeV, as well as two photon candidates. Photon candidates are reconstructed in the fiducial region $|\eta| < 2.37$, excluding the calorimeter barrel/endcap transition region $1.37 \leqslant |\eta| < 1.52$. Photons that convert to electron–positron pairs in the ID material can have one or two reconstructed tracks matched to the clusters in the calorimeter. The photon reconstruction efficiency is about 97% for $E_{\mathrm{T}} > 30$ GeV.

In order to account for energy losses upstream of the calorimeter and energy leakage outside of the cluster, MC simulation results are used to calibrate the energies of the photon candidates; there are separate calibrations for unconverted and converted

candidates. The calibration is refined by applying η-dependent correction factors, which are of the order of $\pm 1\%$, determined from measured $Z \to e^+e^-$ events. The leading (sub-leading) photon candidate is required to have $E_{\mathrm{T}} > 40$ GeV (30 GeV).

Photon candidates are required to pass identification criteria based on shower shapes in the electromagnetic calorimeter and on energy leakage into the hadronic calorimeter [97]. For the 7 TeV data, this information is combined in a neural network, tuned to achieve a similar jet rejection as the cut-based selection described in Ref. [95], but with higher photon efficiency. For the 8 TeV data, cut-based criteria are used to ensure reliable photon performance for recently-recorded data. This cut-based selection has been tuned to be robust against pile-up by relaxing requirements on shower shape criteria more susceptible to pile-up, and tightening others. The photon identification efficiencies, averaged over η, range from 85% to above 95% for the E_{T} range under consideration.

To further suppress the jet background, an isolation requirement is applied. The isolation transverse energy is defined as the sum of the transverse energy of positive-energy topological clusters, as described in Section 4, within a cone of size $\Delta R = 0.4$ around the photon candidate, excluding the region within 0.125×0.175 in $\Delta\eta \times \Delta\phi$ around the photon barycentre. The distributions of the isolation transverse energy in data and simulation have been found to be in good agreement using electrons from $Z \to e^+e^-$ events and photons from $Z \to \ell^+\ell^-\gamma$ events. Remaining small differences are taken into account as a systematic uncertainty. Photon candidates are required to have an isolation transverse energy of less than 4 GeV.

5.2. Invariant mass reconstruction

The invariant mass of the two photons is evaluated using the photon energies measured in the calorimeter, the azimuthal angle ϕ between the photons as determined from the positions of the photons in the calorimeter, and the values of η calculated from the position of the identified primary vertex and the impact points of the photons in the calorimeter.

The primary vertex of the hard interaction is identified by combining the following information in a global likelihood: the directions of flight of the photons as determined using the longitudinal segmentation of the electromagnetic calorimeter (calorimeter pointing), the parameters of the beam spot, and the $\sum p_{\mathrm{T}}^2$ of the tracks associated with each reconstructed vertex. In addition, for the 7 TeV data analysis, the reconstructed conversion vertex is used in the likelihood for converted photons with tracks containing hits in the silicon layers of the ID. The calorimeter pointing is sufficient to ensure that the contribution of the opening angle between the photons to the mass resolution is negligible. Using the calorimeter pointing alone, the resolution of the vertex z coordinate is ~ 15 mm, improving to ~ 6 mm for events with two reconstructed converted photons. The tracking information from the ID improves the identification of the vertex of the hard interaction, which is needed for the jet selection in the 2-jet category.

With the selection described in Section 5.1, in the diphoton invariant mass range between 100 GeV and 160 GeV, 23 788 and 35 251 diphoton candidates are observed in the 7 TeV and 8 TeV data samples, respectively.

Data-driven techniques [98] are used to estimate the numbers of $\gamma\gamma$, γj and jj events in the selected sample. The contribution from the Drell–Yan background is determined from a sample of $Z \to e^+e^-$ decays in data where either one or both electrons pass the photon selection. The measured composition of the selected sample is approximately 74%, 22%, 3% and 1% for the $\gamma\gamma$, γj, jj and Drell–Yan processes, respectively, demonstrating the dominance of the irreducible diphoton production. This decomposition is not directly used in the signal search; however, it is used to study the parameterisation of the background modelling.

5.3. Event categorisation

To increase the sensitivity to a Higgs boson signal, the events are separated into ten mutually exclusive categories having different mass resolutions and signal-to-background ratios. An exclusive category of events containing two jets improves the sensitivity to VBF. The other nine categories are defined by the presence or not of converted photons, η of the selected photons, and p_{Tt}, the component[3] of the diphoton p_{T} that is orthogonal to the axis defined by the difference between the two photon momenta [99,100].

Jets are reconstructed [101] using the anti-k_t algorithm [102] with radius parameter $R = 0.4$. At least two jets with $|\eta| < 4.5$ and $p_{\mathrm{T}} > 25$ GeV are required in the 2-jet selection. In the analysis of the 8 TeV data, the p_{T} threshold is raised to 30 GeV for jets with $2.5 < |\eta| < 4.5$. For jets in the ID acceptance ($|\eta| < 2.5$), the fraction of the sum of the p_{T} of tracks, associated with the jet and matched to the selected primary vertex, with respect to the sum of the p_{T} of tracks associated with the jet (jet vertex fraction, JVF) is required to be at least 0.75. This requirement on the JVF reduces the number of jets from proton–proton interactions not associated with the primary vertex. Motivated by the VBF topology, three additional cuts are applied in the 2-jet selection: the difference of the pseudorapidity between the leading and sub-leading jets (tag jets) is required to be larger than 2.8, the invariant mass of the tag jets has to be larger than 400 GeV, and the azimuthal angle difference between the diphoton system and the system of the tag jets has to be larger than 2.6. About 70% of the signal events in the 2-jet category come from the VBF process.

The other nine categories are defined as follows: events with two unconverted photons are separated into *unconverted central* ($|\eta| < 0.75$ for both candidates) and *unconverted rest* (all other events), events with at least one converted photon are separated into *converted central* ($|\eta| < 0.75$ for both candidates), *converted transition* (at least one photon with $1.3 < |\eta| < 1.75$) and *converted rest* (all other events). Except for the *converted transition* category, each category is further divided by a cut at $p_{\mathrm{Tt}} = 60$ GeV into two categories, *low* p_{Tt} and *high* p_{Tt}. MC studies show that signal events, particularly those produced via VBF or associated production (WH/ZH and $t\bar{t}H$), have on average larger p_{Tt} than background events. The number of data events in each category, as well as the sum of all the categories, which is denoted *inclusive*, are given in Table 4.

5.4. Signal modelling

The description of the Higgs boson signal is obtained from MC, as described in Section 3. The cross sections multiplied by the branching ratio into two photons are given in Table 4 for $m_H = 126.5$ GeV. The number of signal events produced via the ggF process is rescaled to take into account the expected destructive interference between the $gg \to \gamma\gamma$ continuum background and ggF [103], leading to a reduction of the production rate by 2–5% depending on m_H and the event category. For both the 7 TeV and 8 TeV MC samples, the fractions of ggF, VBF, WH, ZH and $t\bar{t}H$ production are approximately 88%, 7%, 3%, 2% and 0.5%, respectively, for $m_H = 126.5$ GeV.

In the simulation, the shower shape distributions are shifted slightly to improve the agreement with the data [97], and the

[3] $p_{\mathrm{Tt}} = |(\mathbf{p}_{\mathrm{T}}^{\gamma_1} + \mathbf{p}_{\mathrm{T}}^{\gamma_2}) \times (\mathbf{p}_{\mathrm{T}}^{\gamma_1} - \mathbf{p}_{\mathrm{T}}^{\gamma_2})| / |\mathbf{p}_{\mathrm{T}}^{\gamma_1} - \mathbf{p}_{\mathrm{T}}^{\gamma_2}|$, where $\mathbf{p}_{\mathrm{T}}^{\gamma_1}$ and $\mathbf{p}_{\mathrm{T}}^{\gamma_2}$ are the transverse momenta of the two photons.

Table 4
Number of events in the data (N_D) and expected number of signal events (N_S) for $m_H = 126.5$ GeV from the $H \to \gamma\gamma$ analysis, for each category in the mass range 100–160 GeV. The mass resolution FWHM (see text) is also given for the 8 TeV data. The Higgs boson production cross section multiplied by the branching ratio into two photons ($\sigma \times B(H \to \gamma\gamma)$) is listed for $m_H = 126.5$ GeV. The statistical uncertainties on N_S and FWHM are less than 1%.

$\sqrt{s}$	7 TeV		8 TeV		
$\sigma \times B(H \to \gamma\gamma)$ [fb]	39		50		FWHM [GeV]
Category	N_D	N_S	N_D	N_S	
Unconv. central, low p_{Tt}	2054	10.5	2945	14.2	3.4
Unconv. central, high p_{Tt}	97	1.5	173	2.5	3.2
Unconv. rest, low p_{Tt}	7129	21.6	12 136	30.9	3.7
Unconv. rest, high p_{Tt}	444	2.8	785	5.2	3.6
Conv. central, low p_{Tt}	1493	6.7	2015	8.9	3.9
Conv. central, high p_{Tt}	77	1.0	113	1.6	3.5
Conv. rest, low p_{Tt}	8313	21.1	11 099	26.9	4.5
Conv. rest, high p_{Tt}	501	2.7	706	4.5	3.9
Conv. transition	3591	9.5	5140	12.8	6.1
2-jet	89	2.2	139	3.0	3.7
All categories (inclusive)	23 788	79.6	35 251	110.5	3.9

photon energy resolution is broadened (by approximately 1% in the barrel calorimeter and 1.2–2.1% in the end-cap regions) to account for small differences observed between $Z \to e^+e^-$ data and MC events. The signal yields expected for the 7 TeV and 8 TeV data samples are given in Table 4. The overall selection efficiency is about 40%.

The shape of the invariant mass of the signal in each category is modelled by the sum of a Crystal Ball function [104], describing the core of the distribution with a width σ_{CB}, and a Gaussian contribution describing the tails (amounting to $< 10\%$) of the mass distribution. The expected full-width-at-half-maximum (FWHM) is 3.9 GeV and σ_{CB} is 1.6 GeV for the inclusive sample. The resolution varies with event category (see Table 4); the FWHM is typically a factor 2.3 larger than σ_{CB}.

5.5. Background modelling

The background in each category is estimated from data by fitting the diphoton mass spectrum in the mass range 100–160 GeV with a selected model with free parameters of shape and normalisation. Different models are chosen for the different categories to achieve a good compromise between limiting the size of a potential bias while retaining good statistical power. A fourth-order Bernstein polynomial function [105] is used for the *unconverted rest* (*low* p_{Tt}), *converted rest* (*low* p_{Tt}) and *inclusive* categories, an exponential function of a second-order polynomial for the *unconverted central* (*low* p_{Tt}), *converted central* (*low* p_{Tt}) and *converted transition* categories, and an exponential function for all others.

Studies to determine the potential bias have been performed using large samples of simulated background events complemented by data-driven estimates. The background shapes in the simulation have been cross-checked using data from control regions. The potential bias for a given model is estimated, separately for each category, by performing a maximum likelihood fit to large samples of simulated background events in the mass range 100–160 GeV, of the sum of a signal plus the given background model. The signal shape is taken to follow the expectation for a SM Higgs boson; the signal yield is a free parameter of the fit. The potential bias is defined by the largest absolute signal yield obtained from the likelihood fit to the simulated background samples for hypothesised Higgs boson masses in the range 110–150 GeV. A pre-selection of background parameterisations is made by requiring that the potential bias, as defined above, is less than 20% of the statistical uncertainty on the fitted signal yield. The pre-selected parameterisation in each category with the best expected sensitivity for $m_H = 125$ GeV is selected as the background model.

The largest absolute signal yield as defined above is taken as the systematic uncertainty on the background model. It amounts to $\pm(0.2$–$4.6)$ and $\pm(0.3$–$6.8)$ events, depending on the category for the 7 TeV and 8 TeV data samples, respectively. In the final fit to the data (see Section 5.7) a signal-like term is included in the likelihood function for each category. This term incorporates the estimated potential bias, thus providing a conservative estimate of the uncertainty due to the background modelling.

5.6. Systematic uncertainties

Hereafter, in cases where two uncertainties are quoted, they refer to the 7 TeV and 8 TeV data, respectively. The dominant experimental uncertainty on the signal yield ($\pm 8\%$, $\pm 11\%$) comes from the photon reconstruction and identification efficiency, which is estimated with data using electrons from Z decays and photons from $Z \to \ell^+\ell^-\gamma$ events. Pile-up modelling also affects the expected yields and contributes to the uncertainty ($\pm 4\%$). Further uncertainties on the signal yield are related to the trigger ($\pm 1\%$), photon isolation ($\pm 0.4\%$, $\pm 0.5\%$) and luminosity ($\pm 1.8\%$, $\pm 3.6\%$). Uncertainties due to the modelling of the underlying event are $\pm 6\%$ for VBF and $\pm 30\%$ for other production processes in the 2-jet category. Uncertainties on the predicted cross sections and branching ratio are summarised in Section 8.

The uncertainty on the expected fractions of signal events in each category is described in the following. The uncertainty on the knowledge of the material in front of the calorimeter is used to derive the amount of possible event migration between the converted and unconverted categories ($\pm 4\%$). The uncertainty from pile-up on the population of the converted and unconverted categories is $\pm 2\%$. The uncertainty from the jet energy scale (JES) amounts to up to $\pm 19\%$ for the 2-jet category, and up to $\pm 4\%$ for the other categories. Uncertainties from the JVF modelling are $\pm 12\%$ (for the 8 TeV data) for the 2-jet category, estimated from $Z+2$-jets events by comparing data and MC. Different PDFs and scale variations in the HqT calculations are used to derive possible event migration among categories ($\pm 9\%$) due to the modelling of the Higgs boson kinematics.

The total uncertainty on the mass resolution is $\pm 14\%$. The dominant contribution ($\pm 12\%$) comes from the uncertainty on the energy resolution of the calorimeter, which is determined from $Z \to e^+e^-$ events. Smaller contributions come from the imperfect knowledge of the material in front of the calorimeter, which affects the extrapolation of the calibration from electrons to photons ($\pm 6\%$), and from pile-up ($\pm 4\%$).

5.7. Results

The distributions of the invariant mass, $m_{\gamma\gamma}$, of the diphoton events, summed over all categories, are shown in Fig. 4(a) and (b). The result of a fit including a signal component fixed to $m_H = 126.5$ GeV and a background component described by a fourth-order Bernstein polynomial is superimposed.

The statistical analysis of the data employs an unbinned likelihood function constructed from those of the ten categories of the 7 TeV and 8 TeV data samples. To demonstrate the sensitivity of this likelihood analysis, Figs. 4(c) and (d) also show the mass spectrum obtained after weighting events with category-dependent factors reflecting the signal-to-background ratios. The weight w_i for events in category $i \in [1, 10]$ for the 7 TeV and 8 TeV data samples is defined to be $\ln(1 + S_i/B_i)$, where S_i is 90% of the expected signal for $m_H = 126.5$ GeV, and B_i is the integral, in

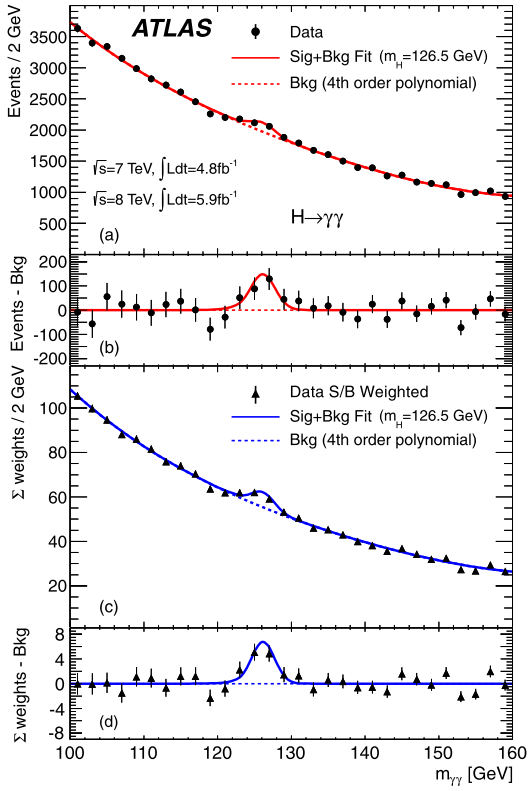

Fig. 4. The distributions of the invariant mass of diphoton candidates after all selections for the combined 7 TeV and 8 TeV data sample. The inclusive sample is shown in (a) and a weighted version of the same sample in (c); the weights are explained in the text. The result of a fit to the data of the sum of a signal component fixed to $m_H = 126.5$ GeV and a background component described by a fourth-order Bernstein polynomial is superimposed. The residuals of the data and weighted data with respect to the respective fitted background component are displayed in (b) and (d).

a window containing S_i, of a background-only fit to the data. The values S_i/B_i have only a mild dependence on m_H.

The statistical interpretation of the excess of events near $m_{\gamma\gamma} = 126.5$ GeV in Fig. 4 is presented in Section 9.

6. $H \to WW^{(*)} \to e\nu\mu\nu$ channel

The signature for this channel is two opposite-charge leptons with large transverse momentum and a large momentum imbalance in the event due to the escaping neutrinos. The dominant backgrounds are non-resonant WW, $t\bar{t}$, and Wt production, all of which have real W pairs in the final state. Other important backgrounds include Drell–Yan events ($pp \to Z/\gamma^{(*)} \to \ell\ell$) with $E_{\mathrm{T}}^{\mathrm{miss}}$ that may arise from mismeasurement, W + jets events in which a jet produces an object reconstructed as the second electron or muon, and $W\gamma$ events in which the photon undergoes a conversion. Boson pair production ($W\gamma^*/WZ^{(*)}$ and $ZZ^{(*)}$) can also produce opposite-charge lepton pairs with additional leptons that are not detected.

The analysis of the 8 TeV data presented here is focused on the mass range $110 < m_H < 200$ GeV. It follows the procedure used for the 7 TeV data, described in Ref. [106], except that more stringent criteria are applied to reduce the W + jets background and some selections have been modified to mitigate the impact of the higher instantaneous luminosity at the LHC in 2012. In particular, the higher luminosity results in a larger Drell–Yan background to the same-flavour final states, due to the deterioration of the missing transverse momentum resolution. For this reason, and the fact that the $e\mu$ final state provides more than 85% of the sensitivity of the search, the same-flavour final states have not been used in the analysis described here.

6.1. Event selection

For the 8 TeV $H \to WW^{(*)} \to e\nu\mu\nu$ search, the data are selected using inclusive single-muon and single-electron triggers. Both triggers require an isolated lepton with $p_{\mathrm{T}} > 24$ GeV. Quality criteria are applied to suppress non-collision backgrounds such as cosmic-ray muons, beam-related backgrounds, and noise in the calorimeters. The primary vertex selection follows that described in Section 4. Candidates for the $H \to WW^{(*)} \to e\nu\mu\nu$ search are pre-selected by requiring exactly two opposite-charge leptons of different flavours, with p_{T} thresholds of 25 GeV for the leading lepton and 15 GeV for the sub-leading lepton. Events are classified into two exclusive lepton channels depending on the flavour of the leading lepton, where $e\mu$ (μe) refers to events with a leading electron (muon). The dilepton invariant mass is required to be greater than 10 GeV.

The lepton selection and isolation have more stringent requirements than those used for the $H \to ZZ^{(*)} \to 4\ell$ analysis (see Section 4), to reduce the larger background from non-prompt leptons in the $\ell\nu\ell\nu$ final state. Electron candidates are selected using a combination of tracking and calorimetric information [85]; the criteria are optimised for background rejection, at the expense of some reduced efficiency. Muon candidates are restricted to those with matching MS and ID tracks [84], and therefore are reconstructed over $|\eta| < 2.5$. The isolation criteria require the scalar sums of the p_{T} of charged particles and of calorimeter topological clusters within $\Delta R = 0.3$ of the lepton direction (excluding the lepton itself) each to be less than 0.12–0.20 times the lepton p_{T}. The exact value differs between the criteria for tracks and calorimeter clusters, for both electrons and muons, and depends on the lepton p_{T}. Jet selections follow those described in Section 5.3, except that the JVF is required to be greater than 0.5.

Since two neutrinos are present in the signal final state, events are required to have large $E_{\mathrm{T}}^{\mathrm{miss}}$. $\mathbf{E}_{\mathrm{T}}^{\mathrm{miss}}$ is the negative vector sum of the transverse momenta of the reconstructed objects, including muons, electrons, photons, jets, and clusters of calorimeter cells not associated with these objects. The quantity $E_{\mathrm{T,rel}}^{\mathrm{miss}}$ used in this analysis is required to be greater than 25 GeV and is defined as: $E_{\mathrm{T,rel}}^{\mathrm{miss}} = E_{\mathrm{T}}^{\mathrm{miss}} \sin\Delta\phi_{\mathrm{min}}$, where $\Delta\phi_{\mathrm{min}}$ is $\min(\Delta\phi, \frac{\pi}{2})$, and $E_{\mathrm{T}}^{\mathrm{miss}}$ is the magnitude of the vector $\mathbf{E}_{\mathrm{T}}^{\mathrm{miss}}$. Here, $\Delta\phi$ is the angle between $\mathbf{E}_{\mathrm{T}}^{\mathrm{miss}}$ and the transverse momentum of the nearest lepton or jet with $p_{\mathrm{T}} > 25$ GeV. Compared to $E_{\mathrm{T}}^{\mathrm{miss}}$, $E_{\mathrm{T,rel}}^{\mathrm{miss}}$ has increased rejection power for events in which the $E_{\mathrm{T}}^{\mathrm{miss}}$ is generated by a neutrino in a jet or the mismeasurement of an object, since in those events the $\mathbf{E}_{\mathrm{T}}^{\mathrm{miss}}$ tends to point in the direction of the object. After the lepton isolation and $E_{\mathrm{T,rel}}^{\mathrm{miss}}$ requirements that define the pre-selected sample, the multijet background is negligible and the Drell–Yan background is much reduced. The Drell–Yan contribution becomes very small after the topological selections, described below, are applied.

The background rate and composition depend significantly on the jet multiplicity, as does the signal topology. Without accompanying jets, the signal originates almost entirely from the ggF process and the background is dominated by WW events. In contrast, when produced in association with two or more jets, the signal contains a much larger contribution from the VBF process compared to the ggF process, and the background is dominated by $t\bar{t}$ production. Therefore, to maximise the sensitivity to SM Higgs events, further selection criteria depending on the jet multiplicity are applied to the pre-selected sample. The data are subdivided into 0-jet, 1-jet and 2-jet search channels according to the number

of jets in the final state, with the 2-jet channel also including higher jet multiplicities.

Owing to spin correlations in the $WW^{(*)}$ system arising from the spin-0 nature of the SM Higgs boson and the V-A structure of the W boson decay vertex, the charged leptons tend to emerge from the primary vertex pointing in the same direction [107]. This kinematic feature is exploited for all jet multiplicities by requiring that $|\Delta\phi_{\ell\ell}| < 1.8$, and the dilepton invariant mass, $m_{\ell\ell}$, be less than 50 GeV for the 0-jet and 1-jet channels. For the 2-jet channel, the $m_{\ell\ell}$ upper bound is increased to 80 GeV.

In the 0-jet channel, the magnitude $p_{\mathrm{T}}^{\ell\ell}$ of the transverse momentum of the dilepton system, $\mathbf{p}_{\mathrm{T}}^{\ell\ell} = \mathbf{p}_{\mathrm{T}}^{\ell 1} + \mathbf{p}_{\mathrm{T}}^{\ell 2}$, is required to be greater than 30 GeV. This improves the rejection of the Drell–Yan background.

In the 1-jet channel, backgrounds from top quark production are suppressed by rejecting events containing a b-tagged jet, as determined using a b-tagging algorithm that uses a neural network and exploits the topology of weak decays of b- and c-hadrons [108]. The total transverse momentum, $p_{\mathrm{T}}^{\mathrm{tot}}$, defined as the magnitude of the vector sum $\mathbf{p}_{\mathrm{T}}^{\mathrm{tot}} = \mathbf{p}_{\mathrm{T}}^{\ell 1} + \mathbf{p}_{\mathrm{T}}^{\ell 2} + \mathbf{p}_{\mathrm{T}}^{j} + \mathbf{E}_{\mathrm{T}}^{\mathrm{miss}}$, is required to be smaller than 30 GeV to suppress top background events that have jets with p_{T} below the threshold defined for jet counting. In order to reject the background from $Z \to \tau\tau$, the $\tau\tau$ invariant mass, $m_{\tau\tau}$, is computed under the assumptions that the reconstructed leptons are τ lepton decay products. In addition the neutrinos produced in these decays are assumed to be the only source of $E_{\mathrm{T}}^{\mathrm{miss}}$ and to be collinear with the leptons [109]. Events with $|m_{\tau\tau} - m_Z| < 25$ GeV are rejected if the collinear approximation yields a physical solution.

The 2-jet selection follows the 1-jet selection described above, with the $p_{\mathrm{T}}^{\mathrm{tot}}$ definition modified to include all selected jets. Motivated by the VBF topology, several additional criteria are applied to the tag jets, defined as the two highest-p_{T} jets in the event. These are required to be separated in rapidity by a distance $|\Delta y_{jj}| > 3.8$ and to have an invariant mass, m_{jj}, larger than 500 GeV. Events with an additional jet with $p_{\mathrm{T}} > 20$ GeV between the tag jets ($y_{j1} < y < y_{j2}$) are rejected.

A transverse mass variable, m_{T} [110], is used to test for the presence of a signal for all jet multiplicities. This variable is defined as:

$$m_{\mathrm{T}} = \sqrt{\left(E_{\mathrm{T}}^{\ell\ell} + E_{\mathrm{T}}^{\mathrm{miss}}\right)^2 - \left|\mathbf{p}_{\mathrm{T}}^{\ell\ell} + \mathbf{E}_{\mathrm{T}}^{\mathrm{miss}}\right|^2},$$

where $E_{\mathrm{T}}^{\ell\ell} = \sqrt{|\mathbf{p}_{\mathrm{T}}^{\ell\ell}|^2 + m_{\ell\ell}^2}$. The statistical analysis of the data uses a fit to the m_{T} distribution in the signal region after the $\Delta\phi_{\ell\ell}$ requirement (see Section 6.4), which results in increased sensitivity compared to the analysis described in Ref. [111].

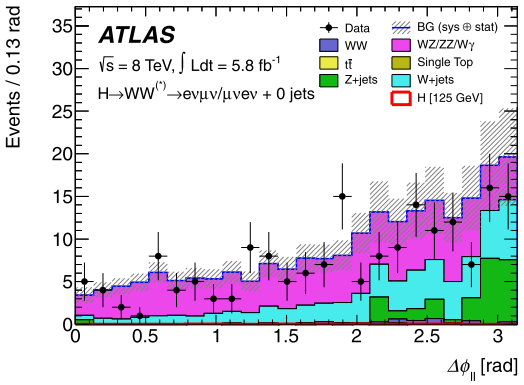
For a SM Higgs boson with $m_H = 125$ GeV, the cross section times branching ratio to the $e\nu\mu\nu$ final state is 88 fb for $\sqrt{s} = 7$ TeV, increasing to 112 fb at $\sqrt{s} = 8$ TeV. The combined acceptance times efficiency of the 8 TeV 0-jet and 1-jet selection relative to the ggF production cross section times branching ratio is about 7.4%. The acceptance times efficiency of the 8 TeV 2-jet selection relative to the VBF production cross section times branching ratio is about 14%. Both of these figures are based on the number of events selected before the final m_{T} criterion is applied (as described in Section 6.4).

6.2. Background normalisation and control samples

The leading backgrounds from SM processes producing two isolated high-p_{T} leptons are WW and top (in this section, "top" background always includes both $t\bar{t}$ and single top, unless otherwise noted). These are estimated using partially data-driven techniques based on normalising the MC predictions to the data in control regions dominated by the relevant background source. The W + jets background is estimated from data for all jet multiplicities. Only the small backgrounds from Drell–Yan and diboson processes other than WW, as well as the WW background for the 2-jet analysis, are estimated using MC simulation.

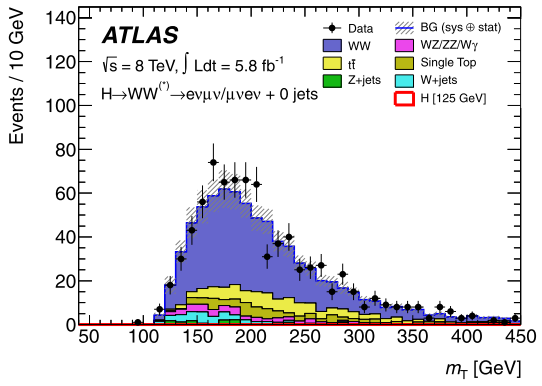
The control and validation regions are defined by selections similar to those used for the signal region but with some criteria reversed or modified to obtain signal-depleted samples enriched in a particular background. The term "validation region" distinguishes these regions from the control regions that are used to directly normalise the backgrounds. Some control regions have significant contributions from backgrounds other than the targeted one, which introduces dependencies among the background estimates. These correlations are fully incorporated in the fit to the m_{T} distribution. In the following sections, each background estimate is described after any others on which it depends. Hence, the largest background (WW) is described last.

6.2.1. W + jets background estimation



The W + jets background contribution is estimated using a control sample of events where one of the two leptons satisfies the identification and isolation criteria described in Section 6.1, and the other lepton fails these criteria but satisfies a loosened selection (denoted "anti-identified"). Otherwise, events in this sample are required to pass all the signal selections. The dominant contribution to this sample comes from W + jets events in which a jet produces an object that is reconstructed as a lepton. This object may be either a true electron or muon from the decay of a heavy quark, or else a product of the fragmentation identified as a lepton candidate.

The contamination in the signal region is obtained by scaling the number of events in the data control sample by a transfer factor. The transfer factor is defined here as the ratio of the number of identified lepton candidates passing all selections to the number of anti-identified leptons. It is calculated as a function of the anti-identified lepton p_{T} using a data sample dominated by QCD jet production (dijet sample) after subtracting the residual contributions from leptons produced by leptonic W and Z decays, as estimated from data. The small remaining lepton contamination, which includes $W\gamma^{(*)}/WZ^{(*)}$ events, is subtracted using MC simulation.



The processes producing the majority of same-charge dilepton events, W + jets, $W\gamma^{(*)}/WZ^{(*)}$ and $Z^{(*)}Z^{(*)}$, are all backgrounds in the opposite-charge signal region. W + jets and $W\gamma^{(*)}$ backgrounds are particularly important in a search optimised for a low Higgs boson mass hypothesis. Therefore, the normalisation and kinematic features of same-charge dilepton events are used to validate the predictions of these backgrounds. The predicted number of same-charge events after the $E_{\mathrm{T,rel}}^{\mathrm{miss}}$ and zero-jet requirements is 216 ± 7 (stat) ± 42 (syst), while 182 events are observed in the data. Satisfactory agreement between data and simulation is observed in various kinematic distributions, including those of $\Delta\phi_{\ell\ell}$ (see Fig. 5(a)) and the transverse mass.

6.2.2. Top control sample

In the 0-jet channel, the top quark background prediction is first normalised using events satisfying the pre-selection criteria described in Section 6.1. This sample is selected without jet multiplicity or b-tagging requirements, and the majority of events contain top quarks. Non-top contributions are subtracted using predictions from simulation, except for W + jets, which is estimated using data. After this normalisation is performed, the fraction of events with zero jets that pass all selections is evaluated. This fraction is small (about 3%), since the top quark decay $t \to Wb$

(a)

(b)

Fig. 5. Validation and control distributions for the $H \to WW^{(*)} \to e\nu\mu\nu$ analysis. (a) $\Delta\phi_{\ell\ell}$ distribution in the same-charge validation region after the $E_{\mathrm{T,rel}}^{\mathrm{miss}}$ and zero-jet requirements. (b) m_{T} distribution in the WW control region for the 0-jet channel. The $e\mu$ and μe final states are combined. The hashed area indicates the total uncertainty on the background prediction. The expected signal for $m_H = 125$ GeV is negligible and therefore not visible.

has a branching ratio of nearly 1. Predictions of this fraction from MC simulation are sensitive to theoretical uncertainties such as the modelling of initial- and final-state radiation, as well as experimental uncertainties, especially that on the jet energy scale. To reduce the impact of these uncertainties, the top quark background determination uses data from a b-tagged control region in which the one-to-two jet ratio is compared to the MC simulation [112]. The resulting correction factor to a purely MC-based background estimate after all selections amounts to 1.11 ± 0.06 (stat).

In the 1-jet and 2-jet analyses, the top quark background predictions are normalised to the data using control samples defined by reversing the b-jet veto and removing the requirements on $\Delta\phi_{\ell\ell}$ and $m_{\ell\ell}$. The $|\Delta y_{\mathrm{jj}}|$ and m_{jj} requirements are included in the definition of the 2-jet control region. The resulting samples are dominated by top quark events. The small contributions from other sources are taken into account using MC simulation and the data-driven W + jets estimate. Good agreement between data and MC simulation is observed for the total numbers of events and the shapes of the m_{T} distributions. The resulting normalisation factors are 1.11 ± 0.05 for the 1-jet control region and 1.01 ± 0.26 for the 2-jet control region. Only the statistical uncertainties are quoted.

6.2.3. WW control sample

The MC predictions of the WW background in the 0-jet and 1-jet analyses, summed over lepton flavours, are normalised using control regions defined with the same selections as for the signal region except that the $\Delta\phi_{\ell\ell}$ requirement is removed and the upper bound on $m_{\ell\ell}$ is replaced with a lower bound: $m_{\ell\ell} > 80$ GeV. The numbers of events and the shape of the m_{T} distribution in the control regions are in good agreement between data and MC, as shown in Fig. 5(b). WW production contributes about 70% of the events in the 0-jet control region and about 45% in the 1-jet region. Contaminations from sources other than WW are derived as for the signal region, including the data-driven W + jets and top estimates. The resulting normalisation factors with their associated statistical uncertainties are 1.06 ± 0.06 for the 0-jet control region and 0.99 ± 0.15 for the 1-jet control region.

6.3. Systematic uncertainties

The systematic uncertainties that have the largest impact on the sensitivity of the search are the theoretical uncertainties associated with the signal. These are described in Section 9. The main experimental uncertainties are associated with the JES, the jet energy resolution (JER), pile-up, $E_{\mathrm{T}}^{\mathrm{miss}}$, the b-tagging efficiency, the W + jets transfer factor, and the integrated luminosity. The largest uncertainties on the backgrounds include WW normalisation and modelling, top normalisation, and $W\gamma^{(*)}$ normalisation. The 2-jet systematic uncertainties are dominated by the statistical uncertainties in the data and the MC simulation, and are therefore not discussed further.

Variations of the jet energy scale within the systematic uncertainties can cause events to migrate between the jet bins. The uncertainty on the JES varies from ±2% to ±9% as a function of jet p_{T} and η for jets with $p_{\mathrm{T}} > 25$ GeV and $|\eta| < 4.5$ [101]. The largest impact of this uncertainty on the total signal (background) yield amounts to 7% (4%) in the 0-jet (1-jet) bin. The uncertainty on the JER is estimated from *in situ* measurements and it impacts mostly the 1-jet channel, where its effect on the total signal and background yields is 4% and 2%, respectively. An additional contribution to the JES uncertainty arises from pile-up, and is estimated to vary between ±1% and ±5% for multiple pp collisions in the same bunch crossing and up to ±10% for neighbouring bunch crossings. This uncertainty affects mainly the 1-jet channel, where its impact on the signal and background yields is 4% and 2%, respectively. JES and lepton momentum scale uncertainties are propagated to the $E_{\mathrm{T}}^{\mathrm{miss}}$ measurement. Additional contributions to the $E_{\mathrm{T}}^{\mathrm{miss}}$ uncertainties arise from jets with $p_{\mathrm{T}} < 20$ GeV and from low-energy calorimeter deposits not associated with reconstructed physics objects [113]. The impact of the $E_{\mathrm{T}}^{\mathrm{miss}}$ uncertainty on the total signal and background yields is ∼3%. The efficiency of the b-tagging algorithm is calibrated using samples containing muons reconstructed in the vicinity of jets [114]. The uncertainty on the b-jet tagging efficiency varies between ±5% and ±18% as a function of the jet p_{T}, and its impact on the total background yield is 10% for the 1-jet channel. The uncertainty in the W + jets transfer factor is dominated by differences in jet properties between dijet and W + jets events as observed in MC simulations. The total uncertainty on this background is approximately ±40%, resulting in an uncertainty on the total background yield of 5%. The uncertainty on the integrated luminosity is ±3.6%.

A fit to the distribution of m_{T} is performed in order to obtain the signal yield for each mass hypothesis (see Section 6.4). Most theoretical and experimental uncertainties do not produce statistically significant changes to the m_{T} distribution. The uncertainties that do produce significant changes of the distribution of m_{T} have no appreciable effect on the final results, with the exception of those associated with the WW background. In this case, an uncertainty is included to take into account differences in the distribution of m_{T} and normalisation observed between the MCFM [115], MC@NLO + HERWIG and POWHEG + PYTHIA

Table 5
The expected numbers of signal ($m_H = 125$ GeV) and background events after all selections, including a cut on the transverse mass of $0.75\,m_H < m_T < m_H$ for $m_H = 125$ GeV. The observed numbers of events in data are also displayed. The $e\mu$ and μe channels are combined. The uncertainties shown are the combination of the statistical and all systematic uncertainties, taking into account the constraints from control samples. For the 2-jet analysis, backgrounds with fewer than 0.01 expected events are marked with '–'.

	0-jet	1-jet	2-jet
Signal	20 ± 4	5 ± 2	0.34 ± 0.07
WW	101 ± 13	12 ± 5	0.10 ± 0.14
$WZ^{(*)}/ZZ/W\gamma^{(*)}$	12 ± 3	1.9 ± 1.1	0.10 ± 0.10
$t\bar{t}$	8 ± 2	6 ± 2	0.15 ± 0.10
$tW/tb/tqb$	3.4 ± 1.5	3.7 ± 1.6	–
$Z/\gamma^* +$ jets	1.9 ± 1.3	0.10 ± 0.10	–
$W +$ jets	15 ± 7	2 ± 1	–
Total background	142 ± 16	26 ± 6	0.35 ± 0.18
Observed	185	38	0

generators. The potential impact of interference between resonant (Higgs-mediated) and non-resonant $gg \to WW$ diagrams [116] for $m_T > m_H$ was investigated and found to be negligible. The effect of the WW normalisation, modelling, and shape systematics on the total background yield is 9% for the 0-jet channel and 19% for the 1-jet channel. The uncertainty on the shape of the total background is dominated by the uncertainties on the normalisations of the individual backgrounds. The main uncertainties on the top background in the 0-jet analysis include those associated with interference effects between $t\bar{t}$ and single top, initial state an final state radiation, b-tagging, and JER. The impact on the total background yield in the 0-jet bin is 3%. For the 1-jet analysis, the impact of the top background on the total yield is 14%. Theoretical uncertainties on the $W\gamma$ background normalisation are evaluated for each jet bin using the procedure described in Ref. [117]. They are $\pm 11\%$ for the 0-jet bin and $\pm 50\%$ for the 1-jet bin. For $W\gamma^*$ with $m_{\ell\ell} < 7$ GeV, a k-factor of 1.3 ± 0.3 is applied to the MadGraph LO prediction based on the comparison with the MCFM NLO calculation. The k-factor for $W\gamma^*/WZ^{(*)}$ with $m_{\ell\ell} > 7$ GeV is 1.5 ± 0.5. These uncertainties affect mostly the 1-jet channel, where their impact on the total background yield is approximately 4%.

6.4. Results

Table 5 shows the numbers of events expected from a SM Higgs boson with $m_H = 125$ GeV and from the backgrounds, as well as the numbers of candidates observed in data, after application of all selection criteria plus an additional cut on m_T of $0.75\,m_H < m_T < m_H$. The uncertainties shown in Table 5 include the systematic uncertainties discussed in Section 6.3, constrained by the use of the control regions discussed in Section 6.2. An excess of events relative to the background expectation is observed in the data.

Fig. 6 shows the distribution of the transverse mass after all selection criteria in the 0-jet and 1-jet channels combined, and for both lepton channels together.

The statistical analysis of the data employs a binned likelihood function constructed as the product of Poisson probability terms for the $e\mu$ channel and the μe channel. The mass-dependent cuts on m_T described above are not used. Instead, the 0-jet (1-jet) signal regions are subdivided into five (three) m_T bins. For the 2-jet signal region, only the results integrated over m_T are used, due to the small number of events in the final sample. The statistical interpretation of the observed excess of events is presented in Section 9.

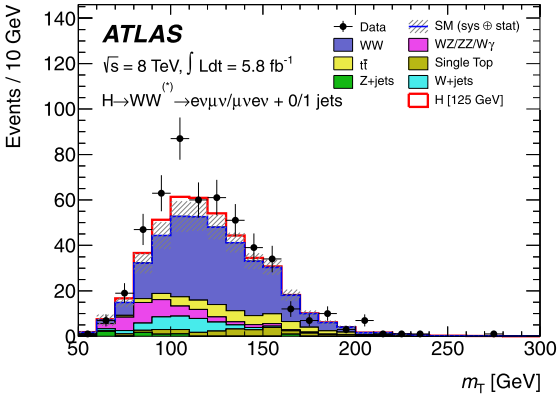


Fig. 6. Distribution of the transverse mass, m_T, in the 0-jet and 1-jet analyses with both $e\mu$ and μe channels combined, for events satisfying all selection criteria. The expected signal for $m_H = 125$ GeV is shown stacked on top of the background prediction. The $W +$ jets background is estimated from data, and WW and top background MC predictions are normalised to the data using control regions. The hashed area indicates the total uncertainty on the background prediction.

7. Statistical procedure

The statistical procedure used to interpret the data is described in Refs. [17,118–121]. The parameter of interest is the global signal strength factor μ, which acts as a scale factor on the total number of events predicted by the Standard Model for the Higgs boson signal. This factor is defined such that $\mu = 0$ corresponds to the background-only hypothesis and $\mu = 1$ corresponds to the SM Higgs boson signal in addition to the background. Hypothesised values of μ are tested with a statistic $\lambda(\mu)$ based on the profile likelihood ratio [122]. This test statistic extracts the information on the signal strength from a full likelihood fit to the data. The likelihood function includes all the parameters that describe the systematic uncertainties and their correlations.

Exclusion limits are based on the CL_s prescription [123]; a value of μ is regarded as excluded at 95% CL when CL_s is less than 5%. A SM Higgs boson with mass m_H is considered excluded at 95% confidence level (CL) when $\mu = 1$ is excluded at that mass. The significance of an excess in the data is first quantified with the local p_0, the probability that the background can produce a fluctuation greater than or equal to the excess observed in data. The equivalent formulation in terms of number of standard deviations, Z_l, is referred to as the local significance. The global probability for the most significant excess to be observed anywhere in a given search region is estimated with the method described in Ref. [124]. The ratio of the global to the local probabilities, the trials factor used to correct for the "look elsewhere" effect, increases with the range of Higgs boson mass hypotheses considered, the mass resolutions of the channels involved in the combination, and the significance of the excess.

The statistical tests are performed in steps of values of the hypothesised Higgs boson mass m_H. The asymptotic approximation [122] upon which the results are based has been validated with the method described in Ref. [17].

The combination of individual search sub-channels for a specific Higgs boson decay, and the full combination of all search channels, are based on the global signal strength factor μ and on the identification of the nuisance parameters that correspond to the correlated sources of systematic uncertainty described in Section 8.

8. Correlated systematic uncertainties

The individual search channels that enter the combination are summarised in Table 6.

Table 6
Summary of the individual channels entering the combination. The transition points between separately optimised m_H regions are indicated where applicable. In channels sensitive to associated production of the Higgs boson, V indicates a W or Z boson. The symbols $\otimes$ and $\oplus$ represent direct products and sums over sets of selection requirements, respectively.

The main uncorrelated systematic uncertainties are described in Sections 4–6 for the $H \to ZZ^{(*)} \to 4\ell$, $H \to \gamma\gamma$ and $H \to WW^{(*)} \to \ell\nu\ell\nu$ channels and in Ref. [17] for the other channels. They include the background normalisations or background model parameters from control regions or sidebands, the Monte Carlo simulation statistical uncertainties and the theoretical uncertainties affecting the background processes.

The main sources of correlated systematic uncertainties are the following.

1. *Integrated luminosity*: The uncertainty on the integrated luminosity is considered as fully correlated among channels and amounts to ±3.9% for the 7 TeV data [132,133], except for the $H \to ZZ^{(*)} \to 4\ell$ and $H \to \gamma\gamma$ channels which were re-analysed; the uncertainty is ±1.8% [92] for these channels. The uncertainty is ±3.6% for the 8 TeV data.

2. *Electron and photon trigger identification*: The uncertainties in the trigger and identification efficiencies are treated as fully correlated for electrons and photons.

3. *Electron and photon energy scales*: The electron and photon energy scales in the $H \to ZZ^{(*)} \to 4\ell$ and $H \to \gamma\gamma$ channels are described by five parameters, which provide a detailed account of the sources of systematic uncertainty. They are related to the calibration method, the presampler energy scale in the barrel and end-cap calorimeters, and the material description upstream of the calorimeters.

4. *Muon reconstruction*: The uncertainties affecting muons are separated into those related to the ID and MS, in order to obtain a better description of the correlated effects among channels using different muon identification criteria and different ranges of muon p_{T}.

5. *Jet energy scale and missing transverse energy*: The jet energy scale and jet energy resolution are affected by uncertainties which depend on the p_{T}, η, and flavour of the jet. A simplified scheme is used in which independent JES and JER nuisance parameters are associated with final states with significantly different kinematic selections and sensitivity to scattering processes with different kinematic distributions or flavour composition. This scheme includes a specific treatment for b-jets. The sensitivity of the results to various assumptions about the correlation between these sources of uncertainty has been found to be negligible. An uncorrelated component of the uncertainty on $E_{\mathrm{T}}^{\mathrm{miss}}$ is included, in addition to the JES uncertainty, which is due to low energy jet activity not associated with reconstructed physics objects.

6. *Theory uncertainties*: Correlated theoretical uncertainties affect mostly the signal predictions. The QCD scale uncertainties for $m_H = 125$ GeV amount to $^{+7\%}_{-8\%}$ for the ggF process, ±1% for the VBF and WH/ZH processes, and $^{+4\%}_{-9\%}$ for the $t\bar{t}H$ process [52,53]; the small dependence of these uncertainties on m_H is taken into account. The uncertainties on the predicted branching ratios amount to ±5%. The uncertainties related to the parton distribution functions amount to ±8% for the predominantly gluon-initiated ggF and $t\bar{t}H$ processes, and ±4% for the predominantly quark-initiated VBF and WH/ZH processes [78,134–136]. The theoretical uncertainty associated with the exclusive Higgs boson production process with additional jets in the $H \to \gamma\gamma$, $H \to WW^{(*)} \to \ell\nu\ell\nu$ and $H \to \tau^+\tau^-$ channels is estimated using the prescription of Refs. [53,117,118], with the noticeable difference that an explicit calculation of the gluon-fusion process at NLO using MCFM [137] in the 2-jet category reduces the uncertainty on this non-negligible contribution to 25%. An additional theoretical uncertainty on the signal normalisation of ±150% × $(m_H/\mathrm{TeV})^3$ (e.g. ±4% for $m_H =$ 300 GeV) accounts for effects related to off-shell Higgs boson production and interference with other SM processes [53].

Sources of systematic uncertainty that affect both the 7 TeV and the 8 TeV data are taken as fully correlated. The uncertainties on background estimates based on control samples in the data are considered uncorrelated between the 7 TeV and 8 TeV data.

9. Results

The addition of the 8 TeV data for the $H \to ZZ^{(*)} \to 4\ell$, $H \to \gamma\gamma$ and $H \to WW^{(*)} \to e\nu\mu\nu$ channels, as well as the improvements to the analyses of the 7 TeV data in the first two of these channels, bring a significant gain in sensitivity in the low-mass region with respect to the previous combined search [17].

9.1. Excluded mass regions

The combined 95% CL exclusion limits on the production of the SM Higgs boson, expressed in terms of the signal strength parameter μ, are shown in Fig. 7(a) as a function of m_H. The expected 95% CL exclusion region covers the m_H range from 110 GeV to

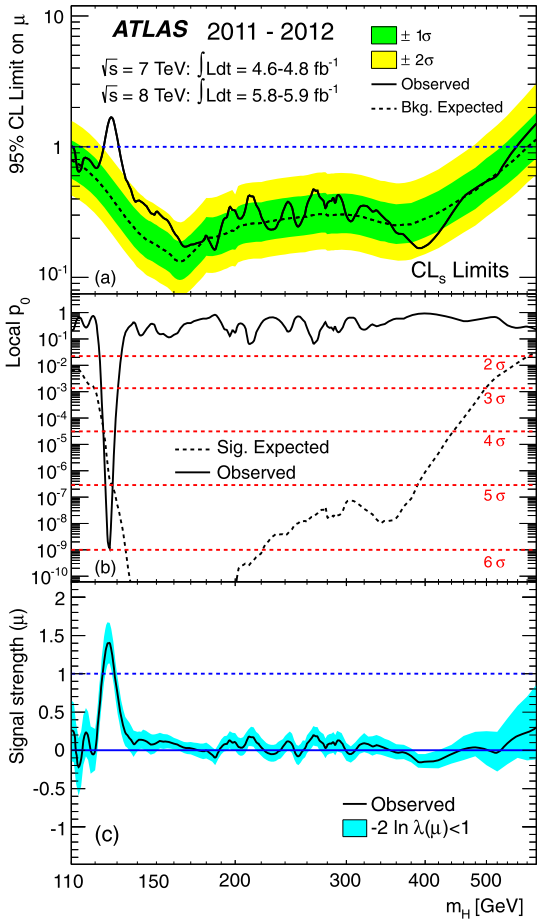

Fig. 7. Combined search results: (a) The observed (solid) 95% CL limits on the signal strength as a function of m_H and the expectation (dashed) under the background-only hypothesis. The dark and light shaded bands show the $\pm 1\sigma$ and $\pm 2\sigma$ uncertainties on the background-only expectation. (b) The observed (solid) local p_0 as a function of m_H and the expectation (dashed) for a SM Higgs boson signal hypothesis ($\mu = 1$) at the given mass. (c) The best-fit signal strength $\hat{\mu}$ as a function of m_H. The band indicates the approximate 68% CL interval around the fitted value.

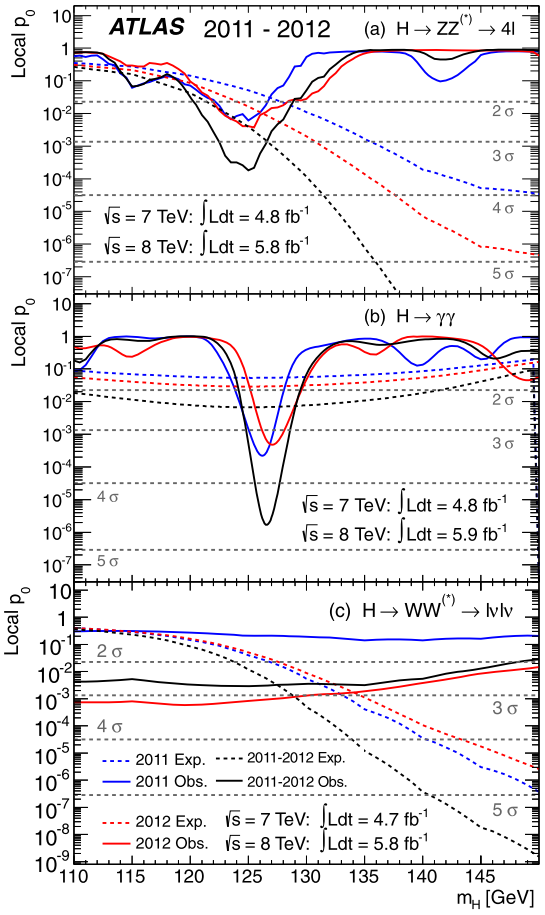

Fig. 8. The observed local p_0 as a function of the hypothesised Higgs boson mass for the (a) $H \to ZZ^{(*)} \to 4\ell$, (b) $H \to \gamma\gamma$ and (c) $H \to WW^{(*)} \to \ell\nu\ell\nu$ channels. The dashed curves show the expected local p_0 under the hypothesis of a SM Higgs boson signal at that mass. Results are shown separately for the $\sqrt{s} = 7$ TeV data (dark, blue in the web version), the $\sqrt{s} = 8$ TeV data (light, red in the web version), and their combination (black).

582 GeV. The observed 95% CL exclusion regions are 111–122 GeV and 131–559 GeV. Three mass regions are excluded at 99% CL, 113–114, 117–121 and 132–527 GeV, while the expected exclusion range at 99% CL is 113–532 GeV.

9.2. Observation of an excess of events

An excess of events is observed near $m_H = 126$ GeV in the $H \to ZZ^{(*)} \to 4\ell$ and $H \to \gamma\gamma$ channels, both of which provide fully reconstructed candidates with high resolution in invariant mass, as shown in Figs. 8(a) and 8(b). These excesses are confirmed by the highly sensitive but low-resolution $H \to WW^{(*)} \to \ell\nu\ell\nu$ channel, as shown in Fig. 8(c).

The observed local p_0 values from the combination of channels, using the asymptotic approximation, are shown as a function of m_H in Fig. 7(b) for the full mass range and in Fig. 9 for the low mass range.

The largest local significance for the combination of the 7 and 8 TeV data is found for a SM Higgs boson mass hypothesis of $m_H = 126.5$ GeV, where it reaches 6.0σ, with an expected value in the presence of a SM Higgs boson signal at that mass of 4.9σ (see also Table 7). For the 2012 data alone, the maximum local significance for the $H \to ZZ^{(*)} \to 4\ell$, $H \to \gamma\gamma$ and $H \to WW^{(*)} \to$

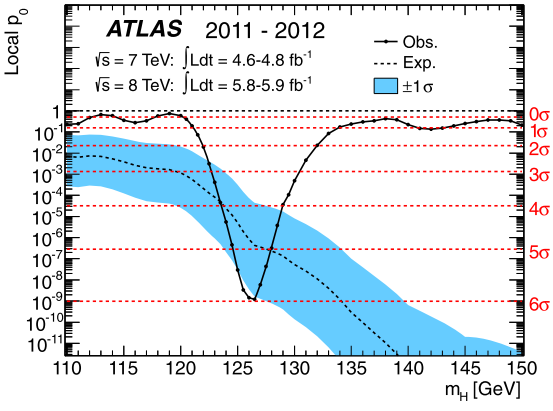

Fig. 9. The observed (solid) local p_0 as a function of m_H in the low mass range. The dashed curve shows the expected local p_0 under the hypothesis of a SM Higgs boson signal at that mass with its $\pm 1\sigma$ band. The horizontal dashed lines indicate the p-values corresponding to significances of 1 to 6 σ.

$e\nu\mu\nu$ channels combined is $4.9\,\sigma$, and occurs at $m_H = 126.5$ GeV (3.8σ expected).

The significance of the excess is mildly sensitive to uncertainties in the energy resolutions and energy scale systematic uncertainties for photons and electrons; the effect of the muon energy scale systematic uncertainties is negligible. The presence of these

Table 7
Characterisation of the excess in the $H \to ZZ^{(*)} \to 4\ell$, $H \to \gamma\gamma$ and $H \to WW^{(*)} \to \ell\nu\ell\nu$ channels and the combination of all channels listed in Table 6. The mass value $m_{\max}$ for which the local significance is maximum, the maximum observed local significance Z_l and the expected local significance $E(Z_l)$ in the presence of a SM Higgs boson signal at $m_{\max}$ are given. The best fit value of the signal strength parameter $\hat{\mu}$ at $m_H = 126$ GeV is shown with the total uncertainty. The expected and observed mass ranges excluded at 95% CL (99% CL, indicated by a *) are also given, for the combined $\sqrt{s} = 7$ TeV and $\sqrt{s} = 8$ TeV data.

Search channel	Dataset	$m_{\max}$ [GeV]	Z_l [σ]	$E(Z_l)$ [σ]	$\hat{\mu}(m_H = 126$ GeV)	Expected exclusion [GeV]	Observed exclusion [GeV]
$H \to ZZ^{(*)} \to 4\ell$	7 TeV	125.0	2.5	1.6	1.4 ± 1.1		
	8 TeV	125.5	2.6	2.1	1.1 ± 0.8		
	7 & 8 TeV	125.0	3.6	2.7	1.2 ± 0.6	124–164, 176–500	131–162, 170–460
$H \to \gamma\gamma$	7 TeV	126.0	3.4	1.6	2.2 ± 0.7		
	8 TeV	127.0	3.2	1.9	1.5 ± 0.6		
	7 & 8 TeV	126.5	4.5	2.5	1.8 ± 0.5	110–140	112–123, 132–143
$H \to WW^{(*)} \to \ell\nu\ell\nu$	7 TeV	135.0	1.1	3.4	0.5 ± 0.6		
	8 TeV	120.0	3.3	1.0	1.9 ± 0.7		
	7 & 8 TeV	125.0	2.8	2.3	1.3 ± 0.5	124–233	137–261
Combined	7 TeV	126.5	3.6	3.2	1.2 ± 0.4		
	8 TeV	126.5	4.9	3.8	1.5 ± 0.4		
	7 & 8 TeV	126.5	6.0	4.9	1.4 ± 0.3	110–582 113–532 (*)	111–122, 131–559 113–114, 117–121, 132–527 (*)

uncertainties, evaluated as described in Ref. [138], reduces the local significance to 5.9σ.

The global significance of a local 5.9σ excess anywhere in the mass range 110–600 GeV is estimated to be approximately 5.1σ, increasing to $5.3\,\sigma$ in the range 110–150 GeV, which is approximately the mass range not excluded at the 99% CL by the LHC combined SM Higgs boson search [139] and the indirect constraints from the global fit to precision electroweak measurements [12].

9.3. Characterising the excess

The mass of the observed new particle is estimated using the profile likelihood ratio $\lambda(m_H)$ for $H \to ZZ^{(*)} \to 4\ell$ and $H \to \gamma\gamma$, the two channels with the highest mass resolution. The signal strength is allowed to vary independently in the two channels, although the result is essentially unchanged when restricted to the SM hypothesis $\mu = 1$. The leading sources of systematic uncertainty come from the electron and photon energy scales and resolutions. The resulting estimate for the mass of the observed particle is 126.0 ± 0.4 (stat) ± 0.4 (sys) GeV.

The best-fit signal strength $\hat{\mu}$ is shown in Fig. 7(c) as a function of m_H. The observed excess corresponds to $\hat{\mu} = 1.4 \pm 0.3$ for $m_H = 126$ GeV, which is consistent with the SM Higgs boson hypothesis $\mu = 1$. A summary of the individual and combined best-fit values of the strength parameter for a SM Higgs boson mass hypothesis of 126 GeV is shown in Fig. 10, while more information about the three main channels is provided in Table 7.

In order to test which values of the strength and mass of a signal hypothesis are simultaneously consistent with the data, the profile likelihood ratio $\lambda(\mu, m_H)$ is used. In the presence of a strong signal, it will produce closed contours around the best-fit point $(\hat{\mu}, \hat{m}_H)$, while in the absence of a signal the contours will be upper limits on μ for all values of m_H.

Asymptotically, the test statistic $-2\ln\lambda(\mu, m_H)$ is distributed as a χ^2 distribution with two degrees of freedom. The resulting 68% and 95% CL contours for the $H \to \gamma\gamma$ and $H \to WW^{(*)} \to \ell\nu\ell\nu$ channels are shown in Fig. 11, where the asymptotic approximations have been validated with ensembles of pseudo-experiments. Similar contours for the $H \to ZZ^{(*)} \to 4\ell$ channel are also shown in Fig. 11, although they are only approximate confidence intervals due to the smaller number of candidates in this channel. These contours in the (μ, m_H) plane take into account uncertainties in the energy scale and resolution.

The probability for a single Higgs boson-like particle to produce resonant mass peaks in the $H \to ZZ^{(*)} \to 4\ell$ and $H \to \gamma\gamma$ channels separated by more than the observed mass difference, allowing the signal strengths to vary independently, is about 8%.

The contributions from the different production modes in the $H \to \gamma\gamma$ channel have been studied in order to assess any tension between the data and the ratios of the production cross

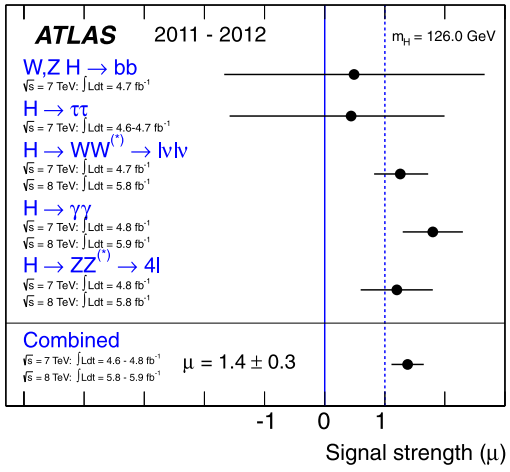

Fig. 10. Measurements of the signal strength parameter μ for $m_H = 126$ GeV for the individual channels and their combination.

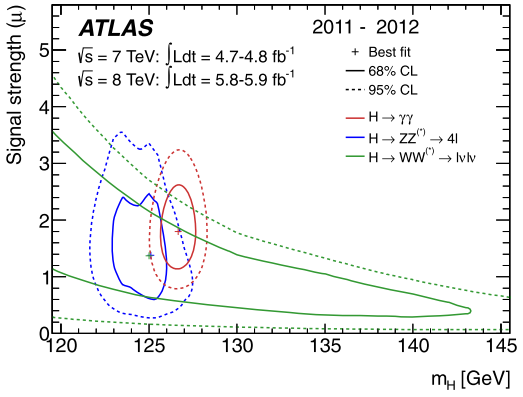

Fig. 11. Confidence intervals in the (μ, m_H) plane for the $H \to ZZ^{(*)} \to 4\ell$, $H \to \gamma\gamma$, and $H \to WW^{(*)} \to \ell\nu\ell\nu$ channels, including all systematic uncertainties. The markers indicate the maximum likelihood estimates $(\hat{\mu}, \hat{m}_H)$ in the corresponding channels (the maximum likelihood estimates for $H \to ZZ^{(*)} \to 4\ell$ and $H \to WW^{(*)} \to \ell\nu\ell\nu$ coincide).

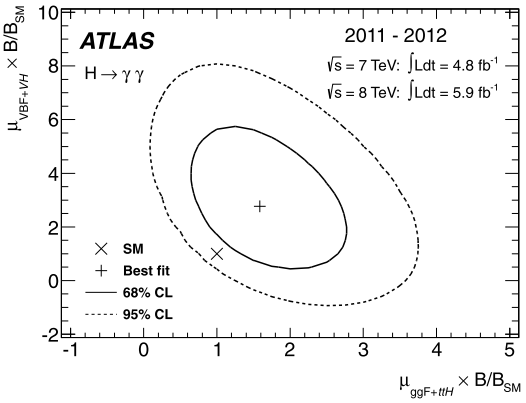

Fig. 12. Likelihood contours for the $H \to \gamma\gamma$ channel in the $(\mu_{\mathrm{ggF}+t\bar{t}H}, \mu_{\mathrm{VBF}+VH})$ plane including the branching ratio factor B/B_{SM}. The quantity $\mu_{\mathrm{ggF}+t\bar{t}H}$ ($\mu_{\mathrm{VBF}+VH}$) is a common scale factor for the ggF and $t\bar{t}H$ (VBF and VH) production cross sections. The best fit to the data (+) and 68% (full) and 95% (dashed) CL contours are also indicated, as well as the SM expectation (×).

sections predicted in the Standard Model. A new signal strength parameter μ_i is introduced for each production mode, defined by $\mu_i = \sigma_i/\sigma_{i,\mathrm{SM}}$. In order to determine the values of (μ_i, μ_j) that are simultaneously consistent with the data, the profile likelihood ratio $\lambda(\mu_i, \mu_j)$ is used with the measured mass treated as a nuisance parameter.

Since there are four Higgs boson production modes at the LHC, two-dimensional contours require either some μ_i to be fixed, or multiple μ_i to be related in some way. Here, μ_{ggF} and $\mu_{t\bar{t}H}$ have been grouped together as they scale with the $t\bar{t}H$ coupling in the SM, and are denoted by the common parameter $\mu_{\mathrm{ggF}+t\bar{t}H}$. Similarly, μ_{VBF} and μ_{VH} have been grouped together as they scale with the WWH/ZZH coupling in the SM, and are denoted by the common parameter $\mu_{\mathrm{VBF}+VH}$. Since the distribution of signal events among the 10 categories of the $H \to \gamma\gamma$ search is sensitive to these factors, constraints in the plane of $\mu_{\mathrm{ggF}+t\bar{t}H} \times B/B_{\mathrm{SM}}$ and $\mu_{\mathrm{VBF}+VH} \times B/B_{\mathrm{SM}}$, where B is the branching ratio for $H \to \gamma\gamma$, can be obtained (Fig. 12). Theoretical uncertainties are included so that the consistency with the SM expectation can be quantified. The data are compatible with the SM expectation at the $1.5\,\sigma$ level.

10. Conclusion

Searches for the Standard Model Higgs boson have been performed in the $H \to ZZ^{(*)} \to 4\ell$, $H \to \gamma\gamma$ and $H \to WW^{(*)} \to e\nu\mu\nu$ channels with the ATLAS experiment at the LHC using 5.8–5.9 fb^{-1} of pp collision data recorded during April to June 2012 at a centre-of-mass energy of 8 TeV. These results are combined with earlier results [17], which are based on an integrated luminosity of 4.6–4.8 fb^{-1} recorded in 2011 at a centre-of-mass energy of 7 TeV, except for the $H \to ZZ^{(*)} \to 4\ell$ and $H \to \gamma\gamma$ channels, which have been updated with the improved analyses presented here.

The Standard Model Higgs boson is excluded at 95% CL in the mass range 111–559 GeV, except for the narrow region 122–131 GeV. In this region, an excess of events with significance 5.9σ, corresponding to $p_0 = 1.7 \times 10^{-9}$, is observed. The excess is driven by the two channels with the highest mass resolution, $H \to ZZ^{(*)} \to 4\ell$ and $H \to \gamma\gamma$, and the equally sensitive but low-resolution $H \to WW^{(*)} \to \ell\nu\ell\nu$ channel. Taking into account the entire mass range of the search, 110–600 GeV, the global significance of the excess is 5.1σ, which corresponds to $p_0 = 1.7 \times 10^{-7}$.

These results provide conclusive evidence for the discovery of a new particle with mass 126.0 ± 0.4 (stat) ± 0.4 (sys) GeV. The signal strength parameter μ has the value 1.4 ± 0.3 at the fitted mass, which is consistent with the SM Higgs boson hypothesis $\mu = 1$. The decays to pairs of vector bosons whose net electric charge is zero identify the new particle as a neutral boson. The observation in the diphoton channel disfavours the spin-1 hypothesis [140, 141]. Although these results are compatible with the hypothesis that the new particle is the Standard Model Higgs boson, more data are needed to assess its nature in detail.

Acknowledgements

The results reported in this Letter would not have been possible without the outstanding performance of the LHC. We warmly thank CERN and the entire LHC exploitation team, including the operation, technical and infrastructure groups, and all the people who have contributed to the conception, design and construction of this superb accelerator. We thank also the support staff at our institutions without whose excellent contributions ATLAS could not have been successfully constructed or operated so efficiently.

We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWF, Austria; ANAS, Azerbaijan; SSTC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR and VSC CR, Czech Republic; DNRF, DNSRC and Lundbeck Foundation, Denmark; EPLANET and ERC, European Union; IN2P3-CNRS, CEA-DSM/IRFU, France; GNAS, Georgia; BMBF, DFG, HGF, MPG and AvH Foundation, Germany; GSRT, Greece; ISF, MINERVA, GIF, DIP and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; RCN, Norway; MNiSW, Poland; GRICES and FCT, Portugal; MERYS (MECTS), Romania; MES of Russia and ROSATOM, Russian Federation; JINR; MSTD, Serbia; MSSR, Slovakia; ARRS and MVZT, Slovenia; DST/NRF, South Africa; MICINN, Spain; SRC and Wallenberg Foundation, Sweden; SER, SNSF and Cantons of Bern and Geneva, Switzerland; NSC, Taiwan; TAEK, Turkey; STFC, the Royal Society and Leverhulme Trust, United Kingdom; DOE and NSF, United States of America.

The crucial computing support from all WLCG partners is acknowledged gratefully, in particular from CERN and the ATLAS Tier-1 facilities at TRIUMF (Canada), NDGF (Denmark, Norway, Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy), NL-T1 (Netherlands), PIC (Spain), ASGC (Taiwan), RAL (UK) and BNL (USA) and in the Tier-2 facilities worldwide.

Parity

ABSTRACT

Studies of the spin and parity quantum numbers of the Higgs boson are presented, based on proton–proton collision data collected by the ATLAS experiment at the LHC. The Standard Model spin–parity $J^P = 0^+$ hypothesis is compared with alternative hypotheses using the Higgs boson decays $H \to \gamma\gamma$, $H \to ZZ^* \to 4\ell$ and $H \to WW^* \to \ell\nu\ell\nu$, as well as the combination of these channels. The analysed dataset corresponds to an integrated luminosity of 20.7 fb^{-1} collected at a centre-of-mass energy of $\sqrt{s} = 8$ TeV. For the $H \to ZZ^* \to 4\ell$ decay mode the dataset corresponding to an integrated luminosity of 4.6 fb^{-1} collected at $\sqrt{s} = 7$ TeV is included. The data are compatible with the Standard Model $J^P = 0^+$ quantum numbers for the Higgs boson, whereas all alternative hypotheses studied in this Letter, namely some specific $J^P = 0^-, 1^+, 1^-, 2^+$ models, are excluded at confidence levels above 97.8%. This exclusion holds independently of the assumptions on the coupling strengths to the Standard Model particles and in the case of the $J^P = 2^+$ model, of the relative fractions of gluon-fusion and quark–antiquark production of the spin-2 particle. The data thus provide evidence for the spin-0 nature of the Higgs boson, with positive parity being strongly preferred.

1. Introduction

In 2012 the ATLAS and CMS Collaborations published the discovery of a new resonance [1,2] in the search for the Standard Model (SM) Higgs boson H [3–8]. The present experimental challenge is to compare its properties with the SM predictions for the Higgs boson. In the SM, the Higgs boson is a spin-0 and CP-even particle ($J^P = 0^+$). The Landau–Yang theorem forbids the direct decay of an on-shell spin-1 particle into a pair of photons [9,10]. The spin-1 hypothesis is therefore strongly disfavoured by the observation of the $H \to \gamma\gamma$ decay. The CMS Collaboration has published a spin–parity study [11] based on the $H \to ZZ^*$ channel where the SM scalar hypothesis is favoured over the pseudoscalar hypothesis at a confidence level (CL) above 95%.

In this Letter the $J^P = 0^+$ hypothesis of the SM is compared to several alternative hypotheses with $J^P = 0^-, 1^+, 1^-, 2^+$. The measurements are based on the kinematic properties of the three final states $H \to \gamma\gamma$, $H \to ZZ^* \to 4\ell$ and $H \to WW^* \to \ell\nu\ell\nu$, where ℓ denotes an electron or a muon. For the alternative hypotheses leading order (LO) calculations are use to predict the kinematic properties. To improve the sensitivity to different spin–parity hypotheses, several final states are combined. To test the 0^- spin–parity hypothesis, only the $H \to ZZ^*$ decay mode is used, while for the 1^+ and 1^- hypotheses the $H \to ZZ^*$ and $H \to WW^*$ channels are combined. For the 2^+ study, all three decay modes are combined. It is assumed that only one single resonance contributes to the various decay modes considered in each combination.

The full dataset collected at $\sqrt{s} = 8$ TeV, corresponding to an integrated luminosity of 20.7 fb^{-1}, is analysed for all three channels. For the $H \to ZZ^*$ decay mode, a dataset corresponding to an integrated luminosity of 4.6 fb^{-1} collected at $\sqrt{s} = 7$ TeV is also included.

While for the SM Higgs boson the Lagrangian structure and its couplings are fully determined, the alternative hypotheses can be described by a wide variety of models, characterised by different structures and effective couplings. Several approaches to describe such signatures can be found in the literature [12–17]. In this Letter, the alternative model descriptions are based on Ref. [12], as described in Section 2. In Ref. [12], the production and decay of a generic boson with various J^P quantum numbers are described by defining the most general amplitudes consistent with Lorentz invariance, angular-momentum conservation, Bose symmetry and the unbroken symmetry of the $SU(3) \times SU(2) \times U(1)$ gauge group.

This Letter is published together with another one [18] reporting the ATLAS measurements of the couplings of the Higgs boson derived from the observed signal production and decay rates. In that Letter the measurement of the mass of the Higgs boson, based on the invariant mass spectra in the $H \to \gamma\gamma$ and $H \to ZZ^* \to 4\ell$ final states, is also reported. On the basis of that measurement, the observed final states are assumed to be produced in the decay of a single particle with a mass of 125.5 GeV [18]. The definitions of the physics objects used in the analyses, the simulation of the different backgrounds and the main systematic uncertainties are described in Ref. [18]. This Letter reports only aspects specific to

the spin and parity analyses. The ATLAS Collaboration has made public a collection of conference notes that document in detail the analyses reported in this Letter [19–21].

The outline of this Letter is as follows: Section 2 describes the spin–parity models considered in all three channels and the signal Monte Carlo (MC) simulation samples used in the analyses. The statistical procedure used to test the different spin–parity hypotheses is presented in Section 3. Sections 4, 5 and 6 provide brief descriptions of the spin–parity analyses in the $H \to \gamma\gamma$, $H \to ZZ^*$ and $H \to WW^*$ decay modes. Finally, in Section 7, the combined results in terms of compatibility with several spin–parity hypotheses are presented.

2. Signal modelling and Monte Carlo samples

The interactions of spin-0, 1 and 2 resonances with Standard Model particles are described in Ref. [12] by Eqs. 2, 4 and 5 for bosons and by Eqs. 8, 9 and 10 for fermions. The choices of the boson and fermion couplings for the specific spin and parity models used in this analysis are presented in Table 1 of Ref. [12].

The implications of these choices are briefly summarised in the following. The quark–antiquark ($q\bar{q}$) annihilation production process is not considered in the case of $J^P = 0^-$, since its contribution is negligible compared to gluon fusion (gg). For the $J^P = 1^+$ and 1^- cases, only the quark–antiquark annihilation production process is considered, since the Landau–Yang theorem also forbids the production of a spin-1 particle through the fusion of two on-shell gluons. Given the large number of possible spin-2 models, a specific one, denoted by 2^+_m from Table 1 of Ref. [12], was chosen. This choice corresponds to a graviton-inspired tensor with minimal couplings to SM particles. In the 2^+_m boson rest frame, its polarisation states projected onto the parton collision axis can take only the values of ± 2 for the gluon-fusion process and ± 1 for the quark–antiquark annihilation process. For the spin-2 model, only these two production mechanisms are considered. The production of the 2^+_m boson is dominated by the gluon-fusion process with a contribution, at leading order in quantum chromodynamics (QCD), of about 4% from quark–antiquark annihilation [16,17]. This proportion could be significantly modified by higher-order QCD corrections. Since the experimental observables are sensitive to different polarisations, the studies were performed for several production admixtures by normalising the samples produced with the two different production processes in order to obtain samples of events corresponding to fractions, $f_{q\bar{q}}$, of $q\bar{q}$ annihilation ranging from 0% to 100% in steps of 25%. In the following, this model is referred to as $J^P = 2^+$.

The production and decay of the SM Higgs boson via the dominant gluon-fusion process is simulated using either the JHU Monte Carlo generator [12] for the $H \to ZZ^*$ process or the POWHEG [22] Monte Carlo generator for the $H \to \gamma\gamma$ and $H \to WW^*$ processes, each interfaced to PYTHIA8 [23] for parton showering and hadronisation. The production and decay of the $J^P = 0^-, 1^+, 1^-$ and 2^+ resonances are modelled using the JHU generator, interfaced to PYTHIA8 for parton showering and hadronisation.

The transverse momentum (p_{T}) distributions for the gluon-fusion signals produced with the JHU generator, which is leading-order in QCD, are weighted to reproduce the POWHEG+PYTHIA8 spectrum. The latter was tuned to reproduce the re-summed calculation of the HqT program [24]. It was checked that the distributions of all kinematic variables used for the spin–parity determination are compatible between the two MC generators after the re-weighting is applied. For the production process via $q\bar{q}$ annihilation, no re-weighting is applied.

The much smaller contributions from other production processes, namely vector-boson fusion and associated production, are also considered. For the $H \to \gamma\gamma$ channel, they are included in the analysis and simulated as described in Ref. [18]. For the $H \to ZZ^*$ channel, they are ignored because they do not affect the kinematic distributions used in the spin analysis. For the $H \to WW^*$ analysis, where only the $e\mu$ final state with no additional jet activity is considered, as described in Section 6, they contribute at a negligible level and are therefore ignored. It should be noted that for the resonance under study, dominant contributions via vector-boson fusion and associated production can be excluded based on the measurements presented in Ref. [18].

For the background processes, the simulated samples are the same as those used in the coupling analyses. A detailed list of the MC generators and samples is given in Ref. [18].

All MC samples are passed through a full simulation of the ATLAS detector [25] based on GEANT4 [26]. The simulation incorporates a model of the event pile-up conditions in the data, including the effects of multiple proton–proton collisions in in-time and nearby bunch crossings.

3. Statistical method

The analyses described in this Letter rely on discriminant observables chosen to be sensitive to the spin and parity of the signal while preserving the discrimination against the various backgrounds, as described in Sections 4, 5 and 6 for the three final states. A likelihood function $\mathcal{L}(J^P, \mu, \boldsymbol{\theta})$ that depends on the spin–parity assumption of the signal is constructed as a product of conditional probabilities over binned distributions of the discriminant observables in each channel:

$$\mathcal{L}\big(J^P, \mu, \boldsymbol{\theta}\big) = \prod_{j}^{N_{\text{chann.}}} \prod_{i}^{N_{\text{bins}}} P\big(N_{i,j} \,\big|\, \mu_j \cdot S_{i,j}^{(J^P)}(\boldsymbol{\theta}) + B_{i,j}(\boldsymbol{\theta})\big) \times \mathcal{A}_j(\boldsymbol{\theta}), \tag{1}$$

where μ_j represents the nuisance parameter associated with the signal rate in each channel j. The symbol $\boldsymbol{\theta}$ represents all other nuisance parameters. The likelihood function is therefore a product of Poisson distributions P corresponding to the observation of $N_{i,j}$ events in each bin i of the discriminant observable(s),[1] given the expectations for the signal, $S_{i,j}^{(J^P)}(\boldsymbol{\theta})$, and for the background, $B_{i,j}(\boldsymbol{\theta})$. Some of the nuisance parameters are constrained by auxiliary measurements through the functions $\mathcal{A}_j(\boldsymbol{\theta})$.

While for the SM Higgs boson the couplings to the SM particles are predicted, they are not known *a priori* for the alternative hypotheses, defined as J^P_{alt}. In order to be insensitive to such assumptions, the numbers of signal events in each channel and for each tested hypothesis are treated as an independent nuisance parameters in the likelihood.

The test statistic q used to distinguish between the two signal spin–parity hypotheses is based on a ratio of likelihoods:

$$q = \log \frac{\mathcal{L}(J^P = 0^+, \hat{\hat{\mu}}_{0^+}, \hat{\hat{\theta}}_{0^+})}{\mathcal{L}(J^P_{\text{alt}}, \hat{\hat{\mu}}_{J^P_{\text{alt}}}, \hat{\hat{\theta}}_{J^P_{\text{alt}}})}, \tag{2}$$

where $\mathcal{L}(J^P, \hat{\hat{\mu}}_{J^P}, \hat{\hat{\theta}}_{J^P})$ is the maximum likelihood estimator, evaluated under either the 0^+ or the J^P_{alt} spin–parity hypothesis. The $\hat{\hat{\mu}}_{J^P}$, $\hat{\hat{\theta}}_{J^P}$ represent the values of the signal strength and nuisance

[1] As explained in the following sections, the sensitivity for spin–parity separation is improved by a simultaneous fit to two discriminants in the $H \to \gamma\gamma$ and $H \to WW^*$ decay modes, while in the $H \to ZZ^*$ channel only one discriminant is used.

parameters fitted to the data under each J^P hypothesis. The distributions of the test statistic for each of the two hypotheses are obtained using ensemble tests (Monte Carlo pseudo-experiments). The generation of the pseudo-experiments uses the numbers of signal and background events in each channel obtained from maximum likelihood fits to data. In the fits of each pseudo-experiment, these and all other nuisance parameters are profiled, i.e. fitted to the value that maximises the likelihood for each value of the parameter of interest. When generating the distributions of the test statistic for a given spin–parity hypothesis, the signal strength μ is fixed to the value obtained in the fit to the data under the same spin–parity assumption. The distributions of q are used to determine the corresponding p_0-values $p_0(0^+)$ and $p_0(J^P_{\rm alt})$. For a tested hypothesis $J^P_{\rm alt}$, the observed (expected) p_0-values are obtained by integrating the corresponding test-statistic distributions above the observed value of q (above the median of the $J^P = 0^+ q$ distribution). When the measured data are in agreement with the tested hypothesis, the observed value of q is expected to be close to the median, corresponding to a p_0-value around 50%. Very small values of the integral of the $J^P_{\rm alt}$ distribution, corresponding to large values of q, are interpreted as the data being in disagreement with the tested hypothesis in favour of the SM hypothesis. An example of such distributions is shown in Section 7 for the 0^+ and 0^- hypotheses.

The exclusion of the alternative $J^P_{\rm alt}$ hypothesis in favour of the Standard Model 0^+ hypothesis is evaluated in terms of the corresponding $\mathrm{CL_s}(J^P_{\rm alt})$, defined as:

$$\mathrm{CL_s}\left(J^P_{\rm alt}\right) = \frac{p_0(J^P_{\rm alt})}{1 - p_0(0^+)}. \tag{3}$$

4. $H \to \gamma\gamma$ analysis

The $H \to \gamma\gamma$ decay mode is sensitive to the spin of the Higgs boson through the measurement of the polar angular distribution of the photons in the resonance rest frame. For this channel, the SM spin hypothesis is compared only to the $J^P = 2^+$ hypothesis. Spin information can be extracted from the distribution of the absolute value of the cosine of the polar angle θ^* of the photons with respect to the z-axis of the Collins–Soper frame [27]:

$$\left|\cos\theta^*\right| = \frac{|\sinh(\Delta\eta^{\gamma\gamma})|}{\sqrt{1 + (p_{\rm T}^{\gamma\gamma}/m_{\gamma\gamma})^2}} \frac{2p_{\rm T}^{\gamma 1} p_{\rm T}^{\gamma 2}}{m_{\gamma\gamma}^2}, \tag{4}$$

where $m_{\gamma\gamma}$ and $p_{\rm T}^{\gamma\gamma}$ are the invariant mass and the transverse momentum of the photon pair, $\Delta\eta^{\gamma\gamma}$ is the separation in pseudo-rapidity of the two photons, and $p_{\rm T}^{\gamma 1}$, $p_{\rm T}^{\gamma 2}$ are the transverse momenta of the photons.

This channel has a large background, dominated by non-resonant diphoton production, whose distribution in $|\cos\theta^*|$ is intermediate between those expected for $J^P = 0^+$ and $J^P = 2^+$ states produced in gluon fusion. Two observables, $|\cos\theta^*|$ and $m_{\gamma\gamma}$, are used in the fit to data: $m_{\gamma\gamma}$ provides better separation power between the signal and the background, and $|\cos\theta^*|$ is sensitive to the spin.

The selected events contain two isolated photon candidates, as described in Ref. [18], but with the important difference that the kinematic requirements on the transverse momenta of the photons are proportional to $m_{\gamma\gamma}$. This choice reduces the correlation between $m_{\gamma\gamma}$ and $|\cos\theta^*|$ for the background to a negligible level. The selection requirements are set to $p_{\rm T}^{\gamma 1} > 0.35 m_{\gamma\gamma}$ and $p_{\rm T}^{\gamma 2} > 0.25 m_{\gamma\gamma}$. The fitted mass range is chosen to be 105 GeV $< m_{\gamma\gamma} <$ 160 GeV.

The intrinsic width of the resonance is assumed to be negligible compared to the detector resolution for both spin hypotheses. For this reason, the same probability density function is used to model the reconstructed mass spectra of both signal hypotheses, independent of the value of $|\cos\theta^*|$. The chosen function is the sum of a Crystal Ball [28] component, accounting for about 95% of the signal events, and a wider Gaussian component to model outlying events, as described in Ref. [18].

The $|\cos\theta^*|$ distributions of the signal, for either spin state, are obtained from simulated samples. The signal yields per $|\cos\theta^*|$ bin for a spin-0 particle are corrected for interference effects with the non-resonant diphoton background $gg \to \gamma\gamma$ [29]. The size of the correction is non-negligible only at high values of $|\cos\theta^*|$ and its value is taken as the systematic uncertainty on this effect. No interference between the spin-2 particle and the diphoton continuum background is assumed, since there are no theoretical models that describe it.

For the spin-2 state, the full size of the correction to the generated $p_{\rm T}$ spectrum of the diphoton system, described in Section 2, is taken as a systematic uncertainty.

The background distributions are derived directly from the observed data, using the two mass sidebands 105 GeV $< m_{\gamma\gamma} <$ 122 GeV and 130 GeV $< m_{\gamma\gamma} <$ 160 GeV, where the signal contribution is negligible. The background shape as a function of $m_{\gamma\gamma}$ is modelled by a fifth-order polynomial with coefficients fitted to the data. The background shape as a function of $|\cos\theta^*|$ is taken from the two mass sidebands, since the remaining correlation between the two observables is small. The statistical uncertainties affecting the determination of the $|\cos\theta^*|$ distribution from the sidebands are propagated into the signal region (SR), 122 GeV $< m_{\gamma\gamma} <$ 130 GeV, independently for each $|\cos\theta^*|$ bin. Detailed studies of the data in the sidebands, reported in [19], show that possible residual correlations between $m_{\gamma\gamma}$ and $|\cos\theta^*|$ are not significant compared to the statistical uncertainties. A study of the background, based on a large sample of simulated events using the SHERPA generator [30], indicates the presence of a residual correlation at the level of 0.6% for $|\cos\theta^*| < 0.8$ and 2% elsewhere. These values are treated as the systematic uncertainties due to possible correlations between $m_{\gamma\gamma}$ and $|\cos\theta^*|$.

The fit to data is carried out simultaneously in the signal region and the two sideband regions. In the signal region, the likelihood is a function of the two discriminant variables $m_{\gamma\gamma}$ and $|\cos\theta^*|$, while in the sidebands only $m_{\gamma\gamma}$ is considered.

The number of data events selected in the signal region is 14977, compared with a background estimate of about 14 300 events and an expected SM Higgs boson signal of about 370 events. Fig. 1 displays the data distribution for $|\cos\theta^*|$ in the signal region, overlaid with the signal and background components, fitted under the $J^P = 0^+$ hypothesis.

The likelihood function is fitted to data for both the spin-0 and spin-2 hypotheses with the signal and background normalisations treated as nuisance parameters. Fig. 2 shows the $|\cos\theta^*|$ distributions in the signal region, obtained after subtracting the estimated background, and compared with the expected distributions for spin-0 and spin-2 signals. The data points differ slightly between the two spin hypotheses, because the fitted background depends on the profiling of the nuisance parameters associated with the bin-by-bin systematic uncertainties.

5. $H \to ZZ^* \to 4\ell$ analysis

The $H \to ZZ^* \to 4\ell$ channel, where $\ell = e$ or μ, benefits from the presence of several observables dependent on spin and parity thanks to the full reconstruction of the four-lepton final state.

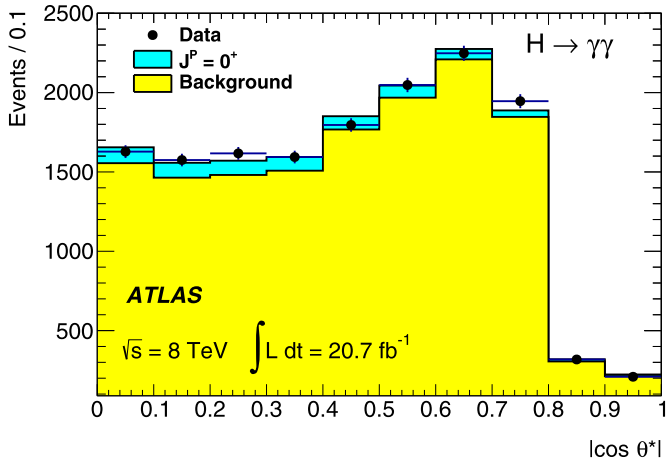

Fig. 1. Distribution of $|\cos\theta^*|$ for events in the signal region defined by 122 GeV $< m_{\gamma\gamma} <$ 130 GeV. The data (dots) are overlaid with the projection of the signal (blue/dark band) and background (yellow/light histogram) components obtained from the inclusive fit of the data under the spin-0 hypothesis.

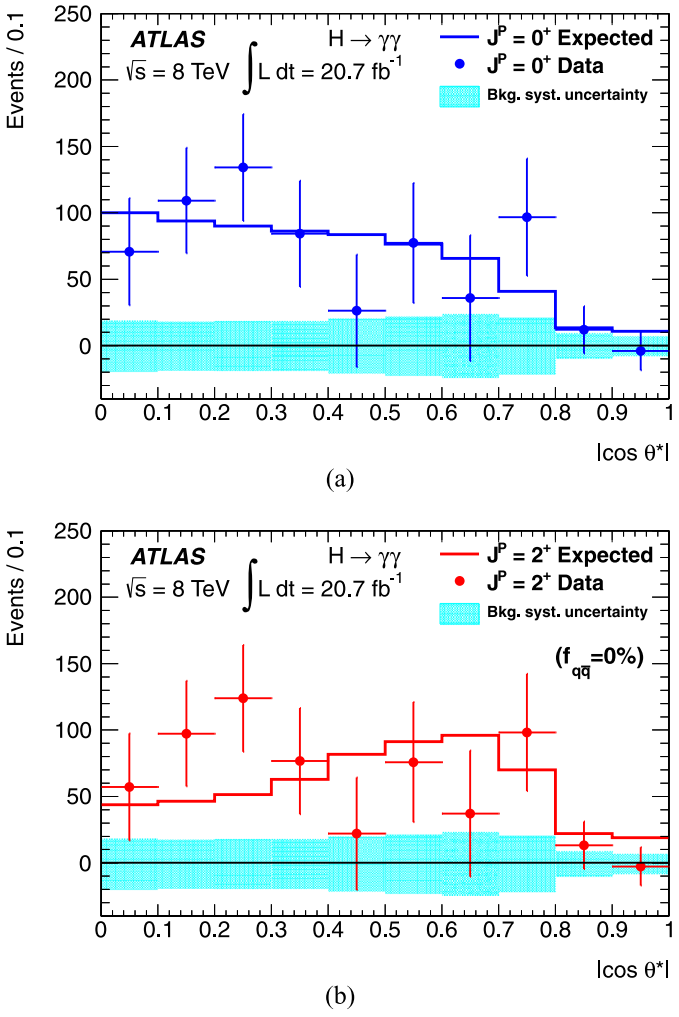

Fig. 2. Distributions of background-subtracted data in the signal region as a function of $|\cos\theta^*|$. The expected distributions for (a) spin-0 and (b) spin-2 signals produced by gluon fusion, normalised to the fitted number of signal events, are overlaid as solid lines. The cyan/grey bands around the horizontal lines at zero show the systematic uncertainties on the background modelling before the fits, which include the statistical uncertainties on the data sidebands.

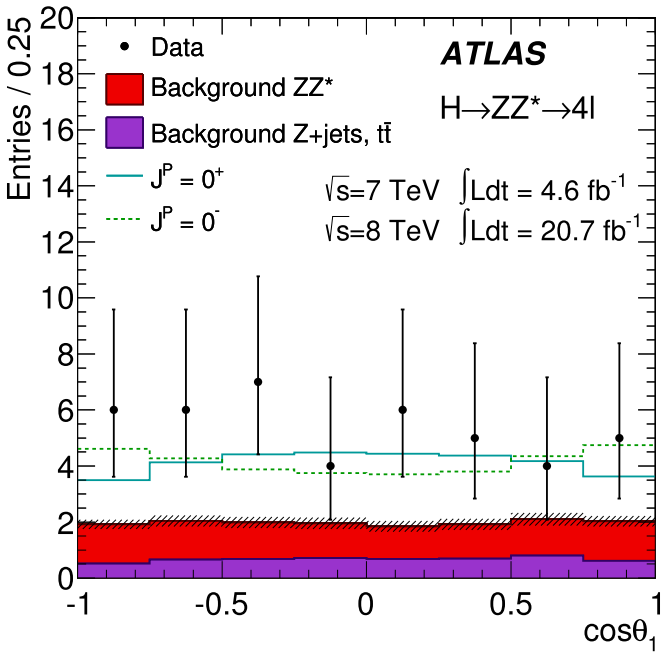
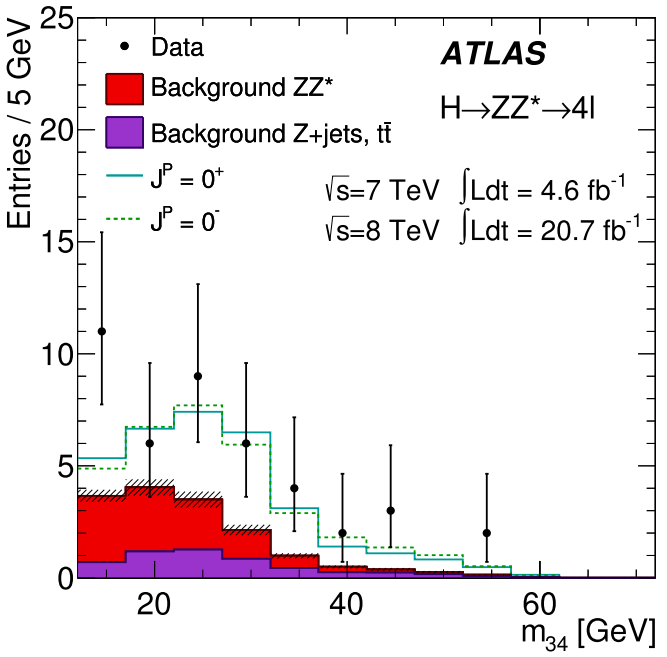
The kinematic observables are the reconstructed masses of the two Z boson candidates and the five production and decay angles described in the following. The Z boson candidates are denoted hereafter as Z_1 and Z_2, where the index 1 refers to the lepton pair with the invariant mass closer to the central value of 91.1876 GeV of the Z boson mass [31]. Their respective masses are defined as m_{12} and m_{34}. The full definition of the production and decay angles as well as the description of their variation for different spin and parity values can be found in Ref. [20]. Here only a brief summary is given: θ_1 (θ_2) is the angle between the negatively charged final-state lepton in the Z_1 (Z_2) rest frame and the direction of flight of the Z_1 (Z_2) boson in the four-lepton rest frame. Φ is the angle between the decay planes defined by the two lepton pairs coming from the Z decays in the four-lepton rest frame. Φ_1 is the angle between the decay plane of the leading lepton pair and a plane defined by the momentum of the Z_1 in the four-lepton rest frame and the direction of the beam axis. θ^* is the production angle of the Z_1 defined in the four-lepton rest frame.



The lepton identification criteria and the analysis requirements follow the inclusive event selection described in Ref. [18]. To increase the sensitivity to the Higgs boson signal the final states are classified depending on the flavours of the lepton pairs. The events used to reconstruct the variables sensitive to the spin and parity of the resonance are selected in the region of reconstructed four-lepton invariant mass 115 GeV $< m_{4\ell} <$ 130 GeV, defined as the signal mass window.

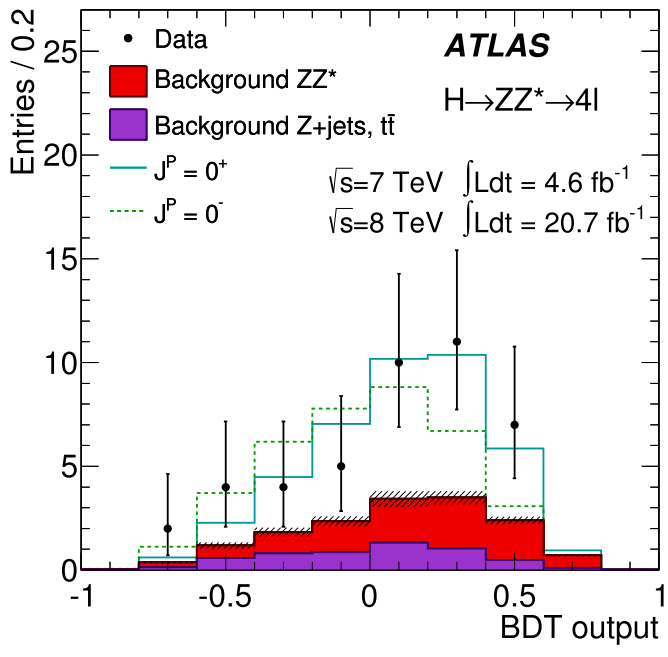
After the analysis requirements 43 candidate events are selected in data in the signal mass window, compared with an expected background of about 16 events, dominated by the continuum ZZ^* process, and about 18 signal events for a SM Higgs boson with a mass of 125.5 GeV. The irreducible ZZ^* background is estimated from Monte Carlo simulation, normalised to NLO calculations, while the reducible $t\bar{t}$, $Zb\bar{b}$ and $Z+$jets backgrounds are estimated from corresponding control regions in data, as described in Ref. [18]. Fig. 3 shows the $\cos(\theta_1)$ and m_{34} distributions for events passing the full selection in the signal mass window.



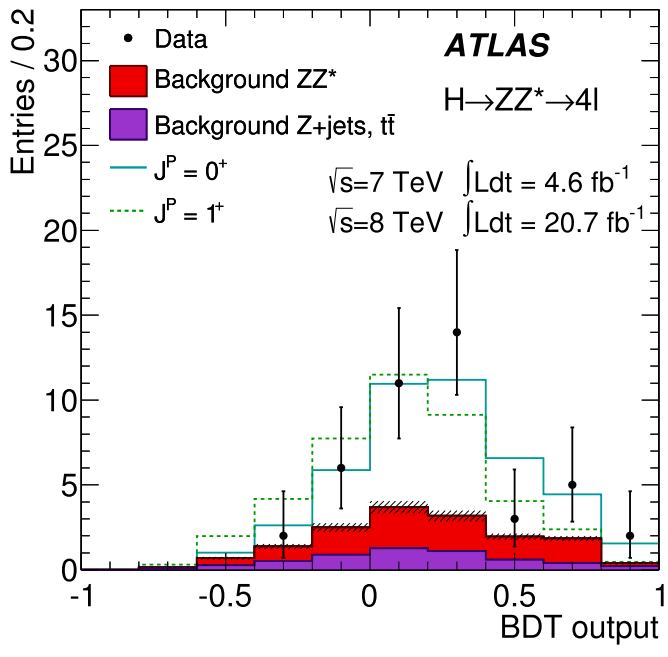
In order to distinguish between pairs of spin and parity states, the reconstructed observables described above, namely the five angles and the two invariant masses, are combined using a multivariate discriminant based on a boosted decision tree (BDT) [32]. The BDT is trained on simulated signal events after full reconstruction and event selection. Dedicated discriminants are defined for the separation between the Standard Model $J^P = 0^+$ hypothesis and each of the considered alternative models, $J^P = 0^-, 1^+, 1^-, 2^+$. In the case of the spin-2 hypothesis, the studies are performed as a function of the $q\bar{q}$ production fraction, $f_{q\bar{q}}$.

The response of the BDT classifiers is evaluated separately for each pair of signal hypotheses, including the expected backgrounds from other SM processes. In addition, to improve the overall sensitivity, the BDT responses are evaluated separately for two $m_{4\ell}$ regions with high and low signal-over-background ratio (S/B): low (115–121 GeV and 127–130 GeV) and high (121–127 GeV).

Systematic uncertainties on the shapes of the BDT output and on the normalisations of the high and low S/B mass regions are considered. These are due to uncertainties on the lepton identification efficiencies, the lepton energy scale and its resolution. A systematic uncertainty of ±10% on the normalisation of the high and low S/B mass regions is applied to take into account the experimental uncertainty on the mass of the Higgs boson. The systematic uncertainties on the overall background yields and on the integrated luminosity are treated as described in Ref. [18]. Fig. 4 shows the BDT discriminant distributions for the $J^P = 0^+$ versus $J^P = 0^-$



(a)



(b)

Fig. 3. Distributions of (a) $\cos(\theta_1)$ and (b) m_{34} for events passing the full selection in the signal mass window 115 GeV $< m_{4\ell} <$ 130 GeV for the combined $\sqrt{s} = 7$ TeV and $\sqrt{s} = 8$ TeV datasets. The expected contributions from the $J^P = 0^+$ (solid line) and $J^P = 0^-$ (dashed line) signal hypotheses, and the irreducible ZZ^* background are shown, together with the measured contribution from reducible non-ZZ^* backgrounds. The hatched areas represent the uncertainty on the background yields from statistical, experimental, and theoretical sources.

(a)

(b)

Fig. 4. Distributions of the BDT output for data (points with error bars) and expectations based on MC simulation (histograms). The distribution of each discriminant is shown for a pair of spin and parity hypotheses for the signal: $J^P = 0^+$ (solid line) and $J^P = 0^-$ (dashed line) in (a), $J^P = 0^+$ (solid line) and $J^P = 1^+$ (dashed line) in (b). The signal contribution for each of the two hypotheses is scaled using the profiled value of the signal strength. The hatched areas represent the uncertainty on the background yields from statistical, experimental, and theoretical sources.

and the $J^P = 0^+$ versus $J^P = 1^+$ hypotheses. The distribution of the BDT output is used as a discriminant observable in the likelihood defined in Section 3.

In addition to the BDT analysis an alternative approach based on the differential decay rate with respect to the angles and the masses, m_{12} and m_{34}, was also studied. These variables, corrected for detector acceptance and analysis selection effects, are used to construct a matrix-element-based discriminant. This alternative analysis yields results compatible with those obtained with the BDT, as described in detail in Ref. [20].

6. $H \to WW^* \to \ell\nu\ell\nu$ analysis

The analysis of the spin and parity in the $H \to WW^* \to \ell\nu\ell\nu$ channel is restricted to events containing two leptons of different flavour (one electron and one muon) and no observed jets with $p_{\mathrm{T}} > 25$ GeV within $|\eta| < 2.5$ or with $p_{\mathrm{T}} > 30$ GeV within $2.5 < |\eta| < 4.5$. The leading lepton is required to have $p_{\mathrm{T}} > 25$ GeV and the sub-leading lepton $p_{\mathrm{T}} > 15$ GeV. At least one of the two selected leptons is required to match a lepton that triggered the recording of the event.

The major sources of background after the dilepton selection are: $Z/\gamma^* +$ jets, diboson (WW, WZ/γ^*, ZZ/γ^*), top-quark ($t\bar{t}$ and single top) production, and W bosons produced in association with hadronic jets where a jet is misidentified as a lepton. The WW background also includes the small fraction of dibosons produced via gluon fusion. The requirement of two high-p_{T} isolated leptons significantly reduces the background contributions from fake leptons. Multi-jet and Z/γ^* events are suppressed by requiring relative missing transverse momentum[2] $E_{\mathrm{T,rel}}^{\mathrm{miss}}$ above 20 GeV.

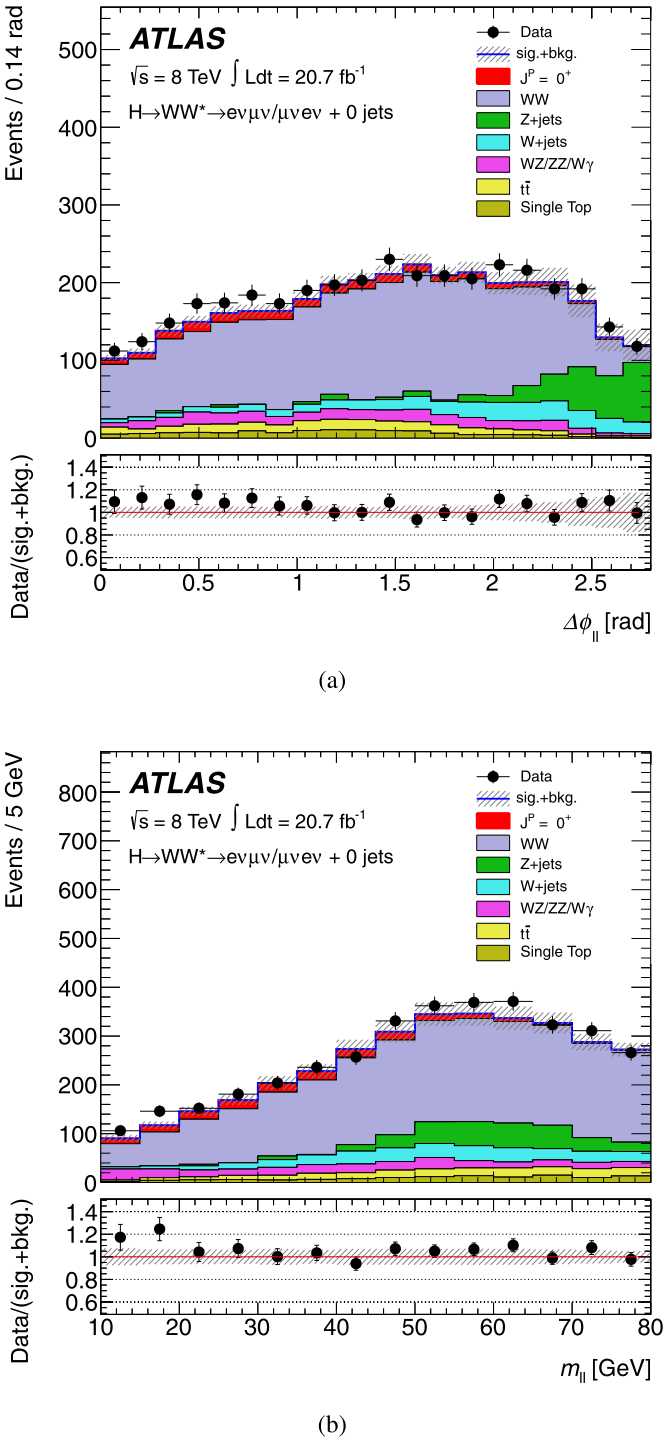
Further lepton topological requirements are applied to optimise the sensitivity for the separation of different spin hypotheses, namely requirements on the dilepton invariant mass $m_{\ell\ell} < 80$ GeV, the transverse momentum of the dilepton system $p_{\mathrm{T}}^{\ell\ell} > 20$ GeV and the azimuthal angular difference between leptons $\Delta\phi_{\ell\ell} < 2.8$ rad. This selection, which significantly reduces the WW continuum and Z/γ^* backgrounds, defines the signal region (SR).

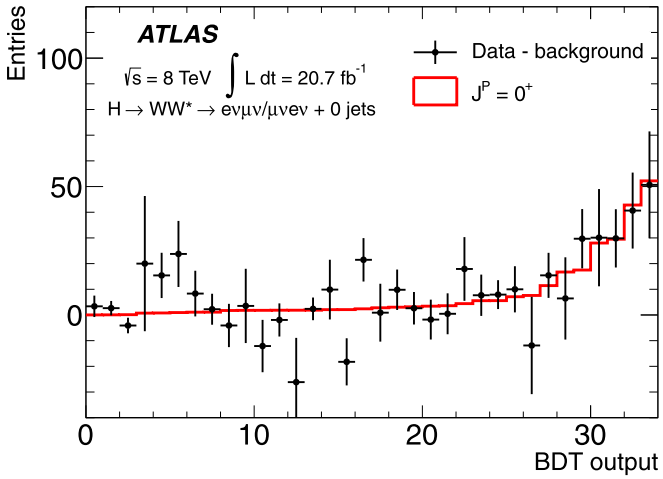
The contributions from WW, top-quark and $Z +$ jets processes predicted by MC simulation are normalised to observed rates in control regions (CRs) dominated by the relevant background sources. The $Z +$ jets CR is defined by inverting the $\Delta\phi_{\ell\ell}$ requirement and removing the $p_{\mathrm{T}}^{\ell\ell}$ one. The $Z +$ jets normalisation factor of 0.92 with a total uncertainty of $\pm 8\%$ is derived from this control region and applied to the simulated sample. The WW CR is defined using the same selection as for the SR except that the $\Delta\phi_{\ell\ell}$ requirement is removed and the $m_{\ell\ell}$ requirement is inverted. The resulting WW normalisation factor applied to the MC prediction is 1.08 with a total uncertainty of $\pm 10\%$. The top-quark background is estimated as described in Ref. [18]. The ratio of the resulting prediction to the one from simulation alone is 1.07 with a total uncertainty of $\pm 14\%$. The $W +$ jets background is estimated entirely from data. The shapes and normalisations of non-WW diboson backgrounds are estimated using simulation and cross-checked in a validation region [18]. The correlations introduced among the different background sources by the presence of other processes in the control regions are fully included in the statistical procedure to test the compatibility between data and the two spin hypotheses, as described in Section 3.

After the selection, the data SR contains 3615 events, with 170 events expected from the SM Higgs boson signal and about 3300 events from background processes, after their normalisation to data in the CRs.

Spin correlations between the decay products affect the $H \to WW^* \to \ell\nu\ell\nu$ event topologies by shaping the angular distributions of the leptons as well as the distributions of the lepton momenta and missing transverse energy. Due to the presence of two neutrinos in the event, a direct calculation of the various decay angles is not possible. Two of the most sensitive variables for measuring the spin of the Higgs boson are the dilepton invariant mass, $m_{\ell\ell}$, and the azimuthal separation of the two leptons, $\Delta\phi_{\ell\ell}$. Fig. 5 shows the distributions of both variables in the signal region. The distributions observed in the data agree well with the MC prediction for the expected SM $J^P = 0^+$ signal. The dilepton transverse momentum, $p_{\mathrm{T}}^{\ell\ell}$, also has sensitivity to different spin hypotheses.

A BDT algorithm is used to distinguish between the spin hypotheses. In addition to the three variables mentioned above, the transverse mass of the dilepton and missing momentum system,





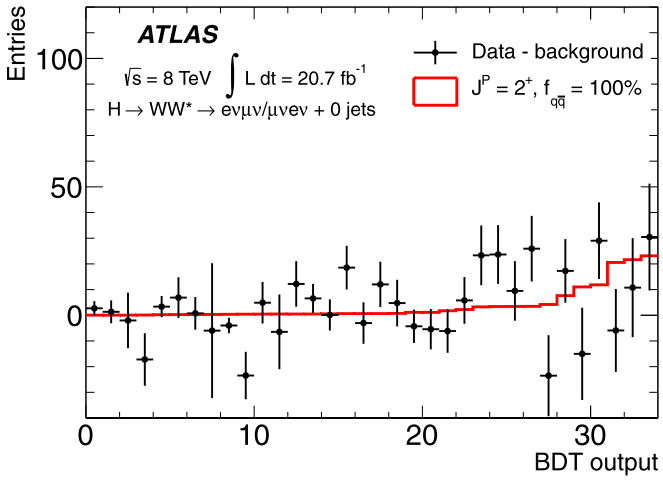


Fig. 5. Distributions of (a) $\Delta\phi_{\ell\ell}$ and (b) $m_{\ell\ell}$ in the signal region for $m_H = 125$ GeV and the $J^P = 0^+$ hypothesis. The signal is normalised to its SM expectation. In the lower part of the figures the ratio between data and the sum of signal and background is shown. The hatched areas represent the uncertainty on the signal and background yields from statistical, experimental, and theoretical sources.

[2] $E_{\mathrm{T,rel}}^{\mathrm{miss}} \equiv E_{\mathrm{T}}^{\mathrm{miss}} \cdot \sin\Delta\phi$, where $\Delta\phi$ is the azimuthal separation between the missing transverse momentum and the nearest reconstructed object (lepton or jet with $p_{\mathrm{T}} > 25$ GeV) or $\pi/2$, whichever is smaller. The missing transverse energy $E_{\mathrm{T}}^{\mathrm{miss}}$ is defined as the modulus of the missing transverse momentum.

(a)

(b)

Fig. 6. One-dimensional distributions of the outputs of the BDT for the $H \to WW^*$ channel after background subtraction, using best-fit values for (a) $J^P = 0^+$ and (b) $J^P = 2^+$ with $f_{q\bar{q}} = 100\%$ hypotheses. In each case, the two-dimensional distribution of the two classifiers is remapped into a one-dimensional distribution, with the bins reordered in increasing number of expected signal events. Empty bins, defined as bins with expected content below 0.1, are removed.

m_{T} [18], is used in the BDT training as it provides a good separation between backgrounds and signals as well as some separation between the different spin hypotheses for the signals. Two separate BDT classifiers are developed for each hypothesis test: one classifier is trained to distinguish the $J^P = 0^+$ signal from the sum of all backgrounds while the second classifier separates the alternative spin–parity hypothesis ($J^P = 2^+$, 1^+ or 1^-) from the sum of all backgrounds. Background processes used to train both classifiers include WW, $t\bar{t}$ and single top, as well as WZ, ZZ, $W\gamma$, $W\gamma^*$, $W+$jets and $Z+$jets.

The resulting two-dimensional distribution of the two classifiers is then used in binned likelihood fits to test the data for compatibility with the presence of a $J^P = 0^+$, 1^+, 1^- or 2^+ particle in the data. The analysis of $J^P = 2^+$, including the retraining of the second classifier with the $J^P = 2^+$ sample as signal, is repeated for each of the five values of $f_{q\bar{q}}$. The BDT output distributions for data, after background subtraction, are shown in Fig. 6, after remapping the two-dimensional distribution of the two classifiers into a one-dimensional distribution.

The BDT relies on a good description of the input variables and their correlations. These were studied in detail and found to be well described by simulation [21]. In addition, dedicated studies were performed to verify that a BDT with the chosen four input variables is able to reliably separate the main backgrounds in a background-enriched region, and that the response is well modelled.

Two different categories of systematic uncertainties are considered: experimental or detector sources, such as the jet energy scale and resolution, or the lepton identification efficiencies, scale and resolution, as well as theoretical sources such as the estimation of the effect of higher-order contributions through variations of the QCD renormalisation and factorisation scales in the Monte Carlo simulation. The experimental uncertainties affect both the signal and background yields and are described in Ref. [18]. Monte Carlo samples with systematically varied parameters were analysed. Both the overall normalisation and shape distortions are included as nuisance parameters in the likelihood.

The WW background in the signal region is evaluated through extrapolation from a control region using the simulation. The theoretical uncertainties on the extrapolation parameter $\alpha = N_{\mathrm{SR}}/N_{\mathrm{CR}}$, the ratio of the number of events passing the signal region selection to the number passing the control region selection, are evaluated according to the prescription of Ref. [33]. Several sources of uncertainty on the normalisation are considered: uncertainties on the QCD renormalisation and factorisation scales, Parton Density Functions (PDF), the choice of Monte Carlo generator, and the underlying event and parton shower model. The total uncertainty on the extrapolation is $\pm 4.8\%$. Another important uncertainty arises from the shape modelling of the irreducible WW continuum background. The uncertainty on the shapes of the BDT discriminants is studied by varying the factorisation and renormalisation scales, by comparing the predictions of HERWIG [34] and PYTHIA8 leading-order parton shower programs, and by evaluating the uncertainties from the CT10 [35] PDF error set and combining them with the difference in central values between NNPDF [36] and CT10. An envelope for the predicted BDT shape for each discriminant is derived and included in the binned likelihood fit as a shape uncertainty.

7. Results

The SM $J^P = 0^+$ hypothesis is tested against several alternative spin–parity hypotheses using the analyses described in the previous sections. Using the statistical procedure described in Section 3, integral probabilities, the p_0-values, are determined to quantify the level of agreement of the data with different spin–parity hypotheses. When giving the confidence level associated with the rejection of a spin–parity hypothesis, the $\mathrm{CL_s}$ approach defined in Eq. (3) is used.

7.1. Systematic uncertainties

The sources of systematic uncertainty accounted for in the analyses of the individual channels are discussed in Sections 4, 5 and 6. In the combination, the correlations among the common sources of systematic uncertainties across channels are taken into account. Systematic uncertainties on electron and muon identification, reconstruction and trigger efficiencies, as well as on their energy and momentum resolution, are common to both the $H \to ZZ^*$ and $H \to WW^*$ channels. Systematic uncertainties on the energy scale of electrons and photons affect all three decay channels. It was also verified that the results presented in the following are insen-

sitive to variations of the Higgs boson mass within the measured accuracy of about ±0.6 GeV [18].

The overall impact of the systematic uncertainties is evaluated by comparing the baseline results of the likelihood fits obtained by profiling all nuisance parameters not directly measured from the data, with the results obtained by fixing them at their nominal values. For all tested hypotheses, the combined rejection significance is found to be degraded by less than 0.3σ when including all nuisance parameters in the fit with respect to fixing them at their nominal values.

The production mode has a significant impact on the underlying p_{T} spectrum of the Higgs boson. For signals produced through gluon fusion, the dependence on the p_{T} modelling was studied by comparing the discriminant observables before and after re-weighting the signal to the POWHEG+PYTHIA8 spectrum. However, the impact on the discriminant observables is found to be negligible compared to other sources of systematic uncertainty and therefore is neglected. For the $q\bar{q}$-initiated processes the p_{T} spectrum is expected to be softer than for processes produced via gluon fusion. Since no higher-order QCD predictions are available for the $q\bar{q}$ annihilation production process, no specific systematic uncertainty is assigned to the p_{T} spectrum of such signals. The impact of the large variation obtained by re-weighting the signals produced at leading order in $q\bar{q}$ annihilation for the $J^P = 2^+$ model to the POHWEG+PYTHIA8 gluon-fusion prediction was evaluated. The resulting weights increase from about unity at low transverse momentum to about four near 100 GeV. The $H \to WW^*$ and $H \to ZZ^*$ channels are almost insensitive to such re-weighting, which leads to changes in the BDT discriminant shapes of the order of a few percent. The $H \to \gamma\gamma$ channel is more sensitive to the signal p_{T} spectrum due to the impact on its acceptance at high $|\cos\theta^*|$ values. For this channel, the expected sensitivity for the spin-2 rejection is reduced by about 30% for $f_{q\bar{q}} = 100\%$, when the re-weighting is applied. Since the combined result for this case is dominated by the $H \to ZZ^*$ and $H \to WW^*$ channels, the overall impact of this re-weighting on the combined $J^P = 2^+$ rejection is negligible, below 0.1σ.

7.2. Test of SM $J^P = 0^+$ against $J^P = 0^-$

The distributions of the test statistics q from the $H \to ZZ^*$ channel for the $J^P = 0^+$ and 0^- hypotheses are shown in Fig. 7 together with the observed value.

The expected and observed rejections of the $J^P = 0^+$ and 0^- hypotheses are summarised in Table 1. The data are in agreement with the $J^P = 0^+$ hypothesis, while the 0^- hypothesis is excluded at 97.8% CL.

7.3. Test of SM $J^P = 0^+$ against $J^P = 1^+$

The expected and observed rejections of the $J^P = 0^+$ and 1^+ hypotheses in the $H \to ZZ^*$ and $H \to WW^*$ channels and their combination are summarised in Table 2. For both channels, the results are in agreement with the $J^P = 0^+$ hypothesis. In the $H \to ZZ^*$ channel, the 1^+ hypothesis is excluded at 99.8% CL, while in the $H \to WW^*$ channel, it is excluded at 92% CL. The combination excludes this hypothesis at 99.97% CL.

7.4. Test of SM $J^P = 0^+$ against $J^P = 1^-$

The expected and observed rejections of the $J^P = 0^+$ and 1^- hypotheses in the $H \to ZZ^*$ and $H \to WW^*$ channels and their combination are summarised in Table 3. For both channels, the results are in agreement with the $J^P = 0^+$ hypothesis. In the $H \to ZZ^*$ channel, the 1^- hypothesis is excluded at 94% CL. In the $H \to WW^*$ channel, the 1^- hypothesis is excluded at 98% CL. The combination excludes this hypothesis at 99.7% CL.

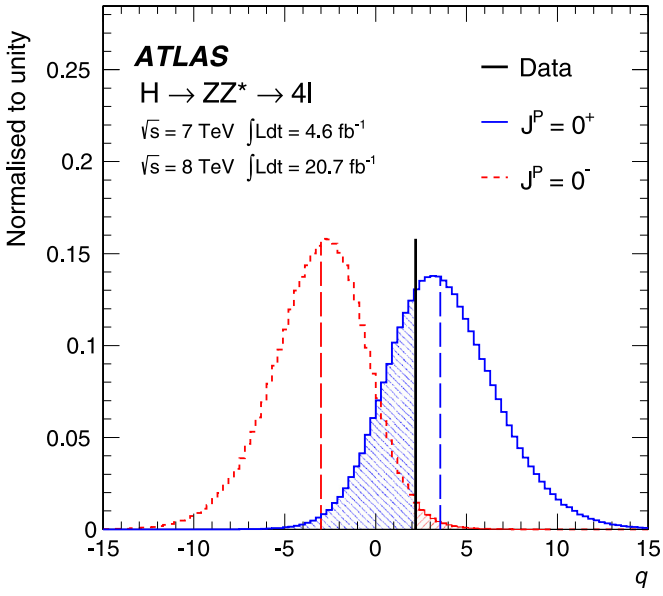

Fig. 7. Expected distributions of $q = \log(\mathcal{L}(J^P = 0^+)/\mathcal{L}(J^P = 0^-))$, the logarithm of the ratio of profiled likelihoods, under the $J^P = 0^+$ and 0^- hypotheses for the Standard Model $J^P = 0^+$ (blue/solid line distribution) or 0^- (red/dashed line distribution) signals. The observed value is indicated by the vertical solid line and the expected medians by the dashed lines. The coloured areas correspond to the integrals of the expected distributions up to the observed value and are used to compute the p_0-values for the rejection of each hypothesis.

7.5. Test of SM $J^P = 0^+$ against $J^P = 2^+$

The expected and observed rejections of the $J^P = 0^+$ and 2^+ hypotheses in the three channels are summarised in Table 4, for all $f_{q\bar{q}}$ values of the spin-2 particle considered. For all three channels, the results are in agreement with the spin-0 hypothesis. The results from the $H \to \gamma\gamma$ channel exclude a spin-2 particle produced via gluon fusion ($f_{q\bar{q}} = 0$) at 99.3% CL. The separation between the two spin hypotheses in this channel decreases with increasing $f_{q\bar{q}}$. For large values of $f_{q\bar{q}}$, the $|\cos\theta^*|$ distributions associated with the spin-0 and spin-2 signals become very similar. In the case of the $H \to ZZ^*$ channel, a separation slightly above one standard deviation is expected between the $J^P = 0^+$ and $J^P = 2^+$ hypotheses, with little dependence on the production mechanism. The $H \to WW^*$ channel has the opposite behaviour to the $H \to \gamma\gamma$ one, with the best expected rejection achieved for large values of $f_{q\bar{q}}$, as illustrated in Table 4. The results for the $H \to WW^*$ channel are also in agreement with the $J^P = 0^+$ hypothesis. The $J^P = 2^+$ hypothesis is excluded with a CL above 95%. The data are in better agreement with the $J^P = 0^+$ hypothesis over the full range of $f_{q\bar{q}}$.

Table 5 shows the expected and observed p_0-values for both the $J^P = 0^+$ and $J^P = 2^+$ hypotheses for the combination of the $H \to \gamma\gamma$, $H \to ZZ^*$ and $H \to WW^*$ channels. The test statistics calculated on data are compared to the corresponding expectations obtained from pseudo-experiments, as a function of $f_{q\bar{q}}$. The data are in good agreement with the Standard Model $J^P = 0^+$ hypothesis over the full $f_{q\bar{q}}$ range. Fig. 8 shows the comparison of the expected and observed $\mathrm{CL_s}$ values for the $J^P = 2^+$ rejection as a function of $f_{q\bar{q}}$. The observed exclusion of the $J^P = 2^+$ hypothesis in favour of the Standard Model $J^P = 0^+$ hypothesis exceeds 99.9% CL for all values of $f_{q\bar{q}}$.

Table 1
Summary of results for the 0^+ versus 0^- test in the $H \to ZZ^*$ channel. The expected p_0-values for rejecting the 0^+ and 0^- hypotheses (assuming the alternative hypothesis) are shown in the second and third columns. Table 5
Expected and observed p_0-values for the $J^P = 0^+$ and $J^P = 2^+$ hypotheses as a function of the fraction $f_{q\bar{q}}$ of the $q\bar{q}$ spin-2 production mechanism. The values are tabulated for the combination of the $H \to \gamma\gamma$, $H \to ZZ^*$ and $H \to WW^*$ channels. The CL_s values for excluding the $J^P = 2^+$ hypothesis are given in the last column.

$f_{q\bar{q}}$	2^+ assumed Exp. $p_0(J^P = 0^+)$	0^+ assumed Exp. $p_0(J^P = 2^+)$	Obs. $p_0(J^P = 0^+)$	Obs. $p_0(J^P = 2^+)$	$CL_s(J^P = 2^+)$
100%	$3.0 \cdot 10^{-3}$	$8.8 \cdot 10^{-5}$	0.81	$1.6 \cdot 10^{-6}$	$0.8 \cdot 10^{-5}$
75%	$9.5 \cdot 10^{-3}$	$8.8 \cdot 10^{-4}$	0.81	$3.2 \cdot 10^{-5}$	$1.7 \cdot 10^{-4}$
50%	$1.3 \cdot 10^{-2}$	$2.7 \cdot 10^{-3}$	0.84	$8.6 \cdot 10^{-5}$	$5.3 \cdot 10^{-4}$
25%	$6.4 \cdot 10^{-3}$	$2.1 \cdot 10^{-3}$	0.80	$0.9 \cdot 10^{-4}$	$4.6 \cdot 10^{-4}$
0%	$2.1 \cdot 10^{-3}$	$5.5 \cdot 10^{-4}$	0.63	$1.5 \cdot 10^{-4}$	$4.2 \cdot 10^{-4}$

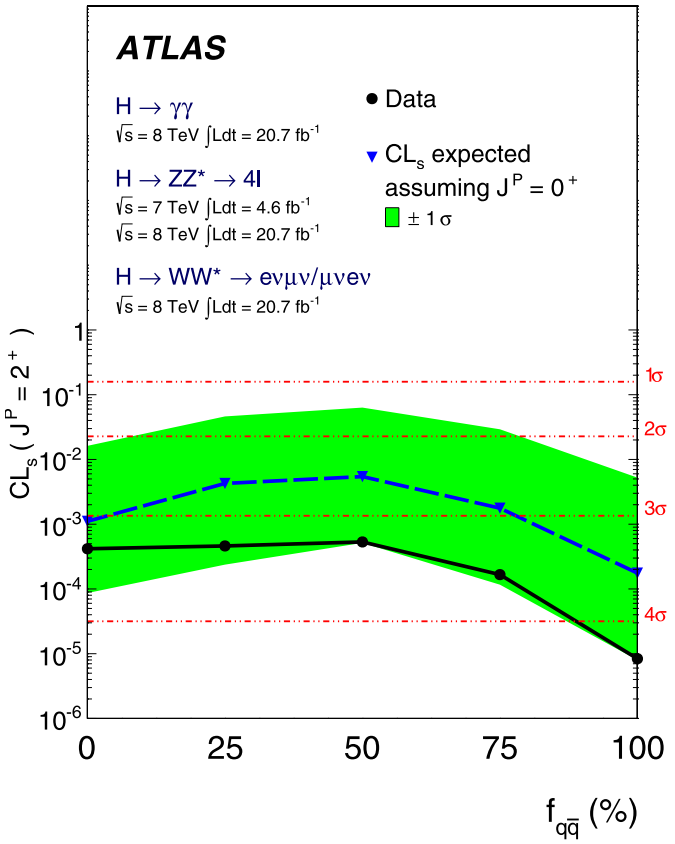

Fig. 8. Expected (blue triangles/dashed line) and observed (black circles/solid line) confidence levels, $CL_s(J^P = 2^+)$, of the $J^P = 2^+$ hypothesis as a function of the fraction $f_{q\bar{q}}$ (see text) for the spin-2 particle. The green bands represent the 68% expected exclusion range for a signal with assumed $J^P = 0^+$. On the right y-axis, the corresponding numbers of Gaussian standard deviations are given, using the one-sided convention.

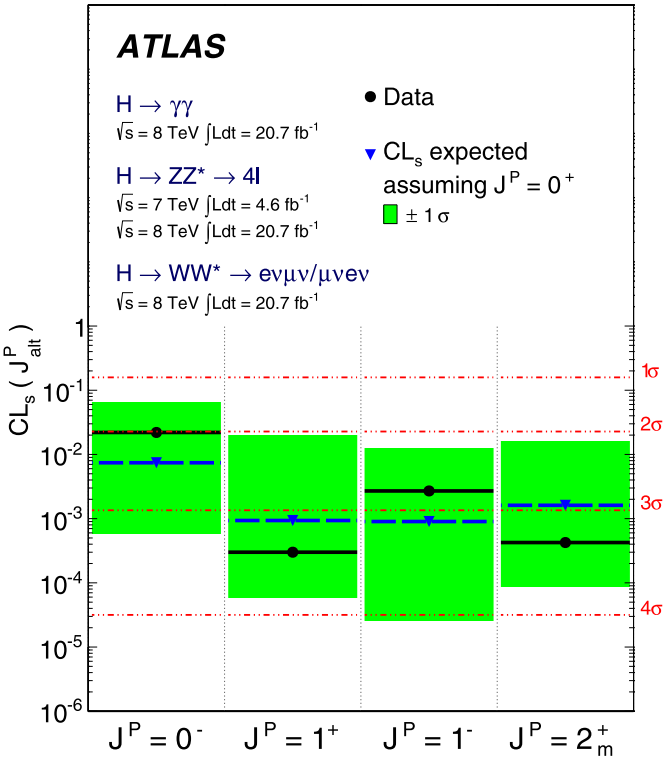

Fig. 9. Expected (blue triangles/dashed lines) and observed (black circles/solid lines) confidence level CL_s for alternative spin–parity hypotheses assuming a $J^P = 0^+$ signal. The green band represents the 68% $CL_s(J^P_{\text{alt}})$ expected exclusion range for a signal with assumed $J^P = 0^+$. For the spin-2 hypothesis, the results for the specific 2^+_m model, discussed in Section 2, are shown. On the right y-axis, the corresponding numbers of Gaussian standard deviations are given, using the one-sided convention.

7.6. Summary

The observed and expected CL_s values for the exclusion of the different spin–parity hypotheses are summarised in Fig. 9. For the spin-2 hypothesis, the CL_s value for the specific 2^+_m model, discussed in Section 2, is displayed.

8. Conclusions

The Standard Model $J^P = 0^+$ hypothesis for the Higgs boson has been compared to alternative spin–parity hypotheses using $\sqrt{s} = 8$ TeV (20.7 fb^{-1}) and 7 TeV (4.6 fb^{-1}) proton–proton collision data collected by the ATLAS experiment at the LHC. The Higgs boson decays $H \to \gamma\gamma$, $H \to ZZ^* \to 4\ell$ and $H \to WW^* \to \ell\nu\ell\nu$ have been used to test several specific alternative models, including $J^P = 0^-, 1^+, 1^-$ and a graviton-inspired $J^P = 2^+$ model with minimal couplings to SM particles. The data favour the Standard Model quantum numbers of $J^P = 0^+$. The 0^- hypothesis is rejected at 97.8% CL by using the $H \to ZZ^* \to 4\ell$ decay alone. The 1^+ and 1^- hypotheses are rejected with a CL of at least 99.7% by combining the $H \to ZZ^* \to 4\ell$ and $H \to WW^* \to \ell\nu\ell\nu$ channels. Finally, the $J^P = 2^+$ model is rejected at more than 99.9% CL by combining all three bosonic channels, $H \to \gamma\gamma$, $H \to ZZ^* \to 4\ell$ and $H \to WW^* \to \ell\nu\ell\nu$, independent of the assumed admixture of gluon-fusion and quark–antiquark production. All alternative models studied in this Letter are excluded without assumptions on the strength of the couplings of the Higgs boson to SM particles. These studies provide evidence for the spin-0 nature of the Higgs boson, with positive parity being strongly preferred.

Acknowledgements

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently.

We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWF and FWF, Austria; ANAS, Azerbaijan; SSTC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR and VSC CR, Czech Republic; DNRF, DNSRC and Lundbeck Foundation, Denmark; EPLANET, ERC and NSRF, European Union; IN2P3-CNRS, CEA-DSM/IRFU, France; GNSF, Georgia; BMBF, DFG, HGF, MPG and AvH Foundation, Germany; GSRT and NSRF, Greece; ISF, MINERVA, GIF, DIP and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; BRF and RCN, Norway; MNiSW, Poland; GRICES and FCT, Portugal; MERYS (MECTS), Romania; MES of Russia and ROSATOM, Russian Federation; JINR; MSTD, Serbia; MSSR, Slovakia; ARRS and MIZŠ, Slovenia; DST/NRF, South Africa; MICINN, Spain; SRC and Wallenberg Foundation, Sweden; SER, SNSF and Cantons of Bern and Geneva, Switzerland; NSC, Taiwan; TAEK, Turkey; STFC, the Royal Society and Leverhulme Trust, United Kingdom; DOE and NSF, United States of America.

The crucial computing support from all WLCG partners is acknowledged gratefully, in particular from CERN and the ATLAS Tier-1 facilities at TRIUMF (Canada), NDGF (Denmark, Norway, Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy),

NL-T1 (Netherlands), PIC (Spain), ASGC (Taiwan), RAL (UK) and BNL (USA) and in the Tier-2 facilities worldwide.

計画研究 A01 班

課題名「ヒッグス粒子の発見による素粒子の質量起源の解明」

研究組織

(1)研究代表者
徳宿　克夫（TOKUSHUKU, Katsuo）
高エネルギー加速器研究機構・素粒子原子核研究所・所長
研究者番号：80207547

(2)研究分担者
海野　義信（UNNO, Yoshinobu）
高エネルギー加速器研究機構・その他部局等・名誉教授
研究者番号：40151956

受川　史彦（UKEGAWA, Fumihiko）
筑波大学・数理物質科学研究科・教授
研究者番号：10312795

(3)連携研究者
津野　総司（TSUNO, Soshi）
高エネルギー加速器研究機構・素粒子原子核研究所・研究機関講師
研究者番号：30451834

増渕　達也（MASUBUCHI, Tatsuya）
東京大学・素粒子物理国際研究センター・特任助教
研究者番号：20512148

中村　浩二（NAKAMURA, Koji）
高エネルギー加速器研究機構・素粒子原子核研究所・助教
研究者番号：00554479

原　和彦（HARA, Kazuhiko）
筑波大学・数理物質科学研究科・講師
　研究者番号：20218613

岩崎　博行（IWASAKI, Hiroyuki） H23-26
高エネルギー加速器研究機構・その他部局等・名誉教授
　研究者番号：40151724

高嶋　隆一（TAKASHIMA, Ryuichi）H23-26
京都教育大学・教育学部・准教授
　研究者番号：60163200

佐藤 構二（SATO, Koji） H26-27
筑波大学・数理物質科学研究科・講師
　研究者番号：30422190

大川 英希（OKAWA Hideki） H27
筑波大学・数理物質科学研究科・助教
　研究者番号：10746960

交付決定額

計画研究 A01 班に配分された交付額を表 1 に示す。

表 1. 交付決定額（配分額）　（金額単位：円）

年度	直接経費	間接経費	合計
平成 23 年度	35,800,000	10,740,000	46,540,000
平成 24 年度	41,200,000	12,360,000	53,560,000
平成 25 年度	44,000,000	13,200,000	57,200,000
平成 26 年度	39,900,000	11,970,000	51,870,000
平成 27 年度	31,700,000	9,510,000	41,210,000
総計	192,600,000	57,780,000	250,380,000

研究成果

1．研究開始当初の背景

素粒子物理学の根幹をなす「標準理論」では、ヒッグス機構とよばれる対称性の自発的な破れによって素粒子が質量を獲得すると考えられている。標準理論はクォークとレプトンの力学をよく説明するすぐれた理論であり、この対称性の破れの直接的証拠となるヒッグス粒子の探索を、様々な実験で長期にわたって進めてきたが未発見であった。スイス・CERN 研究所では、世界最高エネルギーでの陽子・陽子衝突を実現できる大型ハドロン衝突型加速器（LHC）が平成 21 年から稼働を開始した。この加速器は、ヒッグス粒子の発見を目的の一つに掲げて建設され、国際協力でアトラス実験が組織され、我々のグループも測定器の建設と実験準備を進めてきた。
標準理論が素粒子の力学を上手く説明する一方で、その範囲を超える現象が観測されている。例えば、神岡実験で確立したニュートリノ振動現象であり、また宇宙の大部分を占める暗黒エネルギーや暗黒物質である。これらは、標準理論を超える我々がまだ理解していない自然の枠組みがあることを示唆している。理論的にも、標準理論の枠内ではヒッグスの質量が摂動論的に不安定であると指摘されていた。このため、ヒッグス粒子を発見すればすべてが解決するというわけではないが、ヒッグス粒子の性質を精査することが、これらの問題点を理解する鍵となると考えられていた。

2．研究の目的

（1）LHC での陽子・陽子衝突実験で、ヒッグス粒子を直接発見し、ゲージ対称性の破れと質量の起源の謎の解明を目指す。
（2）発見したヒッグス粒子が、標準理論の予言するものであるかを精査することで、テラスケールの新しい物理の探索を進める。現在の真空の性質と宇宙の初期に起った相転移を理解し、宇宙がどのように進化してきたかの知見を得て新しい宇宙像を開拓する。
（3）ヒッグス粒子の精査にあたっては、高エネルギーで生成される短寿命の粒子の同定が重要になり、このためにはより精度の高い飛跡検出器を導入することが望ましい。平成 29 年あるいは 31 年頃にアトラス測定器の飛跡検出器入れ替えが検討されているので、この研究では、新しいピクセル型飛跡検出器の開発を物理の研究と並行して進め、将来のエネルギーフロンティア実験へ

の道筋を立てる。

3．研究の方法

平成 21 年から始まった LHC での陽子・陽子衝突実験を、ほぼ研究期間の 5 年間を通して遂行する。取得したデータからヒッグス粒子の探索を進め、発見できた場合はその性質を精査する。研究開始時点での予定では、重心系エネルギー7TeV での衝突実験から始め、平成 24 年までに積分ルミノシティ 5-7fb^{-1}が得られると想定していた。その後平成 25 年に LHC の運転を 1 年停止し、衝突エネルギーを設計値の 14TeV に上げるための準備を行い、平成 26－27 年の実験では設計値である重心系エネルギー14TeV で、合わせて 100fb^{-1}近く収集すると想定した。標準理論のヒッグス粒子が存在するのであれば、研究期間に発見を迅速に確認した上で、その性質の測定ができる。もし、ヒッグス粒子の徴候がない場合には、標準理論の考え方が違っていることになり、素粒子物理学に大きな波紋を投じることになると考えていた。

測定器開発では、n-in-p 型のピクセル検出器を製作し、外国のグループが開発した読み出しチップと接合（バンプボンディング）をして、性能を調べる。特に放射線損傷の影響を定量的に研究し、バイアス電圧の安定供給の性能などを調べる。狭いバンプボンディング間隔（50μm あるいはそれ以下）での安定接合技術をつかむ。

ピクセルセンサーのデザインでは、将来のヒッグス精密測定のためにどのようなサイズのピクセルが必要かを、シミュレーションをもとに検討を行う。アトラス実験グループ全体の動きを見ながら、次世代検出器の必要パラメータ（ピクセルの形状、厚さなど）の検討をする。

4．研究成果

実際の LHC の運転は、目標をはるかに超えて積分ルミノシティを得ることができ、既に平成 23 年中に 7TeV で $5fb^{-1}$、平成 24 年には重心エネルギーを 8TeV に上げて $23fb^{-1}$ のデータを収集できた。
これらのデータにより、平成 24 年 7 月に質量 125GeV 付近に新粒子を発見し、その崩壊のパターンからこれがヒッグス粒子であることを確信した（論文[5,6],図 1)。LHC スケジュールは 8TeV 運転での実験を当初の予定より少し長くし、このエネルギーでの衝突データから、ヒッグスの性質をできるだけ引き出す方向で予定を修正した。その分平成 25-26 年度は加速器と測定器の改修のための長期シャットダウンとすることになった。これにより、以下に述べるようにヒッグス粒子に関して多くの知見を研究期間内に得ることができた。

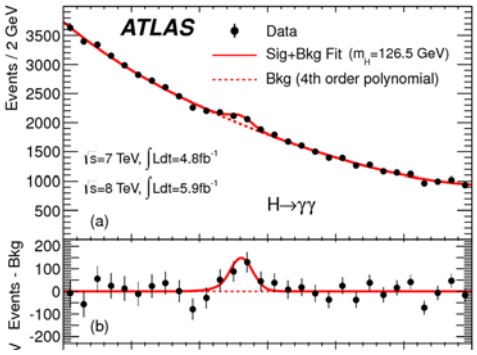

図 1：ヒッグス粒子が 2 光子に崩壊することを示した実験結果（論文[6]）

平成 27 年度に重心系 13TeV で実験を再開した。加速器の調整が時間かかったが $3fb^{-1}$ のデータを収集でき、高いエネルギー衝突エネルギーで、125GeV のヒッグス粒子の確認を進めるとともに、さらに別のヒッグス粒子が存在しないかという探索を開始することができた。加速器・実験装置の面では長期シャットダウンでの改善により、今後の 3 年間でこのエネルギーで $100fb^{-1}$ のデータをためられる見通しとともに、ヒッグス粒子の性質の精査に関しても解析手法等を期間内に確立することができた。

まず得られた全体像を簡単にまとめると、発見した新粒子は、標準理論の予想するヒッグス粒子の性質と非常によくあっており、測定精度の範囲内では有意なずれは見られていない、そして複数のヒッグス粒子があるかどうかの探索も進めているが有意な発見はなかった、という結論になる。
本研究の大きな成果はヒッグス機構を伴う標準理論の正しさを確立した。
ヒッグス粒子の質量は約 125GeV で、様々な崩壊モードを観測できる領域であり、これによって、ヒッグス粒子の精査が、標準理論を超える理論を構築するための重要な実験手段となることを示した。

一方で、これまで標準理論を超える現象を理解する直接的なヒントはヒッグス粒子の測定及び、新粒子の探索のどちらからも得られておらず、研究当初考えていたよりはテラスケールの物理を理解することが単純でないことがわかった。標準理論が非常に高いエネルギーまで成り立つという可能性もあり、これまでの素粒子論・宇宙論的に大きな見直しを迫る実験的結果を与えた。

以下にこれまでにわかったヒッグス粒子の性質をより詳しく述べる。新粒子の発見後、この粒子のスピン・ パリティの解析を行い、ヒッグス粒子と同じで、スピンはゼロで正のパリティとほぼ確定し、この時点でヒッグス粒子であると確信した（論文[4]）。

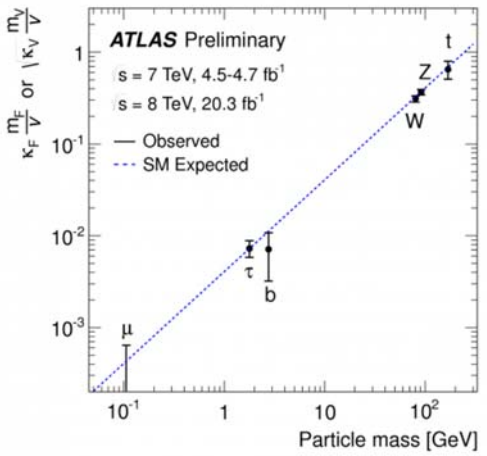

図 2：ヒッグス粒子と他の粒子との結合の強さのまとめ

全データを使った各崩壊モードでの解析と、超対称性粒子等で予想される他のヒッグス粒子の探索が進み、ほぼすべての解析が終了し論文として発表した。W,Z 及び γ への崩壊は確立し、フェルミ粒子への崩壊に関しては τ への崩壊が 4.5σ で観測できている（論文[3]）。一方で μ への崩壊は τ と同レベルでは観測されないことは確定できており、この粒子が二つのレプトン（二つの世代）を区別することを実験的に示し、ここでもヒッグス粒子の特質を明らかにした。

ボトムへの崩壊や、トップクォークとの随伴生成の探索も進めている。これらのモードでは、標準理論のヒッグスと無矛盾であることを示すことができている。各粒子への崩壊をまとめたのを図 2 に示し、各粒子との結合の強さが質量と強く関係するという、ヒッグス粒子の特徴をよく捉えている。

もう一つの LHC 実験である CMS 実験との共同解析も進み、0.2%精度の質量測定を達成した（論文[2]）。結合定数に関する共同研究も暫定結果を平成 25 年の国際会議で発表し、平成 28 年 6 月に論文投稿した。

発見したヒッグス粒子に加えて、新たな荷電及び中性ヒッグス粒子の探索も行った。残念ながら新しい粒子の兆候は得られていない。13TeV の衝突データで二光子への崩壊モードで 750GeV 付近にやや超過がみられることを、平成 27 年 12 月のセミナーで公表し、大きな反響をよんでいるが、まだ統計的には有意でなく、これが今後のデータ収集と共にどうなるかが楽しみである。

ピクセル検出器の開発では、半導体素子自体の開発とともに、放射線照射テスト時の被ばくを軽減するために自動化するシステムを構築するなど、開発環境を大きく改善した。

バイアス電圧の配線レイアウト等を替えた試作機を作りテストを繰り返すことで、
放射線損傷後 飛跡検出効率が落ちる原因を究明し、放射線損傷後でも検出効率 99%を維持している事をビームテストで確認した（論文[1],図 3）。

また、薄型センサー／薄型読み出しチップ（厚み 150/150 μm)の接合（バンプボンディング）においても、バンプ接合不良を発生させる原因を特定し安定した接合技術を確立した。
これらにより、将来の高輝度 LHC でのヒックス粒子の精密測定に導入するピクセル検出器の開発を基本的な部分を完了することができた。

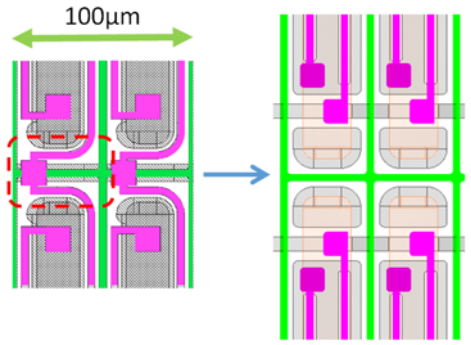

図 3　ピクセル検出器の改善前後のレイアウト。右の赤線で囲んだ部分が放射線照射後に検出効率が落ちることを実験的に示し、改善した。

Measurements of the Higgs boson production and decay rates and constraints on its couplings from a combined ATLAS and CMS analysis of the LHC pp collision data at $\sqrt{s} = 7$ and 8 TeV

The ATLAS and CMS collaborations

E-mail: atlas.publications@cern.ch,
cms-publication-committee-chair@cern.ch

Abstract: Combined ATLAS and CMS measurements of the Higgs boson production and decay rates, as well as constraints on its couplings to vector bosons and fermions, are presented. The combination is based on the analysis of five production processes, namely gluon fusion, vector boson fusion, and associated production with a W or a Z boson or a pair of top quarks, and of the six decay modes $H \to ZZ, WW$, $\gamma\gamma, \tau\tau, bb$, and $\mu\mu$. All results are reported assuming a value of 125.09 GeV for the Higgs boson mass, the result of the combined measurement by the ATLAS and CMS experiments. The analysis uses the CERN LHC proton-proton collision data recorded by the ATLAS and CMS experiments in 2011 and 2012, corresponding to integrated luminosities per experiment of approximately 5 fb^{-1} at $\sqrt{s} = 7$ TeV and 20 fb^{-1} at $\sqrt{s} = 8$ TeV. The Higgs boson production and decay rates measured by the two experiments are combined within the context of three generic parameterisations: two based on cross sections and branching fractions, and one on ratios of coupling modifiers. Several interpretations of the measurements with more model-dependent parameterisations are also given. The combined signal yield relative to the Standard Model prediction is measured to be 1.09 ± 0.11. The combined measurements lead to observed significances for the vector boson fusion production process and for the $H \to \tau\tau$ decay of 5.4 and 5.5 standard deviations, respectively. The data are consistent with the Standard Model predictions for all parameterisations considered.

1 Introduction

The elucidation of the mechanism of electroweak (EW) symmetry breaking has been one of the main goals driving the design of the ATLAS [1] and CMS [2] experiments at the CERN LHC. In the Standard Model (SM) of particle physics [3–6], the breaking of the symmetry is achieved through the introduction of a complex doublet scalar field, leading to the prediction of the existence of one physical neutral scalar particle, commonly known as the Higgs boson [7–12]. Through Yukawa interactions, the Higgs scalar field can also account for fermion masses [4, 13]. While the SM does not predict the value of the Higgs boson mass, m_H, the production cross sections and decay branching fractions (B) of the Higgs boson can be precisely calculated once its mass is known.

In 2012, the ATLAS and CMS Collaborations reported the observation of a new particle with a mass of approximately 125 GeV and Higgs-boson-like properties [14–16]. Subsequent results from both experiments, summarised in refs. [17–21], established that all measurements of the properties of the new particle, including its spin, CP properties, and coupling strengths to SM particles, are consistent within the uncertainties with those expected for the SM Higgs boson. ATLAS and CMS have published a combined measurement of the Higgs boson mass [22], using LHC Run 1 data for the $H \to \gamma\gamma$ and $H \to ZZ$ channels, where Run 1 indicates the LHC proton-proton (pp) data taking period in 2011 and 2012 at centre-of-mass energies $\sqrt{s} = 7$ and 8 TeV. The combined mass measurement is

$$m_H = 125.09 \pm 0.21(\text{stat.}) \pm 0.11(\text{syst.}) \text{ GeV}, \tag{1.1}$$

where the total uncertainty is dominated by the statistical component. The Higgs boson mass is assumed to be $m_H = 125.09$ GeV for all analyses presented in this paper.

This paper reports the first ATLAS and CMS combined measurements of the Higgs boson production and decay rates as well as constraints on its couplings to SM particles. These measurements yield the most precise and comprehensive experimental results on these quantities to date. The main production processes studied are gluon fusion (ggF), vector boson fusion (VBF), and associated production with vector bosons (WH and ZH, denoted together as VH) or a pair of top quarks (ttH). The decay channels considered are those to bosons, $H \to ZZ$, $H \to WW$, and $H \to \gamma\gamma$; and to fermions, $H \to \tau\tau$, $H \to bb$, and $H \to \mu\mu$. Throughout this paper, Z and W indicate both real and virtual vector bosons, and no distinction is made between particles and antiparticles.

All analyses used in the combination are based on the complete Run 1 collision data collected by the ATLAS and CMS experiments. These data correspond to integrated luminosities per experiment of approximately 5 fb^{-1} at $\sqrt{s} =$ 7 TeV (recorded in 2011)

JHEP08(2016)045

and 20 fb^{-1} at $\sqrt{s} = 8\,\text{TeV}$ (recorded in 2012). The results of the ATLAS and CMS individual combinations based on the Run 1 data are reported in refs. [17, 18].

Unless otherwise stated, in this paper it is assumed, as in refs. [17, 18], that the particle under study is a single SM-like Higgs boson state, i.e. a CP-even scalar particle with the tensor coupling structure of the SM for its interactions. The Higgs boson width, predicted to be approximately 4 MeV in the SM, is assumed to be small enough that the narrow-width approximation is valid and that the Higgs boson production and decay mechanisms can be factorised. These assumptions are corroborated by tests of the spin and CP properties of the Higgs boson [20, 21] and by studies of its width [18, 23–25]. The Higgs boson signal modelling is based on the hypothesis of a SM Higgs boson in terms of its production and decay kinematics. Measurements of differential production cross sections [26–29] support these assumptions within the current statistical uncertainties. The inherent model dependence related to these hypotheses applies to all results presented here; the reliance on this model has a negligible impact for small deviations from the SM, but could be important for significant deviations from the SM predictions.

The results presented here for each experiment separately are slightly different from those reported in refs. [17, 18]. Some small variations with respect to the earlier results are related to a different choice for the value of the Higgs boson mass. Other differences arise from minor modifications to the signal parameterisation and to the treatment of systematic uncertainties. These modifications are introduced in the present analysis to allow a fully consistent and correlated treatment of the dominant theoretical uncertainties in the signal modelling between the two experiments.

This paper is organised as described below. Section 2 briefly reviews the theoretical calculations of Higgs boson production and decay, and the modelling of the Higgs boson signal in Monte Carlo (MC) simulation; it also introduces the formalisms of signal strengths and coupling modifiers used for the interpretation of the data. Section 3 gives an overview of the analyses included in this combination, describes the statistical procedure used, together with the treatment of systematic uncertainties, and summarises modifications to the individual analyses for the combination. Section 4 describes the parameterisation of the measured signal yields in generic terms and reports the results using three distinct parameterisations. Section 5 compares the measured Higgs boson yields to the SM predictions for different production processes and decay modes, and reports the results of a test for the possible presence of multiple mass-degenerate states. Section 6 studies the couplings of the Higgs boson to probe for possible deviations from the SM predictions, using various assumptions motivated in many cases by beyond the SM (BSM) physics scenarios. Finally, section 7 presents a summary of the results.

2 Higgs boson phenomenology and interpretation framework

This section briefly reviews Higgs boson phenomenology and introduces the most important aspects of the interpretation framework used to combine the measurements and to assess their compatibility with the SM predictions. The dominant production processes and major decay modes of the SM Higgs boson, along with the theoretical predictions for the cross sections and branching fractions, are presented. The main features of the MC generators used to simulate Higgs boson production and decay in each experiment are described. Finally,

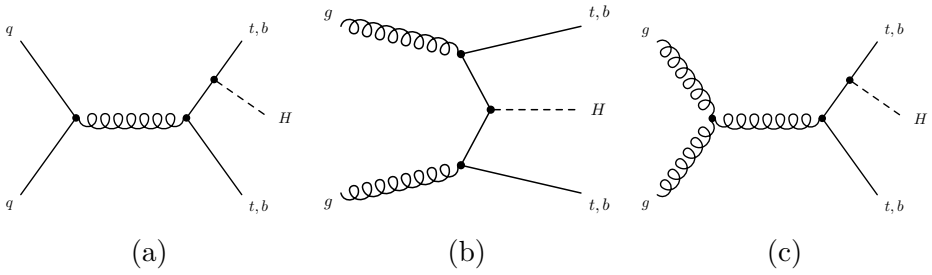

Figure 3. Examples of leading-order Feynman diagrams for Higgs boson production via the $qq/gg \to ttH$ and $qq/gg \to bbH$ processes.

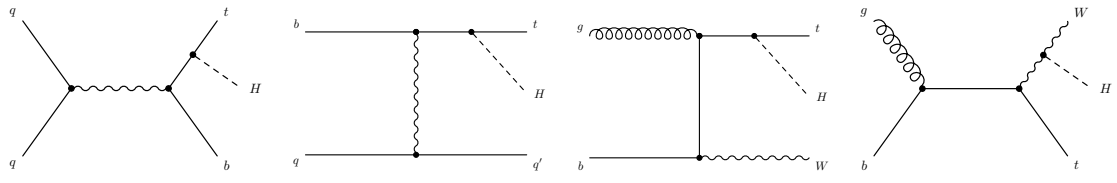
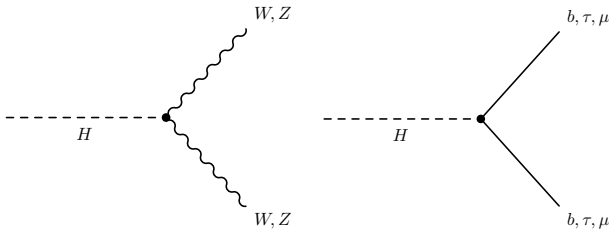


the formalisms of two widely used frameworks, based on signal strengths and coupling modifiers, for the interpretation of the Higgs boson measurements at the LHC, are introduced.

2.1 Higgs boson production and decay

In the SM, Higgs boson production at the LHC mainly occurs through the following processes, listed in order of decreasing cross section at the Run 1 centre-of-mass energies:



- gluon fusion production $gg \to H$ (figure 1a);
- vector boson fusion production $qq \to qqH$ (figure 1b);
- associated production with a W boson, $qq \to WH$ (figure 2a), or with a Z boson, $pp \to ZH$, including a small ($\sim 8\%$) but less precisely known contribution from $gg \to ZH$ ($ggZH$) (figures 2a, 2b, and 2c);
- associated production with a pair of top quarks, $qq, gg \to ttH$ (figure 3).

JHEP08(2016)045

(a) (b)

Figure 5. Examples of leading-order Feynman diagrams for Higgs boson decays (a) to W and Z bosons and (b) to fermions.

(a) (b) (c)

Figure 6. Examples of leading-order Feynman diagrams for Higgs boson decays to a pair of photons.

Other less important production processes in the SM, which are not the target of a direct search but are included in the combination, are $qq, gg \to bbH$ (bbH), also shown in figure 3, and production in association with a single top quark (tH), shown in figure 4. The latter process proceeds through either $qq/qb \to tHb/tHq'$ (tHq) (figures 4a and 4b) or $gb \to tHW$ (tHW) (figures 4c and 4d) production.

Examples of leading-order (LO) Feynman diagrams for the Higgs boson decays considered in the combination are shown in figures 5 and 6. The decays to W and Z bosons (figure 5a) and to fermions (figure 5b) proceed through tree-level processes whereas the $H \to \gamma\gamma$ decay is mediated by W boson or heavy quark loops (figure 6).

The SM Higgs boson production cross sections and decay branching fractions are taken from refs. [30–32] and are based on the extensive theoretical work documented in refs. [33–77]. The inclusive cross sections and branching fractions for the most important production and decay modes are summarised with their overall uncertainties in tables 1 and 2 for a

JHEP08(2016)045

Production process	Cross section [pb] $\sqrt{s} = 7\,\text{TeV}$	Cross section [pb] $\sqrt{s} = 8\,\text{TeV}$	Order of calculation
ggF	15.0 ± 1.6	19.2 ± 2.0	NNLO(QCD) + NLO(EW)
VBF	1.22 ± 0.03	1.58 ± 0.04	NLO(QCD+EW) + APPROX. NNLO(QCD)
WH	0.577 ± 0.016	0.703 ± 0.018	NNLO(QCD) + NLO(EW)

Total	17.4 ± 1.6	22.3 ± 2.0	

Table 1. Standard Model predictions for the Higgs boson production cross sections together with their theoretical uncertainties. The value of the Higgs boson mass is assumed to be $m_H = 125.09\,\text{GeV}$ and the predictions are obtained by linear interpolation between those at 125.0 and 125.1 GeV from ref. [32] except for the tH cross section, which is taken from ref. [78]. The $pp \to ZH$ cross section, calculated at NNLO in QCD, includes both the quark-initiated, i.e. $qq \to ZH$ or $qg \to ZH$, and the $gg \to ZH$ contributions. The contribution from the $gg \to ZH$ production process, calculated only at NLO in QCD and indicated separately in brackets, is given with a theoretical uncertainty assumed to be 30%. The uncertainties in the cross sections are evaluated as the sum in quadrature of the uncertainties resulting from variations of the QCD scales, parton distribution functions, and α_s. The uncertainty in the tH cross section is calculated following the procedure of ref. [79]. The order of the theoretical calculations for the different production processes is also indicated. In the case of bbH production, the values are given for the mixture of five-flavour (5FS) and four-flavour (4FS) schemes recommended in ref. [74].

Higgs boson mass $m_H = 125.09$ GeV. The SM predictions of the branching fractions for $H \to gg, cc$, and $Z\gamma$ are included for completeness. Although not an explicit part of the searches, they impact the combination through their contributions to the Higgs boson width and, at a small level, through their expected yields in some of the individual analyses.

2.2 Signal Monte Carlo simulation

All analyses use MC samples to model the Higgs boson production and decay kinematics, to estimate the acceptance and selection efficiency, and to describe the distributions of variables used to discriminate between signal and background events. The main features of the signal simulation are summarised here; for more details, the reader is referred to the individual publications:

- for ggF and VBF production, both experiments use POWHEG [80–84] for the event generation, interfaced either to PYTHIA8 [85] (ATLAS) or PYTHIA6.4 [86] (CMS) for the simulation of the parton shower, the hadronisation, and the underlying event, collectively referred to in the following as UEPS.

JHEP08(2016)045

Decay mode	Branching fraction [%]
$H \to bb$	57.5 ± 1.9
$H \to WW$	21.6 ± 0.9
$H \to gg$	8.56 ± 0.86
$H \to \tau\tau$	6.30 ± 0.36
$H \to cc$	2.90 ± 0.35
$H \to ZZ$	2.67 ± 0.11
$H \to \gamma\gamma$	0.228 ± 0.011
$H \to Z\gamma$	0.155 ± 0.014
$H \to \mu\mu$	0.022 ± 0.001

Table 2. Standard Model predictions for the decay branching fractions of a Higgs boson with a mass of 125.09 GeV, together with their uncertainties [32]. Included are decay modes that are either directly studied or important for the combination because of their contributions to the Higgs boson width.

- for WH and ZH production, both experiments use LO event generators for all quark-initiated processes, namely Pythia8 in ATLAS and Pythia6.4 in CMS. A prominent exception is the $H \to bb$ decay channel, for which ATLAS uses Powheg interfaced to Pythia8, while CMS uses Powheg interfaced to Herwig++ [87]. The $ggZH$ production process is also considered, even though it contributes only approximately 8% of the total ZH production cross section in the SM, because it is expected to yield a relatively hard Higgs boson transverse momentum (p_{T}) spectrum, enhancing the contribution to the most sensitive categories in the $H \to bb$ decay channel. Both experiments therefore include $ggZH$ production as a separate process in the VH analysis for the $H \to bb$ channel. ATLAS uses Powheg interfaced to Pythia8 while CMS uses a reweighted $qq \to ZH$ sample to model the $ggZH$ contribution, including next-to-leading order (NLO) effects [66, 67]. For the other channels, the contribution from this process is only accounted for as a correction to the overall signal cross section.

- for ttH production, ATLAS uses the NLO calculation of the HELAC-Oneloop package [88] interfaced to Powheg, often referred to as Powhel [89], while CMS simulates this process with the LO Pythia6.4 program.

- within the SM, the contribution from tH production to analyses searching for ttH production is small, but in certain BSM scenarios it may become large through interference effects (see section 2.4). The tH production processes are simulated in both experiments using MadGraph5_aMC@NLO [79] interfaced to Herwig++ in the case of tHW production, while the tHq production process is simulated using

JHEP08(2016)045

MadGraph [90] interfaced to Pythia8 in ATLAS and MadGraph5_aMC@NLO interfaced to Pythia6.4 in CMS.

- finally, bbH production contributes approximately 1% to the total Higgs boson cross section in the SM. It is studied using Pythia8 in ATLAS and Pythia6.4 and MadGraph5_aMC@NLO in CMS, for the categories most sensitive to this production process in the various channels. Given that the selection efficiencies of bbH production are similar to those of the ggF process, the latter process is used to model the bbH signal for all decay channels, with an approximate correction to account for the difference in overall efficiency.

Table 3 summarises the event generators used by ATLAS and CMS for the $\sqrt{s} = 8\,\text{TeV}$ data analyses. For each production process and decay mode, the cross section and branching fraction used correspond to the higher-order state-of-the-art theoretical calculations, namely the values given in tables 1 and 2.

Furthermore, the p_{T} distribution of the Higgs boson in the ggF process, which in many cases affects categorisation and selection efficiencies, is reweighted to match the HRes2.1 prediction [45–47], which accounts for next-to-next-to-leading-order (NNLO) and next-to-next-to-leading-logarithmic (NNLL) QCD corrections. In addition, the Higgs boson p_{T} spectrum in $gg \to H$ events with two or more jets is reweighted to match the prediction of the Powheg MiNLO H+2-jet generator [91]. This consistent treatment by the two experiments of the most prominent theoretical aspects of Higgs boson production and decay is quite important since all theoretical uncertainties in the various signal processes described in table 3 are treated as correlated for the combination (see section 3). The impact of using different generators for the less sensitive channels is negligible compared to their dominant sources of uncertainty.

2.3 Signal strengths

The signal strength μ, defined as the ratio of the measured Higgs boson rate to its SM prediction, is used to characterise the Higgs boson yields. For a specific production process and decay mode $i \to H \to f$, the signal strengths for the production, μ_i, and for the decay, μ^f, are defined as

$$\mu_i = \frac{\sigma_i}{(\sigma_i)_{\text{SM}}} \quad \text{and} \quad \mu^f = \frac{\text{B}^f}{(\text{B}^f)_{\text{SM}}}. \tag{2.1}$$

Here σ_i $(i = gg\text{F}, \text{VBF}, WH, ZH, ttH)$ and B^f $(f = ZZ, WW, \gamma\gamma, \tau\tau, bb, \mu\mu)$ are respectively the production cross section for $i \to H$ and the decay branching fraction for $H \to f$. The subscript "SM" refers to their respective SM predictions, so by definition, $\mu_i = 1$ and $\mu^f = 1$ in the SM. Since σ_i and B^f cannot be separated without additional assumptions, only the product of μ_i and μ^f can be measured experimentally, leading to a signal strength μ_i^f for the combined production and decay:

$$\mu_i^f = \frac{\sigma_i \cdot \text{B}^f}{(\sigma_i)_{\text{SM}} \cdot (\text{B}^f)_{\text{SM}}} = \mu_i \cdot \mu^f. \tag{2.2}$$

Table 3. Summary of the event generators used by ATLAS and CMS to model the Higgs boson production processes and decay channels at $\sqrt{s} = 8$ TeV.

The ATLAS and CMS data are combined and analysed using this signal strength formalism and the results are presented in section 5. For all these signal strength fits, as well as for the generic parameterisations presented in section 4.1, the parameterisations of the expected yields in each analysis category are performed with a set of assumptions, which are needed because some production processes or decay modes, which are not specifically searched for, contribute to other channels. These assumptions are the following: for the production processes, the bbH signal strength is assumed to be the same as for ggF, the tH signal strength is assumed to be the same as for ttH, and the $ggZH$ signal strength is assumed to be the same as for quark-initiated ZH production; for the Higgs boson decays, the $H \to gg$ and $H \to cc$ signal strengths are assumed to be the same as for $H \to bb$ decays, and the $H \to Z\gamma$ signal strength is assumed to be the same as for $H \to \gamma\gamma$ decays.

2.4 Coupling modifiers

Based on a LO-motivated framework [32] (κ-framework), coupling modifiers have been proposed to interpret the LHC data by introducing specific modifications of the Higgs boson couplings related to BSM physics. Within the assumptions already mentioned in section 1, the production and decay of the Higgs boson can be factorised, such that the cross section times branching fraction of an individual channel $\sigma(i \to H \to f)$ contributing to a measured signal yield can be parameterised as:

$$\sigma_i \cdot \mathrm{B}^f = \frac{\sigma_i(\vec{\kappa}) \cdot \Gamma^f(\vec{\kappa})}{\Gamma_H}, \tag{2.3}$$

where Γ_H is the total width of the Higgs boson and Γ^f is the partial width for Higgs boson decay to the final state f. A set of coupling modifiers, $\vec{\kappa}$, is introduced to parameterise

JHEP08(2016)045

possible deviations from the SM predictions of the Higgs boson couplings to SM bosons and fermions. For a given production process or decay mode, denoted "j", a coupling modifier κ_j is defined such that:

$$\kappa_j^2 = \sigma_j/\sigma_j^{\mathrm{SM}} \quad \text{or} \quad \kappa_j^2 = \Gamma^j/\Gamma^j_{\mathrm{SM}}, \tag{2.4}$$

where all κ_j values equal unity in the SM; here, by construction, the SM cross sections and branching fractions include the best available higher-order QCD and EW corrections. This higher-order accuracy is not necessarily preserved for κ_j values different from unity, but the dominant higher-order QCD corrections factorise to a large extent from any rescaling of the coupling strengths and are therefore assumed to remain valid over the entire range of κ_j values considered in this paper. Different production processes and decay modes probe different coupling modifiers, as can be visualised from the Feynman diagrams shown in figures 1–6. Individual coupling modifiers, corresponding to tree-level Higgs boson couplings to the different particles, are introduced, as well as two effective coupling modifiers, κ_g and κ_γ, which describe the loop processes for ggF production and $H \to \gamma\gamma$ decay. This is possible because BSM particles that might be present in these loops are not expected to appreciably change the kinematics of the corresponding process. The $gg \to H$ and $H \to \gamma\gamma$ loop processes can thus be studied, either through these effective coupling modifiers, thereby providing sensitivity to potential BSM particles in the loops, or through the coupling modifiers corresponding to the SM particles. In contrast, the $gg \to ZH$ process, which occurs at LO through box and triangular loop diagrams (figures 2b and 2c), is always taken into account, within the limitations of the framework, by resolving the loop in terms of the corresponding coupling modifiers, κ_Z and κ_t.

Contributions from interference effects between the different diagrams provide some sensitivity to the relative signs of the Higgs boson couplings to different particles. As discussed in section 6.4, such effects are potentially largest for the $H \to \gamma\gamma$ decays, but may also be significant in the case of $ggZH$ and tH production. The ggF production process, when resolved in terms of its SM structure, provides sensitivity, although limited, to the relative signs of κ_t and κ_b through the t–b interference. The relative signs of the coupling modifiers κ_τ and κ_μ with respect to other coupling modifiers are not considered in this paper, since the current sensitivity to possible interference terms is negligible.

As an example of the possible size of such interference effects, the tH cross section is small in the SM, approximately 14% of the ttH cross section, because of destructive interference between diagrams involving the couplings to the W boson and the top quark, as shown in table 4. However, the interference becomes constructive for negative values of the product $\kappa_W \cdot \kappa_t$. In the specific case where $\kappa_W \cdot \kappa_t = -1$, the tHW and tHq cross sections increase by factors of 6 and 13, respectively, so that the tH process displays some sensitivity to the relative sign between the W boson and top quark couplings, despite its small SM cross section.

The relations among the coupling modifiers, the production cross sections σ_i, and partial decay widths Γ^f are derived within this context, as shown in table 4, and are used as a parameterisation to extract the coupling modifiers from the measurements. The coefficients are derived from Higgs production cross sections and decay rates evaluated including the

Table 4. Higgs boson production cross sections σ_i, partial decay widths Γ^f, and total decay width (in the absence of BSM decays) parameterised as a function of the κ coupling modifiers as discussed in the text, including higher-order QCD and EW corrections to the inclusive cross sections and decay partial widths. The coefficients in the expression for Γ_H do not sum exactly to unity because some contributions that are negligible or not relevant to the analyses presented in this paper are not shown.

JHEP08(2016)045

best available higher-order QCD and EW corrections (up to NNLO QCD and NLO EW precision), as indicated in tables 1 and 2. The numerical values are obtained from ref. [32] and are given for $\sqrt{s} = 8$ TeV and $m_H = 125.09$ GeV (they are similar for $\sqrt{s} = 7$ TeV). The current LHC data are insensitive to the coupling modifiers κ_c and κ_s, and have limited sensitivity to κ_μ. Thus, in the following, it is assumed that κ_c varies as κ_t, κ_s as κ_b, and κ_μ as κ_τ. Other coupling modifiers (κ_u, κ_d, and κ_e) are irrelevant for the combination provided they are of order unity. When probing the total width, the partial decay width Γ^{gg} is assumed to vary as κ_g^2. These assumptions are not the same as those described for the signal strength framework in section 2.3, so the two parameterisations are only approximately equivalent. The two sets of assumptions have a negligible impact on the measurements reported here provided that the unmeasured parameters do not deviate strongly from unity.

Changes in the values of the couplings will result in a variation of the Higgs boson width. A new modifier, κ_H, defined as $\kappa_H^2 = \sum_j \mathrm{B}_{\mathrm{SM}}^j \kappa_j^2$ and assumed to be positive without loss of generality, is introduced to characterise this variation. In the case where the SM decays of the Higgs boson are the only ones allowed, the relation $\kappa_H^2 = \Gamma_H/\Gamma_H^{\mathrm{SM}}$ holds. If instead deviations from the SM are introduced in the decays, the width Γ_H can be expressed as:

$$\Gamma_H = \frac{\kappa_H^2 \cdot \Gamma_H^{\mathrm{SM}}}{1 - \mathrm{B}_{\mathrm{BSM}}}, \tag{2.5}$$

where $\mathrm{B}_{\mathrm{BSM}}$ indicates the total branching fraction into BSM decays. Such BSM decays can be of three types: decays into BSM particles that are invisible to the detector because they do not appreciably interact with ordinary matter, decays into BSM particles that are not detected because they produce event topologies that are not searched for, or modifications of the decay branching fractions into SM particles in the case of channels that are not directly measured, such as $H \to cc$. Although direct and indirect experimental constraints on the Higgs boson width exist, they are either model dependent or are not stringent enough to constrain the present fits, and are therefore not included in the combinations. Since Γ_H is not experimentally constrained in a model-independent manner with sufficient precision, only ratios of coupling strengths can be measured in the most generic parameterisation considered in the κ-framework.

3 Combination procedure and experimental inputs

The individual ATLAS and CMS analyses of the Higgs boson production and decay rates are combined using the profile likelihood method described in section 3.2. The combination is based on simultaneous fits to the data from both experiments taking into account the correlations between systematic uncertainties within each experiment and between the two experiments. The analyses included in the combination, the statistical procedure used, the treatment of systematic uncertainties, and the changes made to the analyses for the combination are summarised in this section.

JHEP08(2016)045

3.1 Overview of input analyses

The individual analyses included in the combination were published separately by each experiment. Most of these analyses examine a specific Higgs boson decay mode, with categories related to the various production processes. They are $H \to \gamma\gamma$ [92, 93], $H \to ZZ$ [94, 95], $H \to WW$ [96–98], $H \to \tau\tau$ [99, 100], $H \to bb$ [101, 102], and $H \to \mu\mu$ [103, 104]. The ttH production process was also studied separately [78, 105–108] and the results are included in the combination. The $H \to \mu\mu$ analysis is included in the combination fit only for the measurement of the corresponding decay signal strength reported in section 5.2 and for the specific parameterisation of the coupling analysis described in section 6.2. It provides constraints on the coupling of the Higgs boson to second-generation fermions, but offers no relevant constraints for other parameterisations. The ATLAS [17] and CMS [18] individual combined publications take into account other results, such as upper limits on the $H \to Z\gamma$ decay [109, 110], results on VBF production in the $H \to bb$ decay channel [111], constraints on off-shell Higgs boson production [23, 24], and upper limits on invisible Higgs boson decays [112–114]. These results are not considered further here since they were not included in both combined publications of the individual experiments. In the case of the $H \to bb$ decay mode, the ggF production process is not considered by either experiment because of the overwhelming QCD multijet background.

Almost all input analyses are based on the concept of event categorisation. For each decay mode, events are classified in different categories, based on their kinematic characteristics and their detailed properties. This categorisation increases the sensitivity of the analysis and also allows separation of the different production processes on the basis of exclusive selections that identify the decay products of the particles produced in association with the Higgs boson: W or Z boson decays, VBF jets, and so on. A total of approximately 600 exclusive categories addressing the five production processes explicitly considered are defined for the five main decay channels. The exception is $H \to bb$, for which only the VH and ttH production processes are used in the combination for the reasons stated above.

The signal yield in a category k, $n_{\text{signal}}(k)$, can be expressed as a sum over all possible Higgs boson production processes i, with cross section σ_i, and decay modes f, with branching fraction B^f:

$$\begin{aligned} n_{\text{signal}}(k) &= \mathcal{L}(k) \cdot \sum_i \sum_f \left\{ \sigma_i \cdot A_i^{f,\mathrm{SM}}(k) \cdot \varepsilon_i^f(k) \cdot \mathrm{B}^f \right\} \\ &= \mathcal{L}(k) \cdot \sum_i \sum_f \mu_i \mu^f \left\{ \sigma_i^{\mathrm{SM}} \cdot A_i^{f,\mathrm{SM}}(k) \cdot \varepsilon_i^f(k) \cdot \mathrm{B}_{\mathrm{SM}}^f \right\}, \end{aligned} \tag{3.1}$$

where $\mathcal{L}(k)$ represents the integrated luminosity, $A_i^{f,\mathrm{SM}}(k)$ the detector acceptance assuming SM Higgs boson production and decay, and $\varepsilon_i^f(k)$ the overall selection efficiency for the signal category k. The symbols μ_i and μ^f are the production and decay signal strengths, respectively, defined in section 2.3. As eq. (3.1) shows, the measurements considered in this paper are only sensitive to the products of the cross sections and branching fractions, $\sigma_i \cdot \mathrm{B}^f$.

In the ideal case, each category would only contain signal events from a given production process and decay mode. Most decay modes approach this ideal case, but, in the

JHEP08(2016)045

case of the production processes, the categories are much less pure and there is significant cross-contamination in most channels.

3.2 Statistical treatment

The overall statistical methodology used in the combination to extract the parameters of interest in various parameterisations is the same as that used for the individual ATLAS and CMS combinations, as published in refs. [17, 18]. It was developed by the ATLAS and CMS Collaborations and is described in ref. [115]. Some details of this procedure are important for this combination and are briefly reviewed here.

The statistical treatment of the data is based on the standard LHC data modelling and handling toolkits: RooFit [116], RooStats [117], and HistFactory [118]. The parameters of interest, $\vec{\alpha}$, e.g. signal strengths (μ), coupling modifiers (κ), production cross sections, branching fractions, or ratios of the above quantities, are estimated, together with their corresponding confidence intervals, via the profile likelihood ratio test statistic $\Lambda(\vec{\alpha})$ [119]. The latter depends on one or more parameters of interest, as well as on the nuisance parameters, $\vec{\theta}$, which reflect various experimental or theoretical uncertainties:

$$\Lambda(\vec{\alpha}) = \frac{L\big(\vec{\alpha}\,,\,\hat{\hat{\vec{\theta}}}(\vec{\alpha})\big)}{L(\hat{\vec{\alpha}},\hat{\vec{\theta}})}. \tag{3.2}$$

The likelihood functions in the numerator and denominator of this equation are constructed using products of signal and background probability density functions (pdfs) of the discriminating variables. The pdfs are obtained from simulation for the signal and from both data and simulation for the background, as described in refs. [17, 18]. The vectors $\hat{\vec{\alpha}}$ and $\hat{\vec{\theta}}$ represent the unconditional maximum likelihood estimates of the parameter values, while $\hat{\hat{\vec{\theta}}}$ denotes the conditional maximum likelihood estimate for given values of the parameters of interest $\vec{\alpha}$. Systematic uncertainties and their correlations are a subset of the nuisance parameters $\vec{\theta}$, described by likelihood functions associated with the estimate of the corresponding parameter.

As an example of a specific choice of parameters of interest, the parameterisation considered in section 6.4 assumes that all fermion couplings are scaled by κ_F and all weak vector boson couplings by κ_V. The likelihood ratio is therefore a function of the two parameters of interest, κ_F and κ_V, and the profile likelihood ratio is expressed as:

$$\Lambda(\kappa_F,\kappa_V) = \frac{L\big(\kappa_F,\kappa_V,\hat{\hat{\vec{\theta}}}(\kappa_F,\kappa_V)\big)}{L(\hat{\kappa}_F,\hat{\kappa}_V,\hat{\vec{\theta}})}\,. \tag{3.3}$$

Likelihood fits are performed to determine the parameters of interest and their uncertainties, using the data to obtain the observed values and Asimov data sets to determine the predicted values in the SM. An Asimov data set [119] is a pseudo-data distribution that is equal to the signal plus background prediction for given values of the parameters of interest and of all nuisance parameters, and does not include statistical fluctuations. It is a representative data set of a given parameterisation that yields a result corresponding

JHEP08(2016)045

to the median of an ensemble of pseudo-experiments generated from the same parameterisation. A pre-fit Asimov data set is meant to represent the predictions of the theory, and all parameters are fixed to their estimates prior to the fit to the data.

These fits are rather challenging, involving many parameters of interest and a very large number of nuisance parameters. All the fit results were independently cross-checked to a very high level of precision by ATLAS and CMS, both for the combination and for the individual results. In particular, fine likelihood scans of all the parameters of interest were inspected to verify the convergence and stability of the fits.

For all results presented in this paper, unless otherwise stated, the negative log-likelihood estimator $q(\vec{\alpha}) = -2\ln\Lambda(\vec{\alpha})$ is assumed to follow a χ^2 distribution (asymptotic approximation). The 1σ and 2σ confidence level (CL) intervals for one-dimensional measurements are defined by requiring $q(\alpha_i) = 1$ and $q(\alpha_i) = 4$, respectively. In the case of disjoint intervals, the uncertainties corresponding only to the interval around the best fit value with $q(\alpha_i) < 1$ are also given for some parameterisations. The 68% (95%) confidence level regions for two-dimensional scans are defined at $q(\alpha_i) = 2.30$ (5.99). For the derivation of the upper limit on $\mathrm{B_{BSM}}$ in section 6.1, the test statistic $\tilde{t}(\alpha)$ of ref. [119] is used to account for the constraint $\alpha = \mathrm{B_{BSM}} \geq 0$. This is equivalent to the confidence interval estimation method of ref. [120]. The upper limit at 95% CL corresponds to $\tilde{t}(\alpha) = 3.84$. The p-values, characterising the compatibility of a fit result with a given hypothesis, are likewise computed in the asymptotic approximation.

3.3 Treatment of systematic uncertainties

The treatment of the systematic uncertainties and of their correlations is a crucial aspect of the combination of Higgs boson coupling measurements. The details of the chosen methodology for treating systematic uncertainties, characterised by nuisance parameters, are given in ref. [115]. The combined analysis presented here incorporates approximately 4200 nuisance parameters. A large fraction of these are statistical in nature, i.e. related to the finite size of the simulated samples used to model the expected signals and backgrounds, but are classified as part of the systematic uncertainties, as described below.

Nuisance parameters can be associated with a single analysis category or can be correlated between categories, channels, and/or experiments. A very important and delicate part of this combination is the estimation of the correlations between the various sources of systematic uncertainty, both between the various channels and between the two experiments. The correlations within each experiment are modelled following the procedure adopted for their individual combinations. The systematic uncertainties that are correlated between the two experiments are theoretical systematic uncertainties affecting the signal yield, certain theoretical systematic uncertainties in the background predictions, and a part of the experimental uncertainty related to the measurement of the integrated luminosity.

The main sources of theoretical uncertainties affecting the signal yield are the following: missing higher-order QCD corrections (estimated through variation of the QCD scales, i.e. renormalisation and factorisation scale) and uncertainties in parton distribution functions (PDF), in the treatment of UEPS, and in Higgs boson branching fractions.

JHEP08(2016)045

These uncertainties apply both to the inclusive cross sections and to the acceptances and selection efficiencies in the various categories. The PDF uncertainties in the inclusive rates are correlated between the two experiments for a given production process, but are treated as uncorrelated between different processes, except for the WH, ZH, and VBF production processes, where they are assumed to be fully correlated. A cross-check with the full PDF correlation matrix, as given in ref. [32], yields differences no larger than 1% for the generic parameterisations discussed in section 4. Similarly, QCD scale and UEPS uncertainties are assumed to be correlated between the two experiments in the same production processes and to be uncorrelated between different processes. The effects of correlations between Higgs boson branching fractions were determined to be negligible in general, and are ignored in the fits, except for the uncertainties in the branching fractions to WW and ZZ, which are assumed to be fully correlated. When measuring ratios, however, there are cases, e.g. the measurements of ratios of coupling modifiers described in section 4.2, where such uncertainties become the dominant theoretical uncertainties, and in these cases the full branching fraction correlation model specified in ref. [32] was applied. Other theoretical uncertainties in the signal acceptance and selection efficiencies are also usually small. They are estimated and treated in very different manners by the two experiments and therefore are assumed to be uncorrelated between ATLAS and CMS. It was verified that treating them as correlated would have a negligible impact on the results.

Whereas the signal selection criteria are quite inclusive in most channels, this is not the case for the backgrounds, which are often restricted to very limited regions of phase space and which are often treated differently by the two experiments. For these reasons, the ATLAS and CMS background modelling uncertainties cannot be easily correlated, even though such correlations should be considered for channels where they represent significant contributions to the overall systematic uncertainty. Obvious examples are those where the background estimates are obtained from simulation, as is the case for the ZZ continuum background in the $H \to ZZ$ channel, and for the ttW and ttZ backgrounds in the ttH multi-lepton channel. For these two cases, the background cross section uncertainties are treated as fully correlated between the two experiments. Other more complex examples are the WW continuum background in the $H \to WW$ channel, the $ttbb$ background in the $ttH, H \to bb$ channel, and the Wbb background in the $WH, H \to bb$ channel. In these cases, it was verified that the choice of not implementing correlations in the background modelling uncertainties between the two experiments has only a small impact on the measurements. The most significant impact was found for the $ttbb$ background in the $ttH, H \to bb$ channel, for which the choice of different correlation models between the two experiments yields an impact below 10% of the total uncertainty in the signal strength measurement in this specific channel.

Finally, all experimental systematic uncertainties are treated independently by the two experiments, reflecting independent assessments of these uncertainties, except for the integrated luminosity uncertainties, which are treated as partially correlated through the contribution arising from the imperfect knowledge of the beam currents in the LHC accelerator.

JHEP08(2016)045

The various sources of uncertainties can be broadly classified in four groups:

1. uncertainties (labelled as "stat" in the following) that are statistical in nature. In addition to the data, these include the statistical uncertainties in certain background control regions and certain fit parameters used to describe backgrounds measured from data, but they exclude the finite size of MC simulation samples;

2. theoretical uncertainties affecting the Higgs boson signal (labelled as "thsig" in the following);

3. theoretical uncertainties affecting background processes only (these are not correlated with any of the signal theoretical uncertainties and are labelled as "thbgd" in the following);

4. all other uncertainties (labelled as "expt" in the following), which include the experimental uncertainties and those related to the finite size of the MC simulation samples.

Some of the results are provided with a full breakdown of the uncertainties into these four categories, but, in most cases, the uncertainties are divided only into their statistical and systematic (syst) components. In some cases, as in section 4, when considering ratios of cross sections or coupling strengths, the theoretical systematic uncertainties are very small, because the signal normalisation uncertainties, which are in general dominant, do not affect the measurements. The precision with which the uncertainties and their components are quoted is typically of order 1% relative to the SM prediction.

As mentioned above, the Higgs boson mass is fixed, for all results reported in this paper, at the measured value of 125.09 GeV. The impact of the Higgs boson mass uncertainty (± 0.24 GeV) on the measurements has two main sources. One is the dependence of the $\sigma \cdot \mathrm{B}$ product on the mass. This dependence has an impact only on the measurements of the signal strengths and of the coupling modifiers, in which the SM signal yield predictions enter directly. The associated uncertainties are up to 4% for the signal strengths and 2% for the coupling modifiers. The other source of uncertainty is the dependence of the measured yields on the mass, arising from the fit to the mass spectra in the high-resolution $H \to \gamma\gamma$ and $H \to ZZ$ decay channels. In principle, this uncertainty affects all the measurements, including those related to the generic parameterisations, and is expected to be of the same order as the first one, namely 1% to 2%. In practice, since the measured masses in the $H \to \gamma\gamma$ and $H \to ZZ$ decay channels, resulting from the combination of ATLAS and CMS data, agree within 100 MeV, this uncertainty is less than 1% for all combined ATLAS and CMS measurements reported in this paper. Additional uncertainties of approximately 1% in the measurements of the Higgs boson signal strengths and coupling modifiers arise from the uncertainty in the LHC beam energy, which is estimated to be 0.66% at 8 TeV [121]. The uncertainties in the Higgs boson mass and the LHC beam energy are much smaller than the statistical uncertainties in the measurements and are neglected in the following.

JHEP08(2016)045

3.4 Analysis modifications for the combination

There are some differences in the treatment of signal and background in the combined analysis compared to the published analyses from each experiment. The differences are larger for CMS than for ATLAS, mainly because the CMS analyses were published earlier, before some refinements for the SM Higgs boson predictions were made available. The main differences are the following:

- ATLAS now uses the Stewart-Tackmann prescription [48] for the jet bin uncertainties in the $H \to WW$ channel instead of the jet-veto-efficiency procedure [49];
- CMS now includes the bbH, tH, and $ggZH$ production processes in the signal model for all the channels in which they are relevant;
- CMS now uses the signal cross section calculations from ref. [32] for all channels;
- CMS now adopts a unified prescription for the treatment of the Higgs boson p_{T} in the ggF production process, as described in section 2.2;
- The cross sections for the dominant backgrounds were adjusted to the most recent theoretical calculations in the cases where they are estimated from simulation (ZZ background in the $H \to ZZ$ channel and ttZ and ttW backgrounds in the ttH channels);
- Both experiments have adopted the same correlation scheme for some of the signal theoretical uncertainties: for example, the treatment of the PDF uncertainties in the signal production cross sections now follows a common scheme for all decay channels, as described in section 3.3.

The total effect of these modifications is small, both for the expected and observed results. All measurements differ from the individual combined results by less than approximately 10% of the total uncertainty for CMS and by even less for ATLAS.

Table 5 gives an overview of the Higgs boson decay and production processes that are combined in the following. To provide a snapshot of the relative importance of the various channels, the results from the analysis presented in this paper (tables 12 and 13 in section 5.2) are shown separately for each experiment, as measurements of the overall signal strengths μ, for each of the six decay channels and for the ttH production process. The total observed and expected statistical significances for $m_H = 125.09$ GeV are also shown, except for the $H \to \mu\mu$ channel, which has very low sensitivity. These results are quite close to those published for the individual analyses by each experiment, which are cited in table 5. For several decay channels, these refer only to the most sensitive analyses, e.g. the VH analysis for the $H \to bb$ decay channel. Even though they are less sensitive, the ttH analyses have a contribution from all the decay channels, and this is one of the reasons for quoting this production process specifically in this table. As stated above, the differences between the analysis in this paper and the published ones are also in part due to the different values assumed for the Higgs boson mass, and to adjustments in the various analyses for the purposes of this combination, mostly in terms of the signal modelling and of the treatment of the correlations of the signal theoretical uncertainties between different channels.

Table 5. Overview of the decay channels analysed in this paper. The ttH production process, which has contributions from all decay channels, is also shown. To show the relative importance of the various channels, the results from the combined analysis presented in this paper for $m_H = 125.09$ GeV (tables 12 and 13 in section 5.2) are reported as observed signal strengths μ with their measured uncertainties. The expected uncertainties are shown in parentheses. Also shown are the observed statistical significances, together with the expected significances in parentheses, except for the $H \to \mu\mu$ channel, which has very low sensitivity. For most decay channels, only the most sensitive analyses are quoted as references, e.g. the ggF and VBF analyses for the $H \to WW$ decay channel or the VH analysis for the $H \to bb$ decay channel. Although not exactly the same, the results are close to those from the individual publications, in which slightly different values for the Higgs boson mass were assumed and in which the signal modelling and signal uncertainties were slightly different, as discussed in the text.

4 Generic parameterisations of experimental results

This section describes three generic parameterisations and presents their results. The first two are based on cross sections and branching fractions, either expressed as independent products $\sigma_i \cdot \mathrm{B}^f$ for each channel $i \to H \to f$, or as ratios of cross sections and branching fractions plus one reference $\sigma_i \cdot \mathrm{B}^f$ product. In these parameterisations, the theoretical uncertainties in the signal inclusive cross sections for the various production processes do not affect the measured observables, in contrast to measurements of signal strengths, such

σ and B ratio parameterisation	Coupling modifier ratio parameterisation
$\sigma(gg \to H \to ZZ)$	$\kappa_{gZ} = \kappa_g \cdot \kappa_Z / \kappa_H$
$\sigma_{\mathrm{VBF}}/\sigma_{gg\mathrm{F}}$	
$\sigma_{WH}/\sigma_{gg\mathrm{F}}$	
$\sigma_{ZH}/\sigma_{gg\mathrm{F}}$	$\lambda_{Zg} = \kappa_Z/\kappa_g$
$\sigma_{ttH}/\sigma_{gg\mathrm{F}}$	$\lambda_{tg} = \kappa_t/\kappa_g$
$\mathrm{B}^{WW}/\mathrm{B}^{ZZ}$	$\lambda_{WZ} = \kappa_W/\kappa_Z$
$\mathrm{B}^{\gamma\gamma}/\mathrm{B}^{ZZ}$	$\lambda_{\gamma Z} = \kappa_\gamma/\kappa_Z$
$\mathrm{B}^{\tau\tau}/\mathrm{B}^{ZZ}$	$\lambda_{\tau Z} = \kappa_\tau/\kappa_Z$
$\mathrm{B}^{bb}/\mathrm{B}^{ZZ}$	$\lambda_{bZ} = \kappa_b/\kappa_Z$

Table 6. Parameters of interest in the two generic parameterisations described in sections 4.1.2 and 4.2. For both parameterisations, the $gg \to H \to ZZ$ channel is chosen as a reference, expressed through the first row in the table. All other measurements are expressed as ratios of cross sections or branching fractions in the first column and of coupling modifiers in the second column. There are fewer parameters of interest in the case of the coupling parameterisation, in which the ratios of cross sections for the WH, ZH, and VBF processes can all be expressed as functions of the two parameters, λ_{Zg} and λ_{WZ}. The slightly different additional assumptions in each parameterisation are discussed in the text.

as those described in section 2.3. These analyses lead to the most model-independent results presented in this paper and test, with minimal assumptions, the compatibility of the measurements with the SM. The third generic parameterisation is derived from the one described in section 2.4 and is based on ratios of coupling modifiers. None of these parameterisations incorporate any assumption about the Higgs boson total width other than the narrow-width approximation. Some theoretical and experimental systematic uncertainties largely cancel in the parameterisations involving ratios but at the current level of sensitivity the impact is small.

Table 6 gives an overview of the parameters of interest for the two generic parameterisations involving ratios which are described in more detail in sections 4.1.2 and 4.2. The first row makes explicit that the $gg \to H \to ZZ$ channel is chosen as a reference. The $\lambda_{Zg} = \kappa_Z/\kappa_g$ term in the fourth row is related to the ratio of the ZH and ggF production cross sections. Once $\lambda_{WZ} = \kappa_W/\kappa_Z$ is also specified, the VBF, WH, and ZH production cross sections are fully defined. This explains the smaller number of independent parameters of interest in the coupling modifier ratio parameterisation compared to the parameterisation based mostly on ratios of cross sections and branching fractions. In addition, these two parameterisations rely on slightly different assumptions and approximations, which are summarised in sections 2.3 and 2.4. These approximations are due to the fact that one cannot experimentally constrain all possible Higgs boson production processes and decay modes, in particular those that are expected to be small in the SM, but might be enhanced, should specific BSM physics scenarios be realised in nature.

Table 7. The signal parameterisation used to express the $\sigma_i \cdot \mathrm{B}^f$ values for each specific channel $i \to H \to f$. The values labelled with a "–" are not measured and are therefore fixed to the SM predictions.

4.1 Parameterisations using cross sections and branching fractions

4.1.1 Parameterisation using independent products of cross sections and branching fractions

In a very generic approach, one can extract for each specific channel $i \to H \to f$ a measurement of the product $\sigma_i \cdot \mathrm{B}^f$ and then compare it to the theoretical prediction. Based on all the categories considered in the various analyses and on the five production processes (ggF, VBF, WH, ZH, and ttH) and five main decay channels ($H \to ZZ$, $H \to WW$, $H \to \gamma\gamma$, $H \to \tau\tau$, and $H \to bb$) considered in this paper, there are in principle 25 such independent products to be measured. In practice, as already mentioned, the ggF and VBF production processes are not probed in the case of the $H \to bb$ decay mode and are assumed to have the values predicted by the SM, so the fit is performed with 23 parameters of interest, which are specified in table 7. The individual experiments cannot provide constraints on all the parameters of interest because of the low overall expected and observed yields in the current data. Even when combining the ATLAS and CMS data, the ZH, WH, and ttH production processes cannot be measured with meaningful precision in the $H \to ZZ$ decay channel. The fit results are therefore quoted only for the remaining 20 parameters and for the combined ATLAS and CMS data.

Table 8. Best fit values of $\sigma_i \cdot \mathrm{B}^f$ for each specific channel $i \to H \to f$, as obtained from the generic parameterisation with 23 parameters for the combination of the ATLAS and CMS measurements, using the $\sqrt{s} = 7$ and 8 TeV data. The cross sections are given for $\sqrt{s} = 8$ TeV, assuming the SM values for $\sigma_i(7\text{ TeV})/\sigma_i(8\text{ TeV})$. The results are shown together with their total uncertainties and their breakdown into statistical and systematic components. The expected uncertainties in the measurements are displayed in parentheses. The SM predictions [32] and the ratios of the results to these SM predictions are also shown. The values labelled with a "–" are either not measured with a meaningful precision and therefore not quoted, in the case of the $H \to ZZ$ decay channel for the WH, ZH, and ttH production processes, or not measured at all and therefore fixed to their corresponding SM predictions, in the case of the $H \to bb$ decay mode for the ggF and VBF production processes.

JHEP08(2016)045

Table 8 presents, for the combination of ATLAS and CMS, the fit results for each $\sigma_i \cdot \mathrm{B}^f$ product along with its statistical and systematic uncertainties. The corresponding SM predictions are also given. The ratios of the fit results to SM predictions are included in table 8 and displayed in figure 7. Figure 7 additionally shows the theoretical uncertainties in the SM predictions for the fitted parameters. In almost all cases, the dominant uncertainty is statistical. The results presented in table 8 and figure 7 clearly exhibit which decay modes are probed best for each production process, and conversely which production processes are probed best for each decay mode. With the current sensitivity of the combination, six of the $\sigma_i \cdot \mathrm{B}^f$ products can be measured with a precision better than 40%, namely the $H \to \gamma\gamma$, $H \to ZZ$, and $H \to WW$ decay modes for the ggF production process, and the $H \to \gamma\gamma$, $H \to WW$, and $H \to \tau\tau$ decay modes for the VBF production process. Because of the sizeable cross-contamination between the ggF and VBF categories, the corresponding results are significantly anticorrelated, as illustrated by the measured correlation matrix in figure 27 of appendix A.

4.1.2 Parameterisation using ratios of cross sections and branching fractions

If there is only one Higgs boson, each row or column in table 7 can be derived from the others by identical ratios of cross sections for the rows and of branching fractions for the columns. Therefore, in a second generic approach, ratios of cross sections and of branching fractions can be extracted from a combined fit to the data by normalising the yield of any specific channel $i \to H \to f$ to a reference process. In this paper, the $gg \to H \to ZZ$ channel is chosen as the reference because it has very little background and is one of the channels with the smallest overall and systematic uncertainties. The $gg \to H \to WW$ channel, which has the smallest overall uncertainty but larger systematic uncertainties, is used as an alternate reference for comparison, and the corresponding results are reported in appendix B.

The product of the cross section and the branching fraction of $i \to H \to f$ can then be expressed using the ratios as:

$$\sigma_i \cdot \mathrm{B}^f = \sigma(gg \to H \to ZZ) \cdot \left(\frac{\sigma_i}{\sigma_{gg\mathrm{F}}}\right) \cdot \left(\frac{\mathrm{B}^f}{\mathrm{B}^{ZZ}}\right), \tag{4.1}$$

where $\sigma(gg \to H \to ZZ) = \sigma_{gg\mathrm{F}} \cdot \mathrm{B}^{ZZ}$ in the narrow-width approximation. With $\sigma(gg \to H \to ZZ)$ constraining the overall normalisation, the ratios in eq. (4.1) can be determined separately, based on the five production processes (ggF, VBF, WH, ZH, and ttH) and five decay modes ($H \to ZZ$, $H \to WW$, $H \to \gamma\gamma$, $H \to \tau\tau$, and $H \to bb$). The combined fit results can be presented as a function of nine parameters of interest: one reference cross section times branching fraction, $\sigma(gg \to H \to ZZ)$, four ratios of production cross sections, $\sigma_i/\sigma_{gg\mathrm{F}}$, and four ratios of branching fractions, $\mathrm{B}^f/\mathrm{B}^{ZZ}$, as reported in the left column of table 6.

Expressing the measurements through ratios of cross sections and branching fractions has the advantage that the ratios are independent of the theoretical predictions for the inclusive production cross sections and decay branching fractions of the Higgs boson. In particular, they are not subject to the dominant signal theoretical uncertainties in the inclusive cross sections for the various production processes. These measurements will

JHEP08(2016)045

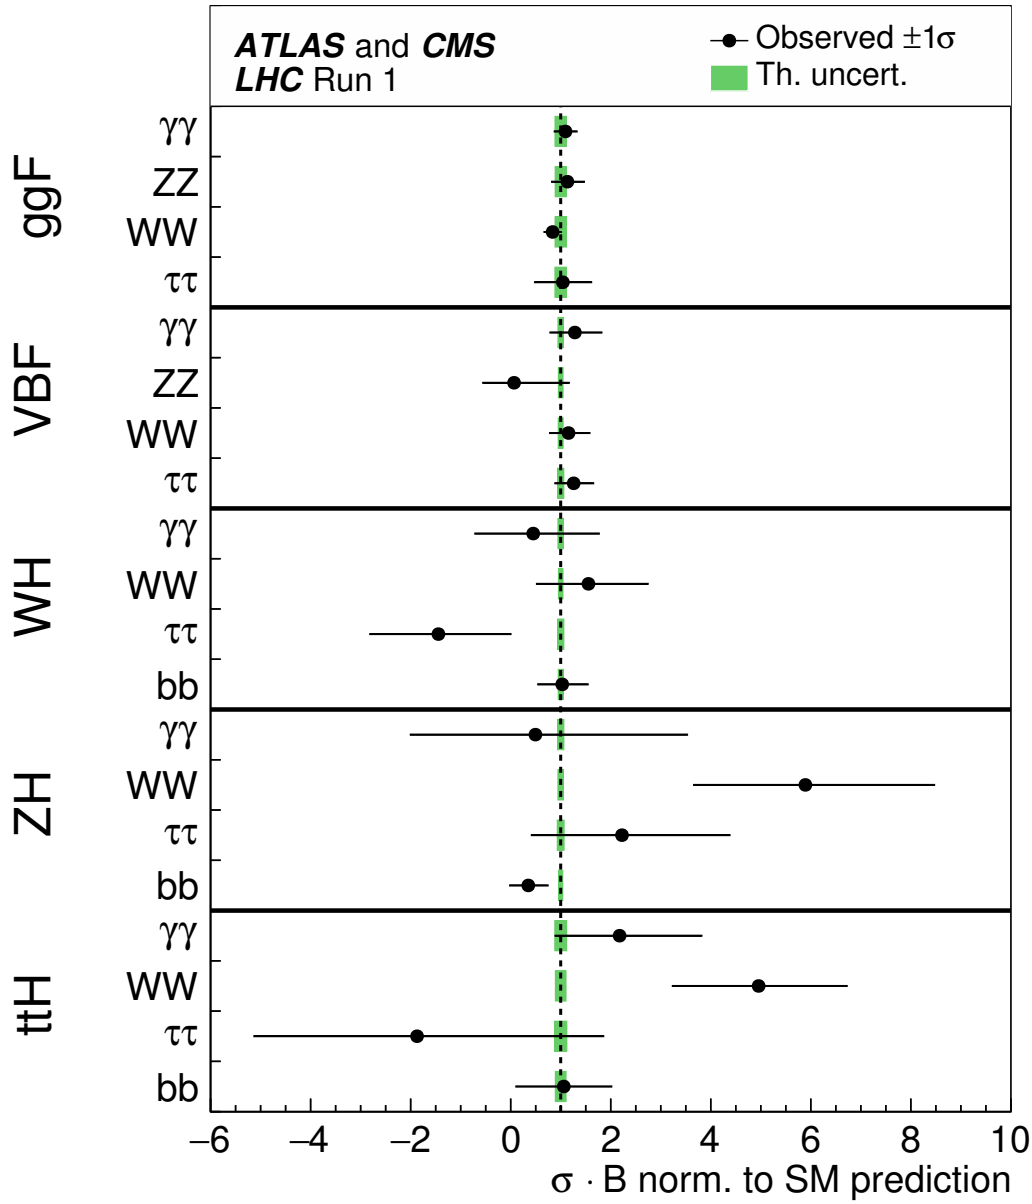

Figure 7. Best fit values of $\sigma_i \cdot \mathrm{B}^f$ for each specific channel $i \to H \to f$, as obtained from the generic parameterisation with 23 parameters for the combination of the ATLAS and CMS measurements. The error bars indicate the 1σ intervals. The fit results are normalised to the SM predictions for the various parameters and the shaded bands indicate the theoretical uncertainties in these predictions. Only 20 parameters are shown because some are either not measured with a meaningful precision, in the case of the $H \to ZZ$ decay channel for the WH, ZH, and ttH production processes, or not measured at all and therefore fixed to their corresponding SM predictions, in the case of the $H \to bb$ decay mode for the ggF and VBF production processes.

Table 9. Best fit values of $\sigma(gg \to H \to ZZ)$, $\sigma_i/\sigma_{gg\mathrm{F}}$, and $\mathrm{B}^f/\mathrm{B}^{ZZ}$, as obtained from the generic parameterisation with nine parameters for the combined analysis of the $\sqrt{s} = 7$ and 8 TeV data. The values involving cross sections are given for $\sqrt{s} = 8$ TeV, assuming the SM values for $\sigma_i(7\text{ TeV})/\sigma_i(8\text{ TeV})$. The results are reported for the combination of ATLAS and CMS and also separately for each experiment, together with their total uncertainties and their breakdown into statistical and systematic components. The expected uncertainties in the measurements are displayed in parentheses. The SM predictions [32] are also shown with their total uncertainties.

therefore remain valid when, for example, improved theoretical calculations of Higgs boson production cross sections become available. The remaining theoretical uncertainties are those related to the acceptances and selection efficiencies in the various categories, for which SM Higgs boson production and decay kinematics are assumed in the simulation, based on the MC generators discussed in section 2.2.

Table 9 shows the results of the fit to the data with a breakdown of the uncertainties into their statistical and systematic components. The full breakdown of the uncertainties into the four components is shown in table 20 of appendix B, while the measured correlation matrix can be found in figure 28 of appendix A. The results are shown for the combination of ATLAS and CMS and also separately for each experiment. They are illustrated in figure 8, where the fit result for each parameter is normalised to the corresponding SM prediction. Also shown in figure 8 are the theoretical uncertainties in the SM predictions for the fitted parameters. For the ratios of branching fractions, the theoretical uncertainties in the predictions are barely visible since they are below 5%. Compared to the results of the fit of table 8, where the ggF parameters are independent for each decay mode, the uncertainties

JHEP08(2016)045

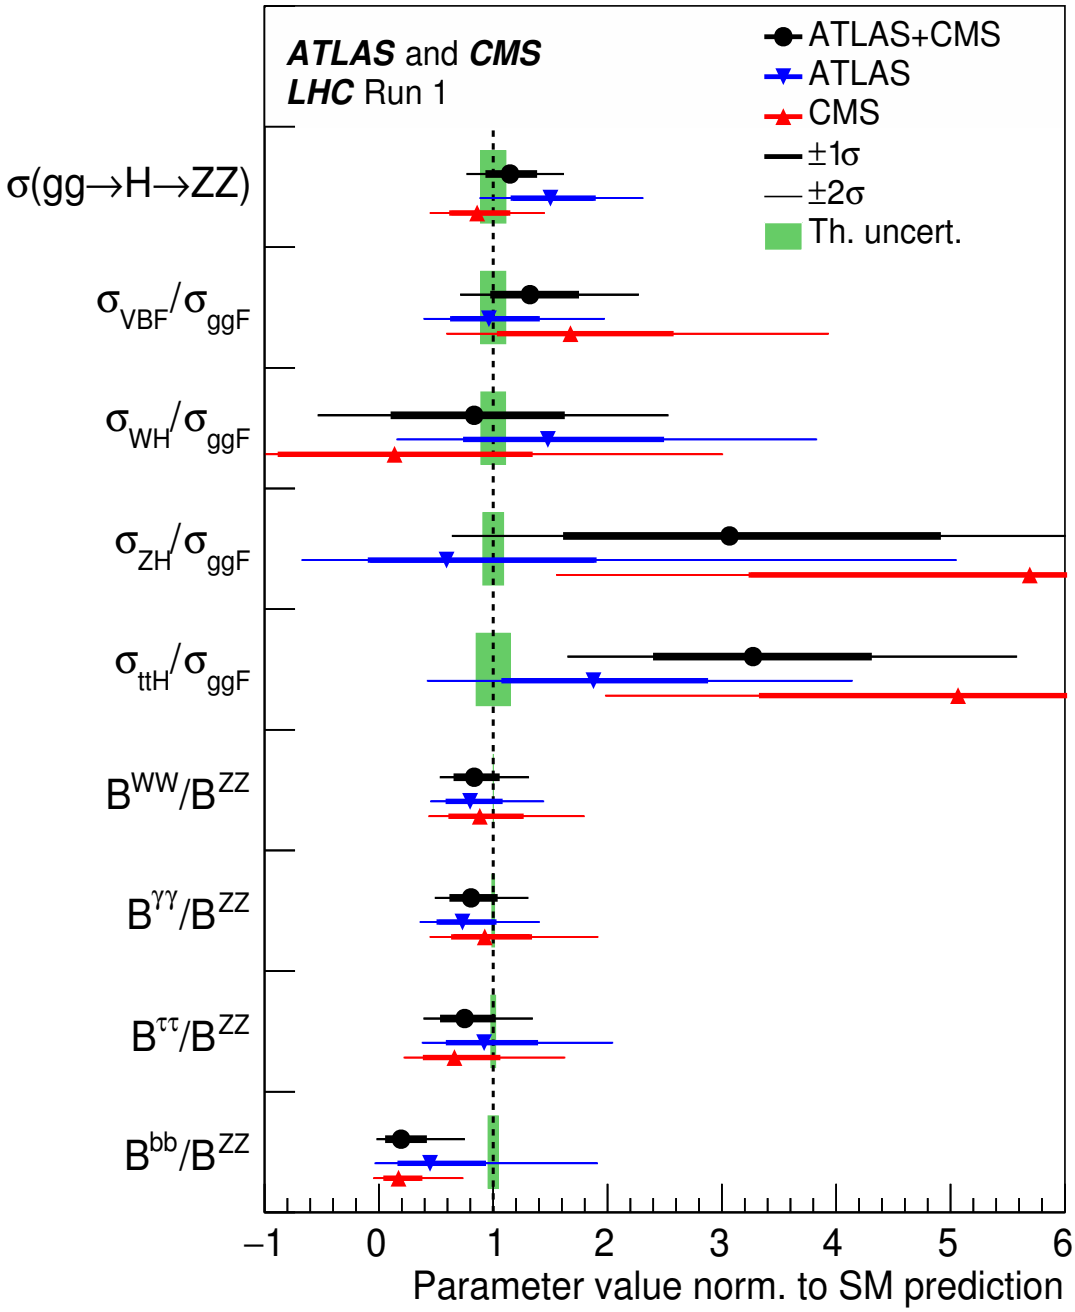

Figure 8. Best fit values of the $\sigma(gg \to H \to ZZ)$ cross section and of ratios of cross sections and branching fractions, as obtained from the generic parameterisation with nine parameters and tabulated in table 9 for the combination of the ATLAS and CMS measurements. Also shown are the results from each experiment. The values involving cross sections are given for $\sqrt{s} = 8\,\text{TeV}$, assuming the SM values for $\sigma_i(7\ \text{TeV})/\sigma_i(8\ \text{TeV})$. The error bars indicate the 1σ (thick lines) and 2σ (thin lines) intervals. The fit results are normalised to the SM predictions for the various parameters and the shaded bands indicate the theoretical uncertainties in these predictions.

JHEP08(2016)045

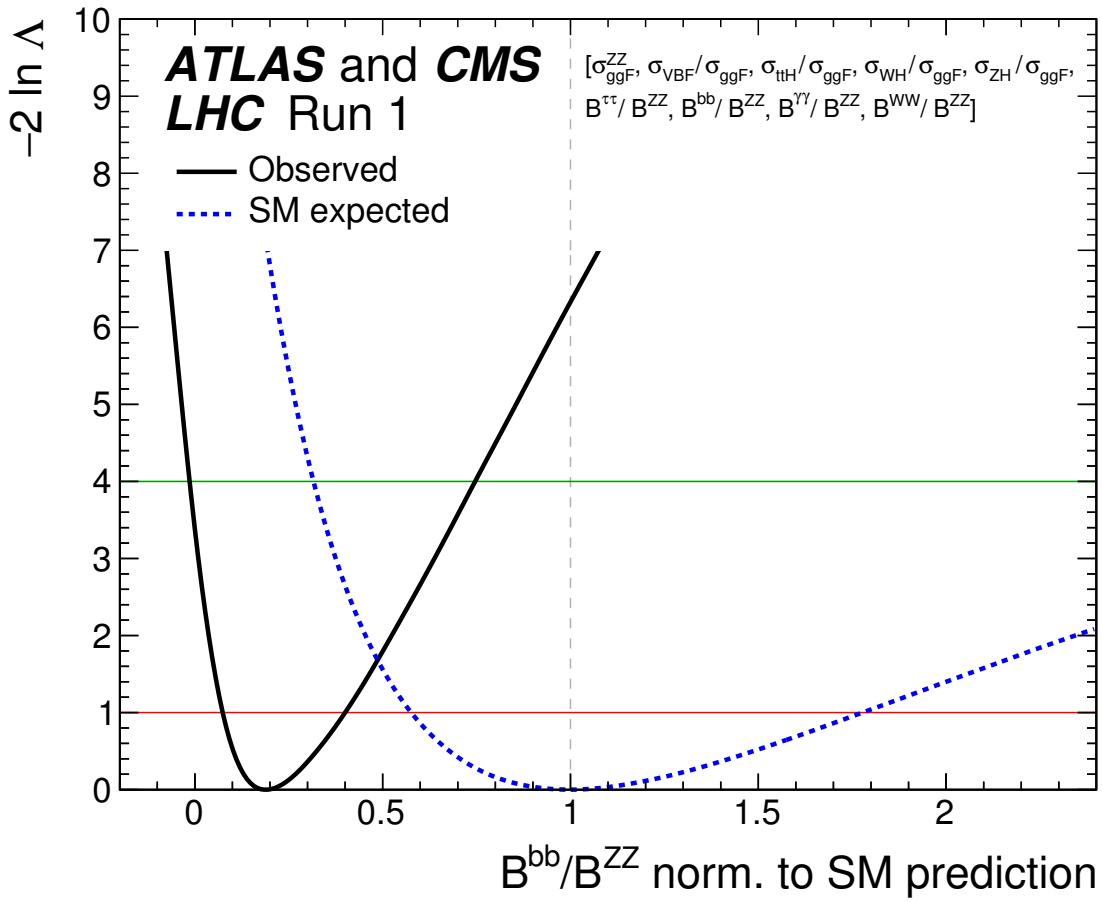

Figure 9. Observed (solid line) and expected (dashed line) negative log-likelihood scan of the B^{bb}/B^{ZZ} parameter normalised to the corresponding SM prediction. All the other parameters of interest are also varied in the minimisation procedure. The red (green) horizontal line at the $-2\Delta \ln \Lambda$ value of 1 (4) indicates the value of the profile likelihood ratio corresponding to a 1σ (2σ) CL interval for the parameter of interest, assuming the asymptotic χ^2 distribution of the test statistic. The vertical dashed line indicates the SM prediction.

in $\sigma(gg \to H \to ZZ)$ are reduced by almost a factor of two in table 9, owing to the contributions from the other decay channels (mainly $H \to \gamma\gamma$ and $H \to WW$). The total uncertainty in $\sigma(gg \to H \to ZZ)$ is approximately 18%, with its main contribution coming from the statistical uncertainty. The total relative systematic uncertainty is only ∼4%. Appendix B shows the results obtained when choosing the $H \to WW$ decay mode as an alternative reference process. This yields a smaller total uncertainty of approximately 15% in $\sigma(gg \to H \to WW)$, but with a much larger contribution of ∼11% from the systematic uncertainties. The ratios $\sigma_{\mathrm{VBF}}/\sigma_{gg\mathrm{F}}$, B^{WW}/B^{ZZ}, $B^{\gamma\gamma}/B^{ZZ}$, and $B^{\tau\tau}/B^{ZZ}$ are measured with relative uncertainties of 30–40%.

The p-value of the compatibility between the data and the SM predictions is 16%. Most measurements are consistent with the SM predictions within less than 2σ; however, the

Table 10. Best fit values of $\kappa_{gZ} = \kappa_g \cdot \kappa_Z/\kappa_H$ and of the ratios of coupling modifiers, as defined in the parameterisation studied in the context of the κ-framework, from the combined analysis of the $\sqrt{s} = 7$ and 8 TeV data. The results are shown for the combination of ATLAS and CMS and also separately for each experiment, together with their total uncertainties and their breakdown into statistical and systematic components. The uncertainties in λ_{tg} and λ_{WZ}, for which a negative solution is allowed, are calculated around the overall best fit value. The combined 1σ CL intervals are $\lambda_{tg} = [-2.00, -1.59] \cup [1.50, 2.07]$ and $\lambda_{WZ} = [-0.96, -0.82] \cup [0.80, 0.98]$. The expected uncertainties in the measurements are displayed in parentheses. For those parameters with no sensitivity to the sign, only the absolute values are shown.

production cross section ratio $\sigma_{ttH}/\sigma_{ggF}$ relative to the SM ratio is measured to be $3.3^{+1.0}_{-0.9}$, corresponding to an excess of approximately 3.0σ relative to the SM prediction. This excess is mainly due to the multi-lepton categories. The ratio σ_{ZH}/σ_{ggF} relative to the SM ratio is measured to be $3.2^{+1.8}_{-1.4}$, with the observed excess mainly due to the ZH, $H \to WW$ measurements. The ratio of branching fractions B^{bb}/B^{ZZ} is measured to be $0.19^{+0.21}_{-0.12}$ relative to the SM prediction. In this parameterisation, the high values found for the production cross section ratios for the ZH and ttH processes induce a low value for the $H \to bb$ decay branching fraction because the $H \to bb$ decay mode does not contribute to the observed excesses. The likelihood scan of the B^{bb}/B^{ZZ} parameter is very asymmetric, as shown in figure 9, resulting in an overall deficit of approximately 2.5σ relative to the SM prediction. This deviation is anticorrelated with the ones quoted above for the $\sigma_{ttH}/\sigma_{ggF}$ and σ_{ZH}/σ_{ggF} production cross section ratios, as shown in figure 28 of appendix A.

JHEP08(2016)045

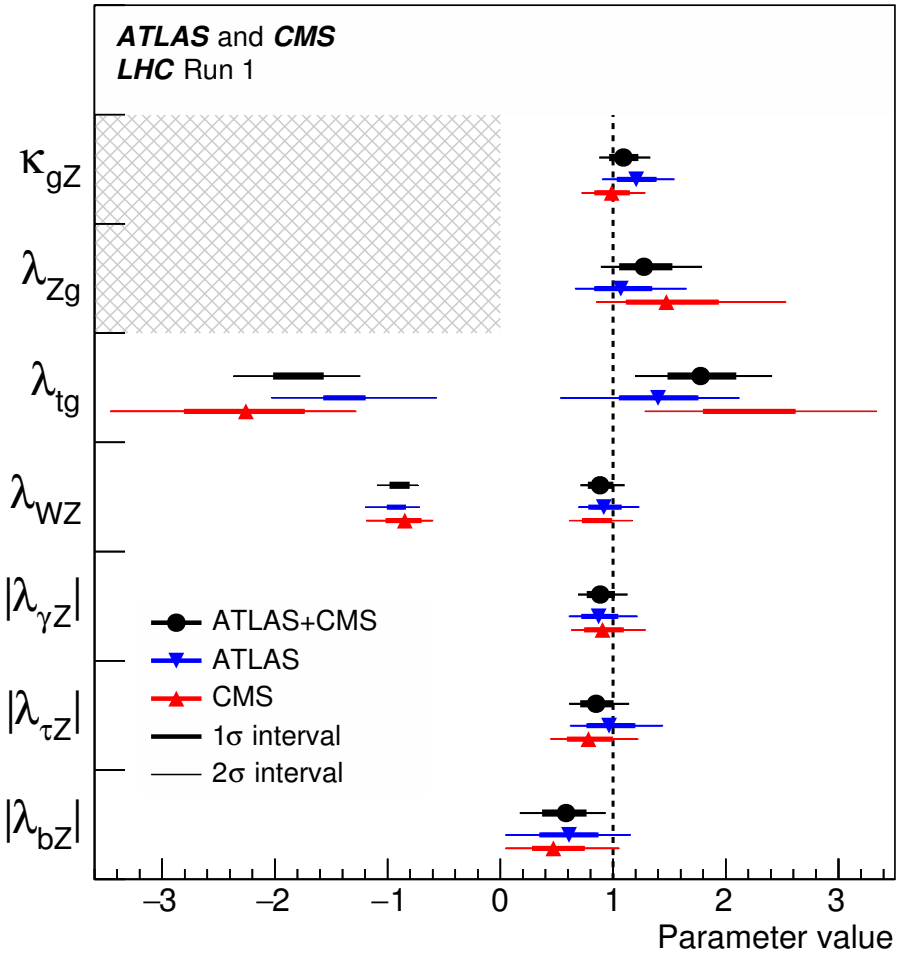

Figure 10. Best fit values of ratios of Higgs boson coupling modifiers, as obtained from the generic parameterisation described in the text and as tabulated in table 10 for the combination of the ATLAS and CMS measurements. Also shown are the results from each experiment. The error bars indicate the 1σ (thick lines) and 2σ (thin lines) intervals. The hatched areas indicate the non-allowed regions for the parameters that are assumed to be positive without loss of generality. For those parameters with no sensitivity to the sign, only the absolute values are shown.

In the various fits, the combination of the 7 and 8 TeV data is performed assuming that the ratios of the production cross sections at 7 and 8 TeV are the same as in the SM. One can introduce as free parameters in the fit the ratios of the production cross sections at 7 and 8 TeV of the five main production processes: $\sigma_i(7\text{TeV})/\sigma_i(8\text{TeV})$. Given the limited size of the data samples at 7 TeV, only the ggF and VBF ratios can be extracted with a meaningful precision. The results are: $\sigma_{gg\text{F}}(7\text{ TeV})/\sigma_{gg\text{F}}(8\text{ TeV}) = 1.12^{+0.33}_{-0.29}$ and $\sigma_{\text{VBF}}(7\text{ TeV})/\sigma_{\text{VBF}}(8\text{ TeV}) = 0.37^{+0.49}_{-0.43}$. Both values are consistent with the SM predictions of $\sigma_{gg\text{F}}(7\text{ TeV})/\sigma_{gg\text{F}}(8\text{ TeV}) = 0.78$ and $\sigma_{\text{VBF}}(7\text{ TeV})/\sigma_{\text{VBF}}(8\text{ TeV}) = 0.77$.

JHEP08(2016)045

4.2 Parameterisation using ratios of coupling modifiers

The parameterisation using the Higgs boson coupling modifiers is based on the κ-framework described in section 2.4 and the parameters of interest are listed in the right column of table 6. The cross section times branching fraction for the $gg \to H \to ZZ$ channel is parameterised as a function of $\kappa_{gZ} = \kappa_g \cdot \kappa_Z/\kappa_H$, where κ_g is the effective coupling modifier of the Higgs boson to the gluon in ggF production, which in the SM occurs mainly through loops involving top and bottom quarks. The $\lambda_{Zg} = \kappa_Z/\kappa_g$ parameter is probed by the measurements of VBF and ZH production, while the measurements of the ttH production process are sensitive to $\lambda_{tg} = \kappa_t/\kappa_g$. Three of the decay modes, namely $H \to WW$, $H \to \tau\tau$, and $H \to bb$, probe the three ratios $\lambda_{WZ} = \kappa_W/\kappa_Z$, $\lambda_{\tau Z} = \kappa_\tau/\kappa_Z$, and $\lambda_{bZ} = \kappa_b/\kappa_Z$, through their respective ratios to the $H \to ZZ$ branching fraction. The remaining decay mode, $H \to \gamma\gamma$, which in the SM occurs through loops involving predominantly the top quark and the W boson, is sensitive to the ratio $\lambda_{\gamma Z} = \kappa_\gamma/\kappa_Z$. In this parameterisation, $\lambda_{WZ} = \kappa_W/\kappa_Z$ is also probed by the VBF, WH, and ZH production processes. Without any loss of generality, the signs of κ_Z and κ_g can be assumed to be the same, constraining λ_{Zg} and κ_{gZ} to be positive.

Table 10 shows the results of the fit to the data with a breakdown of uncertainties into their statistical and systematic components, while the complete breakdown of the uncertainties into the four components is shown in table 22 of appendix B. The measured correlation matrix can be found in figure 29 of appendix A. The coupling modifiers are assumed to be the same at the two centre-of-mass energies, as in the parameterisation based on the ratios of cross sections and branching fractions. Figure 10 illustrates the complete ranges of allowed values with their total uncertainties, including the negative ranges allowed for λ_{WZ} and λ_{tg}, the two parameters chosen to illustrate possible interference effects due to $ggZH$ or tH production. Figure 11 shows the likelihood scan results for these two parameters for the combination of ATLAS and CMS, both for the observed and expected results. As described in section 2.4, the interference terms are responsible for the small asymmetry between the likelihood curves for the positive and negative values of the parameters of interest. In both cases, the best fit values correspond to the positive sign, but the sensitivity to the interference terms remains small. Appendix C, with the specific example of λ_{bZ} (shown in figure 31), describes how the four possible sign combinations between λ_{WZ} and λ_{tg} may impact the best fit value and the uncertainty in the other parameters of interest. The p-value of the compatibility between the data and the SM predictions is 13%. All results are consistent with the SM predictions within less than 2σ, except those for λ_{tg} and λ_{bZ}, which exhibit deviations from the SM similar to those reported and explained in section 4.1.2 for the measurement of the ratios of the ttH and ggF production cross sections, and of the ratios of the bb and ZZ decay branching fractions.

5 Measurements of signal strengths

Section 4.1 presents the results from generic parameterisations, expressed in terms of cross sections and branching fractions. This section probes more specific parameterisations, with additional assumptions. Results for these parameterisations are presented, starting with

JHEP08(2016)045

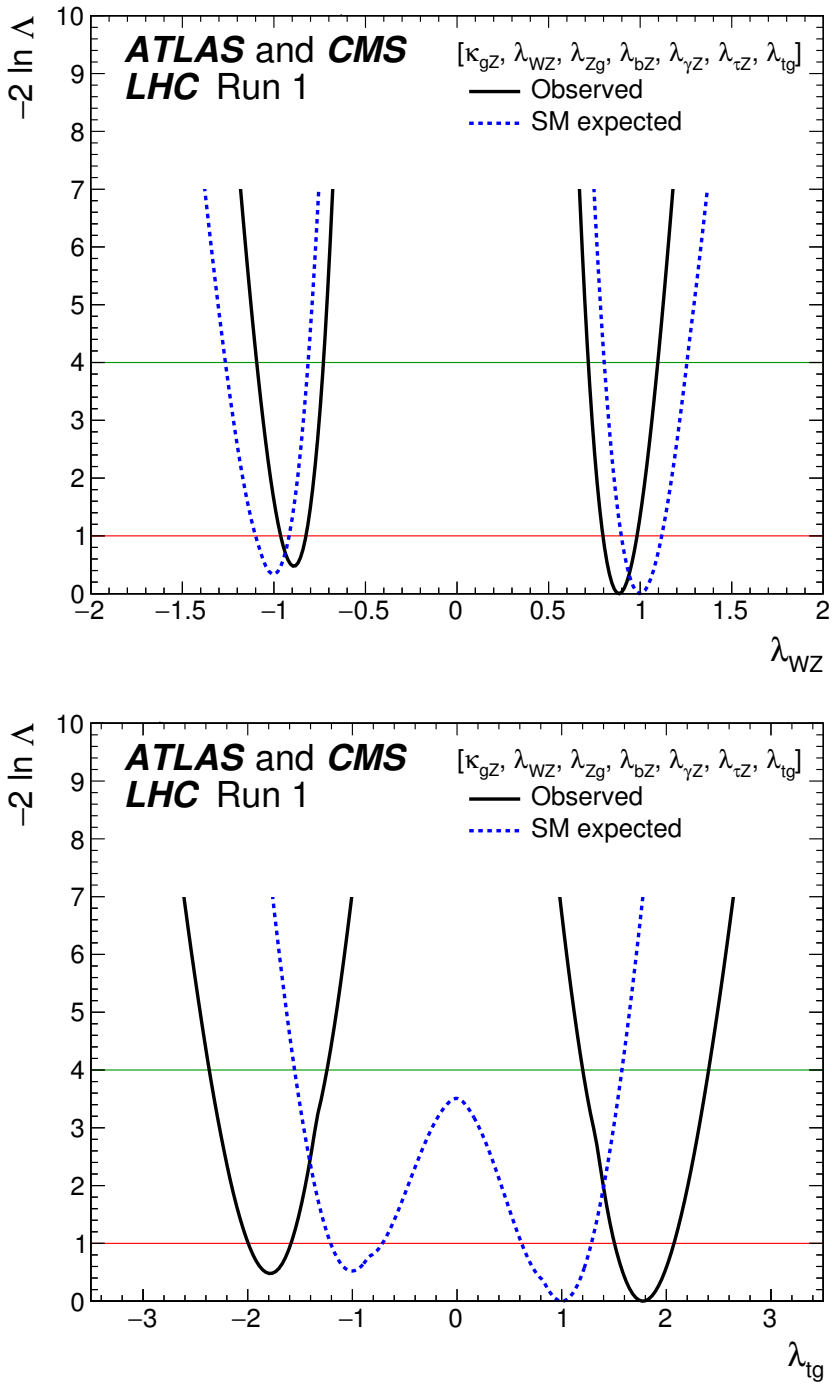

Figure 11. Observed (solid line) and expected (dashed line) negative log-likelihood scans for λ_{WZ} (top) and λ_{tg} (bottom), the two parameters of figure 10 that are of interest in the negative range in the generic parameterisation of ratios of Higgs boson coupling modifiers described in the text. All the other parameters of interest from the list in the legend are also varied in the minimisation procedure. The red (green) horizontal lines at the $-2\Delta \ln \Lambda$ value of 1 (4) indicate the value of the profile likelihood ratio corresponding to a 1σ (2σ) CL interval for the parameter of interest, assuming the asymptotic χ^2 distribution of the test statistic.

Table 11. Measured global signal strength μ and its total uncertainty, together with the breakdown of the uncertainty into its four components as defined in section 3.3. The results are shown for the combination of ATLAS and CMS, and separately for each experiment. The expected uncertainty, with its breakdown, is also shown.

the most restrictive one using a single parameter of interest, which was used to assess the sensitivity of the experimental analyses to the presence of a Higgs boson at the time of its discovery. Section 5.4 describes the test of a hypothesis that two or more neutral Higgs bosons might be present with similar masses.

5.1 Global signal strength

The simplest and most restrictive signal strength parameterisation is to assume that the values of the signal strengths μ_i^f, as defined in eq. (2.2), are the same for all production processes i and decay channels f. In this case, the SM predictions of signal yields in all categories are scaled by a global signal strength μ. Such a parameterisation provides the simplest test of the compatibility of the experimental data with the SM predictions. A fit to the ATLAS and CMS data at $\sqrt{s} = 7$ and 8 TeV with μ as the parameter of interest results in the best fit value:

$$\mu = 1.09^{+0.11}_{-0.10} = 1.09^{+0.07}_{-0.07}\ (\text{stat})\ ^{+0.04}_{-0.04}\ (\text{expt})\ ^{+0.03}_{-0.03}\ (\text{thbgd})^{+0.07}_{-0.06}\ (\text{thsig}),$$

where the breakdown of the uncertainties into their four components is performed as described in section 3.3. The overall systematic uncertainty of $^{+0.09}_{-0.08}$ is larger than the statistical uncertainty and its largest component is the theoretical uncertainty in the ggF cross section. This result is consistent with the SM prediction of $\mu = 1$ within less than 1σ and the p-value of the compatibility between the data and the SM predictions is 40%. This result is shown in table 11, together with that from each experiment, including the breakdown of the uncertainties into their four components. The expected uncertainties and their breakdown are also given.

Table 12. Measured signal strengths μ and their total uncertainties for different Higgs boson production processes. The results are shown for the combination of ATLAS and CMS, and separately for each experiment, for the combined $\sqrt{s} = 7$ and 8 TeV data. The expected uncertainties in the measurements are displayed in parentheses. These results are obtained assuming that the Higgs boson branching fractions are the same as in the SM.

5.2 Signal strengths of individual production processes and decay channels

The global signal strength is the most precisely measured Higgs boson coupling-related observable, but this simple parameterisation is very model dependent, since all Higgs boson production and decay measurements are combined assuming that all their ratios are the same as in the SM. The compatibility of the measurements with the SM can be tested in a less model-dependent way by relaxing these assumptions separately for the production cross sections and the decay branching fractions.

Assuming the SM values for the Higgs boson branching fractions, namely $\mu^f = 1$ in eq. (3.1), the five main Higgs boson production processes are explored with independent signal strengths: μ_{ggF}, μ_{VBF}, μ_{WH}, μ_{ZH}, and μ_{ttH}. A combined analysis of the ATLAS and CMS data is performed with these five signal strengths as parameters of interest. The results are shown in table 12 for the combined $\sqrt{s} = 7$ and 8 TeV data sets. The signal strengths at the two energies are assumed to be the same for each production process. Figure 12 illustrates these results with their total uncertainties. The p-value of the compatibility between the data and the SM predictions is 24%.

JHEP08(2016)045

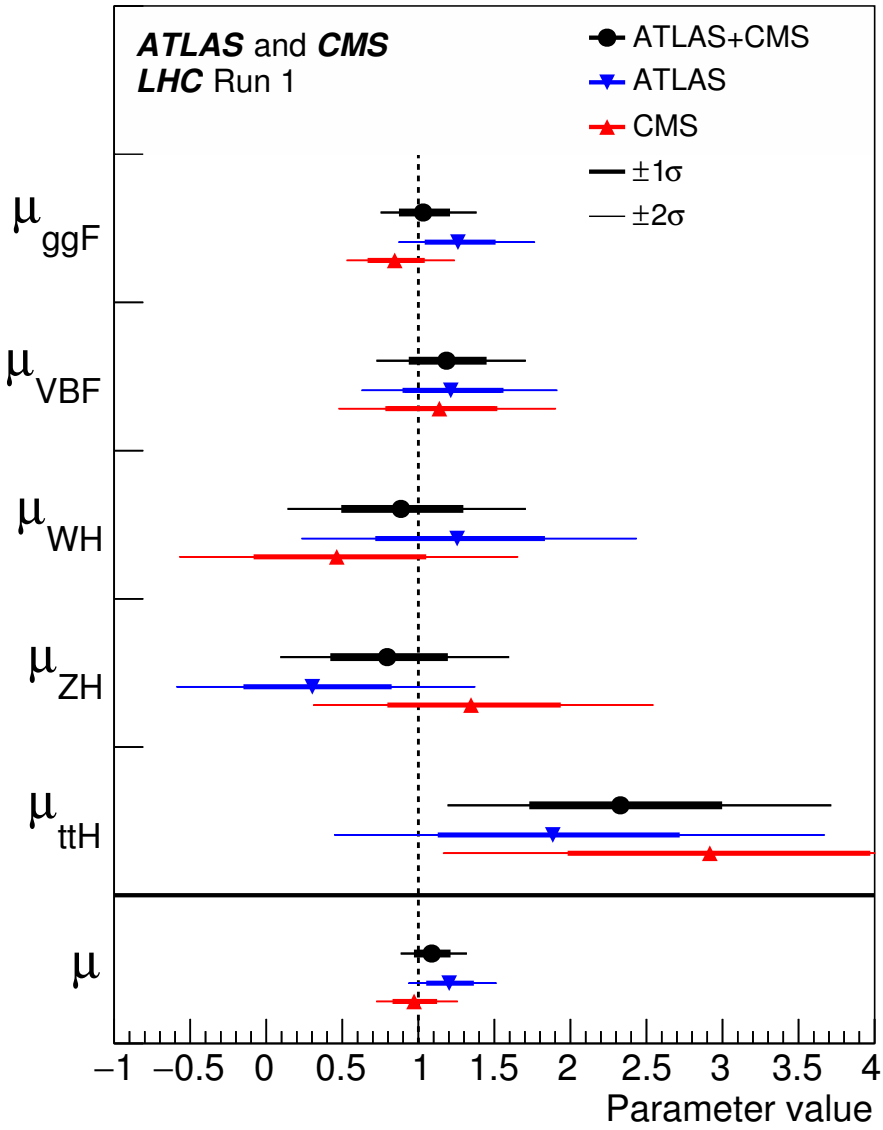

Figure 12. Best fit results for the production signal strengths for the combination of ATLAS and CMS data. Also shown are the results from each experiment. The error bars indicate the 1σ (thick lines) and 2σ (thin lines) intervals. The measurements of the global signal strength μ are also shown.

Higgs boson decays are also studied with six independent signal strengths, one for each decay channel included in the combination, assuming that the Higgs boson production cross sections are the same as in the SM. Unlike the production signal strengths, these decay-based signal strengths are independent of the collision centre-of-mass energy and therefore the $\sqrt{s} = 7$ and 8 TeV data sets can be combined without additional assumptions. Table 13 and figure 13 present the best fit results for the combination of ATLAS and CMS, and separately for each experiment (the results for $\mu^{\mu\mu}$ are only reported in table 13). The p-value of the compatibility between the data and the SM predictions is 75%.

JHEP08(2016)045

$\mu^{\gamma\gamma}$	$1.14\,^{+0.19}_{-0.18}$ $\left(^{+0.18}_{-0.17}\right)$	$1.14\,^{+0.27}_{-0.25}$ $\left(^{+0.26}_{-0.24}\right)$	$1.11\,^{+0.25}_{-0.23}$ $\left(^{+0.23}_{-0.21}\right)$
μ^{ZZ}	$1.29\,^{+0.26}_{-0.23}$ $\left(^{+0.23}_{-0.20}\right)$	$1.52\,^{+0.40}_{-0.34}$ $\left(^{+0.32}_{-0.27}\right)$	$1.04\,^{+0.32}_{-0.26}$ $\left(^{+0.30}_{-0.25}\right)$
μ^{WW}	$1.09\,^{+0.18}_{-0.16}$ $\left(^{+0.16}_{-0.15}\right)$	$1.22\,^{+0.23}_{-0.21}$ $\left(^{+0.21}_{-0.20}\right)$	$0.90\,^{+0.23}_{-0.21}$ $\left(^{+0.23}_{-0.20}\right)$
$\mu^{\tau\tau}$	$1.11\,^{+0.24}_{-0.22}$ $\left(^{+0.24}_{-0.22}\right)$	$1.41\,^{+0.40}_{-0.36}$ $\left(^{+0.37}_{-0.33}\right)$	$0.88\,^{+0.30}_{-0.28}$ $\left(^{+0.31}_{-0.29}\right)$
μ^{bb}	$0.70\,^{+0.29}_{-0.27}$ $\left(^{+0.29}_{-0.28}\right)$	$0.62\,^{+0.37}_{-0.37}$ $\left(^{+0.39}_{-0.37}\right)$	$0.81\,^{+0.45}_{-0.43}$ $\left(^{+0.45}_{-0.43}\right)$
$\mu^{\mu\mu}$	$0.1\,^{+2.5}_{-2.5}$ $\left(^{+2.4}_{-2.3}\right)$	$-0.6\,^{+3.6}_{-3.6}$ $\left(^{+3.6}_{-3.6}\right)$	$0.9\,^{+3.6}_{-3.5}$ $\left(^{+3.3}_{-3.2}\right)$

Table 13. Measured signal strengths μ and their total uncertainties for different Higgs boson decay channels. The results are shown for the combination of ATLAS and CMS, and separately for each experiment, for the combined $\sqrt{s} = 7$ and 8 TeV data. The expected uncertainties in the measurements are displayed in parentheses. These results are obtained assuming that the Higgs boson production process cross sections at $\sqrt{s} = 7$ and 8 TeV are the same as in the SM.

From the combined likelihood scans it is possible to evaluate the significances for the observation of the different production processes and decay channels. The combination of the data from the two experiments corresponds to summing their recorded integrated luminosities and consequently increases the sensitivity by approximately a factor of $\sqrt{2}$, since the theoretical uncertainties in the Higgs boson signal are only weakly relevant for this evaluation and all the other significant uncertainties are uncorrelated between the two experiments. The results are reported in table 14 for all production processes and decay channels, except for those that have already been clearly observed, namely the ggF production process and the $H \to ZZ$, $H \to WW$, and $H \to \gamma\gamma$ decay channels. The combined significances for the observation of the VBF production process and of the $H \to \tau\tau$ decay are each above 5σ, and the combined significance for the VH production process is above 3σ. The combined significance for the ttH process is 4.4σ, whereas only 2.0σ is expected, corresponding to a measured excess of 2.3σ with respect to the SM prediction.

JHEP08(2016)045

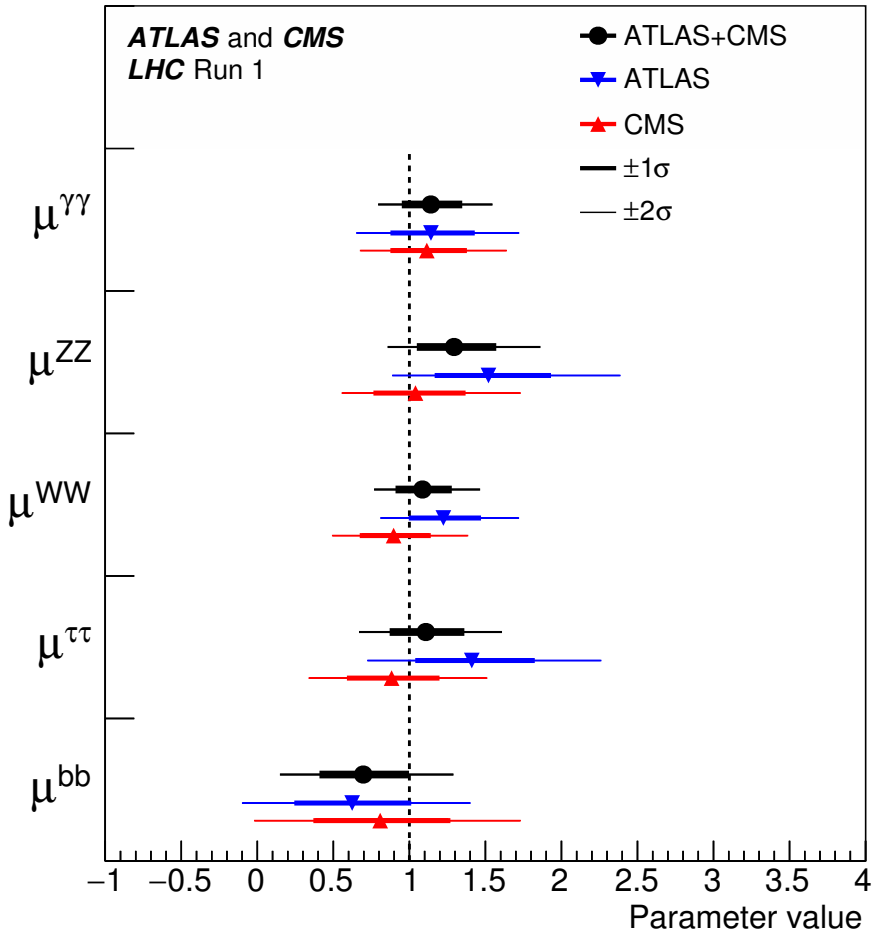

Figure 13. Best fit results for the decay signal strengths for the combination of ATLAS and CMS data (the results for $\mu^{\mu\mu}$ are reported in table 13). Also shown are the results from each experiment. The error bars indicate the 1σ (thick lines) and 2σ (thin lines) intervals.

5.3 Boson- and fermion-mediated production processes

The Higgs boson production processes can be associated with Higgs boson couplings to either fermions (ggF and ttH) or vector bosons (VBF, WH, and ZH). Potential deviations of these couplings from the SM predictions can be tested by using a parameterisation with two signal strengths for each decay channel f: $\mu_F^f = \mu_{gg\mathrm{F}+ttH}^f$ for the fermion-mediated production processes and $\mu_V^f = \mu_{\mathrm{VBF}+VH}^f$ for the vector-boson-mediated production processes. The branching fraction cancels in the ratio μ_V^f/μ_F^f that can be formed for each Higgs boson decay channel. Two fits are performed for the combination of ATLAS and CMS, and also separately for each experiment. The first is a ten-parameter fit of μ_F^f and μ_V^f for each of the five decay channels, while the second is a six-parameter fit of μ_V/μ_F and μ_F^f for each of the five decay channels.

JHEP08(2016)045

Production process	Measured significance (σ)	Expected significance (σ)
VBF	5.4	4.6
WH	2.4	2.7
ZH	2.3	2.9
VH	3.5	4.2
ttH	4.4	2.0
Decay channel		
$H \to \tau\tau$	5.5	5.0
$H \to bb$	2.6	3.7

Table 14. Measured and expected significances for the observation of Higgs boson production processes and decay channels for the combination of ATLAS and CMS. Not included are the ggF production process and the $H \to ZZ$, $H \to WW$, and $H \to \gamma\gamma$ decay channels, which have already been clearly observed. All results are obtained constraining the decay branching fractions to their SM values when considering the production processes, and constraining the production cross sections to their SM values when studying the decays.

Figure 14 shows the 68% CL region for the ten-parameter fit of the five decay channels included in the combination of the ATLAS and CMS measurements. These results are obtained by combining the $\sqrt{s} = 7$ and 8 TeV data, assuming that μ_F^f and μ_V^f are the same at the two energies. The SM predictions of $\mu_F^f = 1$ and $\mu_V^f = 1$ lie within the 68% CL regions of all these measurements. Combinations of these regions would require assumptions about the branching fractions and are therefore not performed. Table 15 reports the best fit values and the total uncertainties for all the parameters of the fits, together with the expected uncertainties for the combination of ATLAS and CMS. The p-values of the compatibility between the data and the SM predictions are 90% and 75% for the ten-parameter and six-parameter fits, respectively. The six-parameter fit, without any additional assumptions about the Higgs boson branching fractions, yields: $\mu_V/\mu_F = 1.09^{+0.36}_{-0.28}$, in agreement with the SM.

JHEP08(2016)045

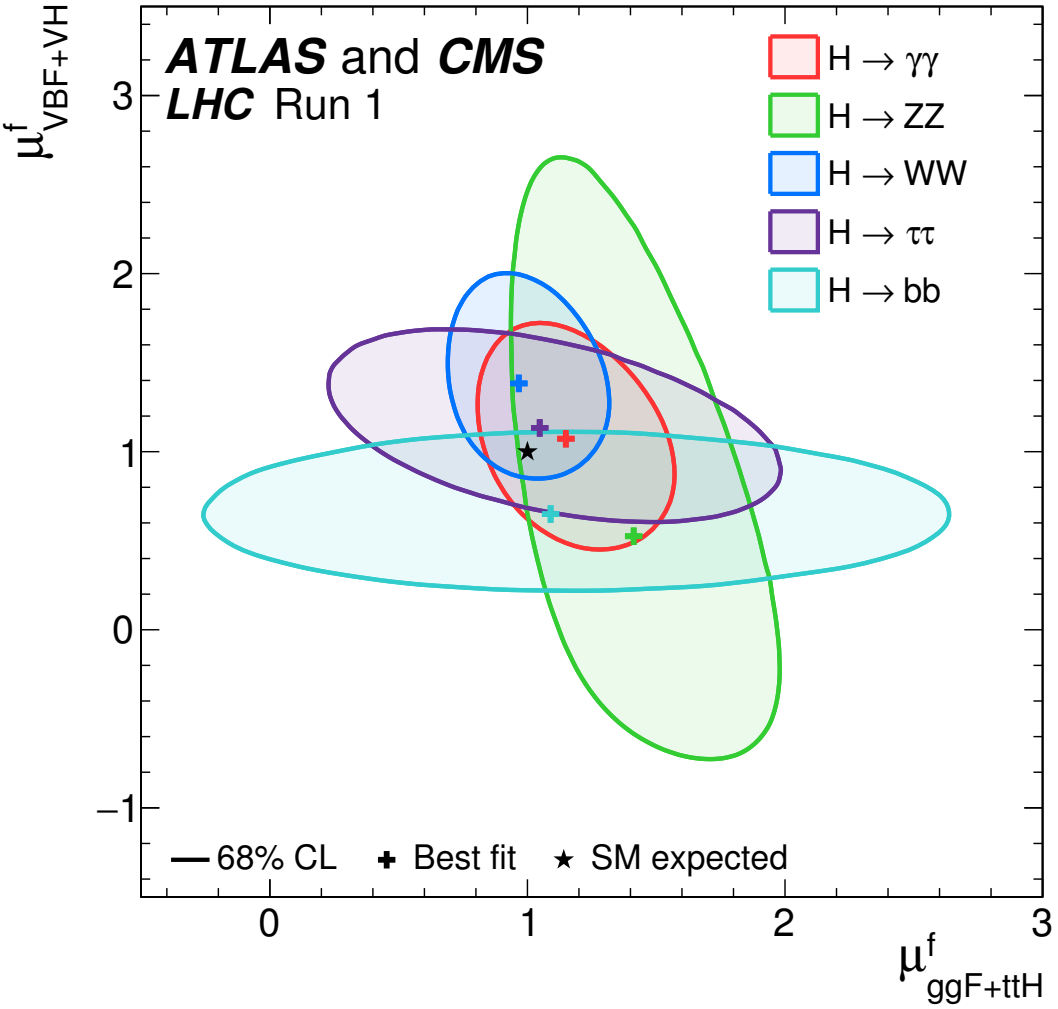

Figure 14. Negative log-likelihood contours at 68% CL in the $(\mu^f_{ggF+ttH}, \mu^f_{VBF+VH})$ plane for the combination of ATLAS and CMS, as obtained from the ten-parameter fit described in the text for each of the five decay channels $H \to ZZ$, $H \to WW$, $H \to \gamma\gamma$, $H \to \tau\tau$, and $H \to bb$. The best fit values obtained for each of the five decay channels are also shown, together with the SM expectation.

5.4 Search for mass-degenerate states with different coupling structures

One important assumption underlying all the results reported elsewhere in this paper is that the observations are due to the presence of a single particle with well defined mass that has been precisely measured [22]. This section addresses the case in which the observed signal could be due to the presence of two or more particles with similar masses, such that they cannot be resolved within the current precision of the mass measurements in the different channels. Several BSM models predict, for example, a superposition of states with indistinguishable mass values [122–125], possibly with different coupling structures to the SM particles. With such an assumption, it may be possible to distinguish between single and multiple states by measuring the cross sections of individual production processes

Table 16. The two signal parameterisations used to scale the expected yields of the 5×5 combinations of production processes and decay modes. The first parameterisation corresponds to the most general case with 25 independent parameters, while the second parameterisation corresponds to that expected for a single Higgs boson state. As explained in the text for the case of the general matrix parameterisation, the two parameters μ^{bb}_{ggF} and $\lambda^{bb}_{\text{VBF}}$ are set to unity in the fits, since the current analyses are not able to constrain them.

independently for each decay mode, as described in section 4.1.1. Several methods have been proposed to assess the compatibility of the data with a single state [126, 127]. A test for the possible presence of overlapping Higgs boson states is performed, based on a profile likelihood ratio suggested in ref. [128]. This test accounts both for missing measurements, such as the $H \to bb$ decay mode in the ggF and VBF production processes, and for uncertainties in the measurements, including their correlations.

The 25 possible combinations resulting from five production processes times five decay modes can be parameterised using a 5×5 matrix $\mathcal{M}$ in two ways:

- allowing full freedom for all yields except the two mentioned above, which are not addressed in the combined analyses, leading to 23 free parameters, similarly to the fit performed for all products of cross sections times branching fractions and presented in section 4.1.1;

- assuming that all yields originate from five production processes and five decay modes, leading to nine free parameters, as shown in table 6, similarly to the fit performed for one reference cross section times branching fraction and eight ratios of cross sections and branching fractions, described in section 4.1.2.

There is a direct relation between the rank of the 5×5 matrix $\mathcal{M}$ and the number of degenerate states. More specifically, if the observations are due to a single state, the

JHEP08(2016)045

matrix can be obtained from one of its rows by using one common multiplier per row and therefore rank($\mathcal{M}$) = 1, in contrast to rank($\mathcal{M}$) = 5 in the most general case. The two parameterisations of $\mathcal{M}$ used in this test are shown in table 16. They are both expressed in terms of μ^j_{ggF}, defined as in eq. (2.2). Then, for the general case, the other parameters are $\lambda^j_i = \mu^j_i/\mu^j_{ggF}$, whereas for the rank($\mathcal{M}$) = 1 case the other parameters are $\lambda_i = \mu_i/\mu_{ggF}$. In this section, the index i runs over the VBF, WH, ZH, and ttH production processes and the index j runs over the five decay modes. The two statistical parameterisations are nested since the second one can be obtained from the first by imposing $\lambda^j_i = \lambda_i$. The SM prediction corresponds to the rank($\mathcal{M}$) =1 case, where $\mu^j_{ggF} = \lambda_i = \lambda^j_i = 1$.

In contrast to the fits described previously, all the parameters of interest are constrained to be positive for the fits performed in this section. This choice to restrict the parameter space to the physically meaningful region improves the convergence of the fits. The results of the fits to the data are consistent with those presented in section 4.1 for the two similar parameterisations and are not reported here.

In order to quantify the compatibility of the data with the single-state hypothesis, a profile likelihood ratio test statistic, q_λ, is built that compares the hypothesis of a single-state matrix with rank($\mathcal{M}$) = 1 to the general hypothesis with rank($\mathcal{M}$) = 5:

$$q_\lambda = -2\ln\frac{L(\text{data}|\lambda^j_i = \hat{\lambda}_i, \hat{\mu}^j_{ggF})}{L(\text{data}|\hat{\lambda}^j_i, \hat{\mu}'^j_{ggF})}, \tag{5.1}$$

where $\hat{\mu}^j_{ggF}$ and $\hat{\mu}'^j_{ggF}$ represent the best fit values of the parameters of interest, respectively for the single-state and general hypotheses. The observed value of q_λ in data is compared with the expected distribution, as obtained from pseudo-data samples randomly generated from the best fit values of the rank($\mathcal{M}$) =1 hypothesis. The p-value of the data with the single-state hypothesis is (29±2)%, where the uncertainty reflects the finite number of pseudo-data samples generated, and does not show any significant departure from the single-state hypothesis. The p-values obtained for the individual experiments are 58% and 33% for ATLAS and CMS, respectively. These p-values can only be considered as the results of compatibility tests with the single-state hypothesis, represented by the rank($\mathcal{M}$) = 1 parameterisation described above.

6 Constraints on Higgs boson couplings

Section 4.2 discusses the fit results from the most generic parameterisation in the context of the κ-framework. This section probes more specific parameterisations with additional assumptions. In the following, results from a few selected parameterisations, with increasingly restrictive assumptions, are presented. The results are obtained from the combined fits to the $\sqrt{s} = 7$ and 8 TeV data assuming that the coupling modifiers are the same at the two energies.

JHEP08(2016)045

6.1 Parameterisations allowing contributions from BSM particles in loops and in decays

As discussed in sections 2 and 3, the rates of Higgs boson production in the various decay modes are inversely proportional to the Higgs boson width, which is sensitive to potential invisible or undetected decay modes predicted by BSM theories. To directly measure the individual coupling modifiers, an assumption about the Higgs boson width is necessary. Two possible scenarios are considered in this section: the first leaves B_{BSM} free, provided that $B_{BSM} \geq 0$, but assumes that $|\kappa_W| \leq 1$ and $|\kappa_Z| \leq 1$ and that the signs of κ_W and κ_Z are the same, assumptions denoted $|\kappa_V| \leq 1$ in the following; the second assumes $B_{BSM} = 0$. The constraints assumed in the first scenario are compatible with a wide range of BSM physics, which may become manifest in the loop-induced processes of $gg \to H$ production and $H \to \gamma\gamma$ decay. These processes are particularly sensitive to loop contributions from new heavy particles, carrying electric or colour charge, or both, and such new physics can be probed using the effective coupling modifiers κ_g and κ_γ. Furthermore, potential deviations from the SM of the tree-level couplings to ordinary particles are parameterised with their respective coupling modifiers. The parameters of interest in the fits to data are thus the seven independent coupling modifiers, κ_Z, κ_W, κ_t, κ_τ, κ_b, κ_g, and κ_γ, one for each SM particle involved in the production processes and decay modes studied, plus B_{BSM} in the case of the first fit. Here and in section 6.2, the coupling modifier κ_t is assumed to be positive, without any loss of generality.

Figure 15 and table 17 show the results of the two fits, assuming either $|\kappa_V| \leq 1$ and $B_{BSM} \geq 0$ or $B_{BSM} = 0$. In the former case, an upper limit of $B_{BSM} = 0.34$ at 95% CL is obtained, compared to an expected upper limit of 0.39. The corresponding negative log-likelihood scan is shown in figure 16. Appendix C describes how the two possible sign combinations between κ_W and κ_Z impact the likelihood scan of B_{BSM} for the observed and expected results, as illustrated in figure 32. The p-value of the compatibility between the data and the SM predictions is 11% with the assumption that $B_{BSM} = 0$.

Another fit, motivated, for example, by BSM scenarios with new heavy particles that may contribute to loop processes in Higgs boson production or decay, assumes that all the couplings to SM particles are the same as in the SM, that there are no BSM decays ($B_{BSM} = 0$), and that only the gluon-gluon production and $\gamma\gamma$ decay loops may be affected by the presence of additional particles. The results of this fit, which has only the effective coupling modifiers κ_γ and κ_g as free parameters, with all other coupling modifiers fixed to their SM values of unity, are shown in figure 17. The point $\kappa_\gamma = 1$ and $\kappa_g = 1$ lies within the 68% CL region and the p-value of the compatibility between the data and the SM predictions is 82%.

6.2 Parameterisation assuming SM structure of the loops and no BSM decays

In this section it is assumed that there are no new particles in the loops entering ggF production and $H \to \gamma\gamma$ decay. This assumption is supported by the measurements of the effective coupling modifiers κ_g and κ_γ, which are consistent with the SM predictions. The cross section for ggF production and the branching fraction for the $H \to \gamma\gamma$ decay are expressed in terms of the coupling modifiers of the SM particles in the loops, as indicated

Table 17. Fit results for two parameterisations allowing BSM loop couplings discussed in the text: the first one assumes that $\lvert\kappa_V\rvert \leq 1$, where κ_V denotes κ_Z or κ_W, and that $\mathrm{B_{BSM}} \geq 0$, while the second one assumes that there are no additional BSM contributions to the Higgs boson width, i.e. $\mathrm{B_{BSM}} = 0$. The results for the combination of ATLAS and CMS are reported with their measured and expected uncertainties. Also shown are the results from each experiment. For the parameters with both signs allowed, the 1σ intervals are shown on a second line. When a parameter is constrained and reaches a boundary, namely $\mathrm{B_{BSM}} = 0$, the uncertainty is not indicated. For those parameters with no sensitivity to the sign, only the absolute values are shown.

JHEP08(2016)045

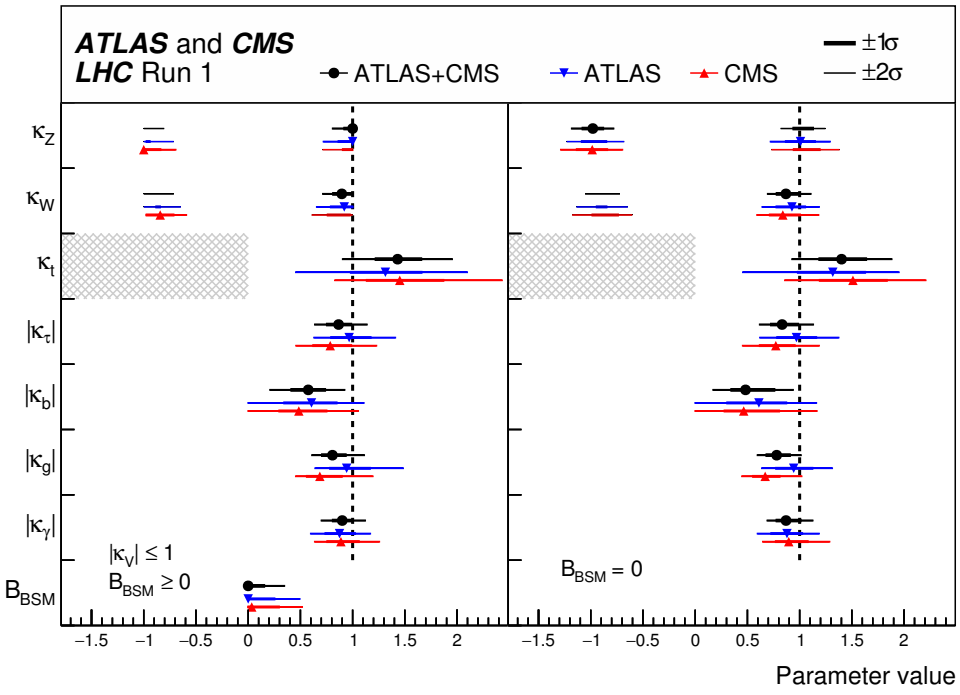

Figure 15. Fit results for two parameterisations allowing BSM loop couplings discussed in the text: the first one assumes that $B_{BSM} \geq 0$ and that $|\kappa_V| \leq 1$, where κ_V denotes κ_Z or κ_W, and the second one assumes that there are no additional BSM contributions to the Higgs boson width, i.e. $B_{BSM} = 0$. The measured results for the combination of ATLAS and CMS are reported together with their uncertainties, as well as the individual results from each experiment. The hatched areas show the non-allowed regions for the κ_t parameter, which is assumed to be positive without loss of generality. The error bars indicate the 1σ (thick lines) and 2σ (thin lines) intervals. When a parameter is constrained and reaches a boundary, namely $|\kappa_V| = 1$ or $B_{BSM} = 0$, the uncertainty is not defined beyond this boundary. For those parameters with no sensitivity to the sign, only the absolute values are shown.

in table 4. This leads to a parameterisation with six free coupling modifiers: κ_W, κ_Z, κ_t, κ_τ, κ_b, and κ_μ; the results of the $H \to \mu\mu$ analysis are included for this specific case. In this more constrained fit, it is also assumed that $B_{BSM} = 0$.

Figure 18 and table 18 show the results of the fit for the combination of ATLAS and CMS, and separately for each experiment. Compared to the results from the fitted decay signal strengths (table 13) or the global signal strength $\mu = 1.09 \pm 0.11$ (section 5.1), this fit yields values of the coupling modifiers lower than those predicted by the SM. This is a consequence of the low value of κ_b, as measured by the combination of ATLAS and CMS and by each experiment. A low value of κ_b decreases the total Higgs boson width through the dominant Γ^{bb} partial decay width, and, as a consequence, the measured values of all the coupling modifiers decrease, such that the values of $\sigma_i(\vec{\kappa}) \cdot B^f$ remain consistent with the observed signal yields. The p-value of the compatibility between the data and the SM predictions is 74%.

JHEP08(2016)045

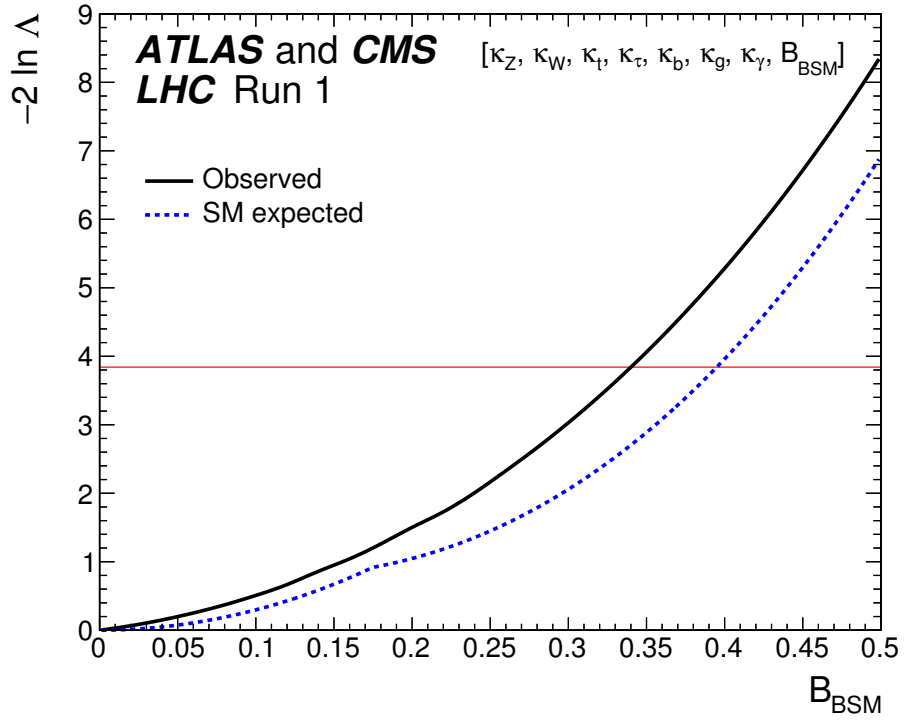

Figure 16. Observed (solid line) and expected (dashed line) negative log-likelihood scan of B_{BSM}, shown for the combination of ATLAS and CMS when allowing additional BSM contributions to the Higgs boson width. The results are shown for the parameterisation with the assumptions that $|\kappa_V| \leq 1$ and $B_{BSM} \geq 0$ in figure 15. All the other parameters of interest from the list in the legend are also varied in the minimisation procedure. The red horizontal line at 3.84 indicates the log-likelihood variation corresponding to the 95% CL upper limit, as discussed in section 3.2.

A different view of the relation between the fitted coupling modifiers and the SM predictions is presented in figure 19. New parameters are derived from the coupling modifiers, to make explicit the dependence on the particle masses: linear for the Yukawa couplings to the fermions and quadratic for the gauge couplings of the Higgs boson to the weak vector bosons. These new parameters are all assumed in this case to be positive. For fermions with mass $m_{F,i}$, the parameters are $\kappa_{F,i} \cdot y_{F,i}/\sqrt{2} = \kappa_{F,i} \cdot m_{F,i}/v$, where $y_{F,i}$ is the Yukawa coupling strength, assuming a SM Higgs boson with a mass of 125.09 GeV, and $v = 246$ GeV is the vacuum expectation value of the Higgs field. For the weak vector bosons with mass $m_{V,i}$, the new parameters are $\sqrt{\kappa_{V,i}} \cdot g_{V,i}/2v = \sqrt{\kappa_{V,i}} \cdot m_{V,i}/v$, where $g_{V,i}$ is the absolute Higgs boson gauge coupling strength. The linear scaling of these new parameters as a function of the particle masses observed in figure 19 indicates qualitatively the compatibility of the measurements with the SM. For the b quark, the running mass evaluated at a scale equal to m_H, $m_b(m_H) = 2.76$ GeV, is used.

Following the phenomenological model suggested in ref. [129], the coupling modifiers can also be expressed as a function of a mass scaling parameter ϵ, with a value $\epsilon = 0$ in the SM, and a free parameter M, equal to v in the SM: $\kappa_{F,i} = v \cdot m_{F,i}^{\epsilon}/M^{1+\epsilon}$ and $\kappa_{V,i} =$

JHEP08(2016)045

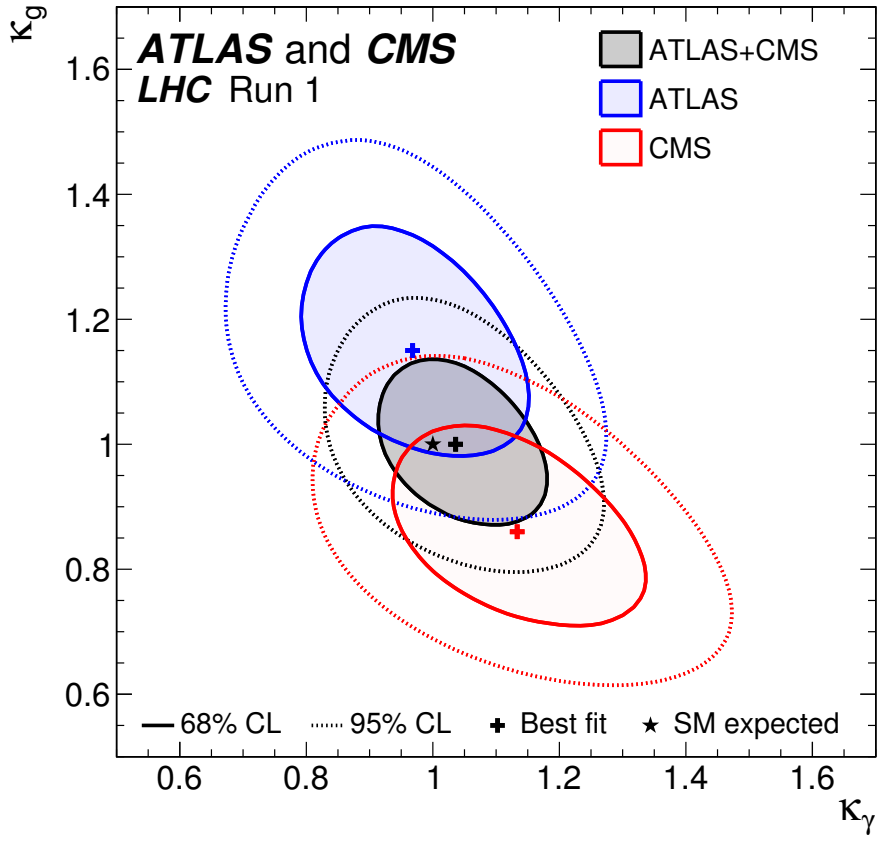

Figure 17. Negative log-likelihood contours at 68% and 95% CL in the (κ_γ, κ_g) plane for the combination of ATLAS and CMS and for each experiment separately, as obtained from the fit to the parameterisation constraining all the other coupling modifiers to their SM values and assuming $B_{BSM} = 0$.

$v \cdot m_{V,i}^{2\epsilon}/M^{1+2\epsilon}$. A fit is then performed with the same assumptions as those of table 18 with ϵ and M as parameters of interest. The results for the combination of ATLAS and CMS are $\epsilon = 0.023^{+0.029}_{-0.027}$ and $M = 233^{+13}_{-12}$ GeV, and are compatible with the SM predictions. Figure 19 shows the results of this fit with its corresponding 68% and 95% CL bands.

6.3 Parameterisations related to the fermion sector

Common coupling modifications for up-type fermions versus down-type fermions or for leptons versus quarks are predicted by many extensions of the SM. One such class of theoretically well motivated models is the 2HDM [130].

The ratios of the coupling modifiers are tested in the most generic parameterisation proposed in ref. [32], in which the total Higgs boson width is also allowed to vary. The main parameters of interest for these tests are $\lambda_{du} = \kappa_d/\kappa_u$ for the up- and down-type fermion symmetry, and $\lambda_{lq} = \kappa_l/\kappa_q$ for the lepton and quark symmetry, where both are allowed to be positive or negative. In this parameterisation, the loops are resolved in terms of their expected SM contributions.

JHEP08(2016)045

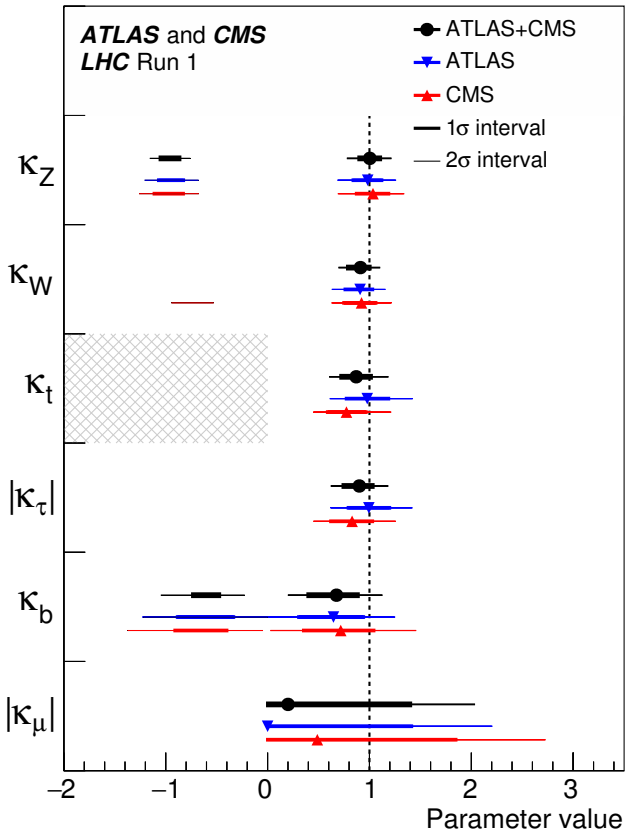

Figure 18. Best fit values of parameters for the combination of ATLAS and CMS data, and separately for each experiment, for the parameterisation assuming the absence of BSM particles in the loops, $B_{BSM} = 0$. The hatched area indicates the non-allowed region for the parameter that is assumed to be positive without loss of generality. The error bars indicate the 1σ (thick lines) and 2σ (thin lines) intervals. When a parameter is constrained and reaches a boundary, namely $|\kappa_\mu| = 0$, the uncertainty is not defined beyond this boundary. For those parameters with no sensitivity to the sign, only the absolute values are shown.

6.3.1 Probing the up- and down-type fermion symmetry

The free parameters for this test are: $\lambda_{du} = \kappa_d/\kappa_u$, $\lambda_{Vu} = \kappa_V/\kappa_u$, and $\kappa_{uu} = \kappa_u \cdot \kappa_u/\kappa_H$, where this latter term is positive definite since κ_H is always assumed to be positive. The up-type fermion couplings are mainly probed by the ggF production process, the $H \to \gamma\gamma$ decay channel, and to a certain extent the ttH production process. The down-type fermion couplings are mainly probed by the $H \to bb$ and $H \to \tau\tau$ decays. A small sensitivity to the relative sign arises from the interference between top and bottom quarks in the gluon fusion loop.

The results of the fit are reported in table 19 and figure 20. The p-value of the compatibility between the data and the SM predictions is 72%. The likelihood scan for the λ_{du} parameter is shown in figure 21 for the combination of ATLAS and CMS. Negative values for the parameter λ_{Vu} are excluded by more than 4σ.

JHEP08(2016)045

Parameter	ATLAS+CMS Measured	ATLAS+CMS Expected uncertainty	ATLAS Measured	CMS Measured
κ_Z	1.00 $[-1.05,-0.86]\cup$ $[0.90,1.11]$	 $[-1.00,-0.88]\cup$ $[0.90,1.10]$	0.98 $[-1.07,-0.83]\cup$ $[0.84,1.12]$	1.03 $[-1.11,-0.83]\cup$ $[0.87,1.19]$

κ_t	$0.87^{+0.15}_{-0.15}$	$^{+0.15}_{-0.18}$	$0.98^{+0.21}_{-0.20}$	$0.77^{+0.20}_{-0.18}$
$\lvert\kappa_\tau\rvert$	$0.90^{+0.14}_{-0.16}$	$^{+0.15}_{-0.14}$	$0.99^{+0.20}_{-0.20}$	$0.83^{+0.20}_{-0.21}$
κ_b	0.67 $[-0.73,-0.47]\cup$ $[0.40,0.89]$	 $[-1.24,-0.76]\cup$ $[0.74,1.24]$	0.64 $[-0.89,-0.33]\cup$ $[0.30,0.94]$	0.71 $[-0.91,-0.40]\cup$ $[0.35,1.04]$
$\lvert\kappa_\mu\rvert$	$0.2^{+1.2}$	$^{+0.9}$	$0.0^{+1.4}$	$0.5^{+1.4}$

Table 18. Fit results for the parameterisation assuming the absence of BSM particles in the loops ($B_{BSM} = 0$). The results with their measured and expected uncertainties are reported for the combination of ATLAS and CMS, together with the individual results from each experiment. For the parameters with both signs allowed, the 1σ CL intervals are shown on a second line. When a parameter is constrained and reaches a boundary, namely $|\kappa_\mu| = 0$, the uncertainty is not indicated. For those parameters with no sensitivity to the sign, only the absolute values are shown.

6.3.2 Probing the lepton and quark symmetry

The parameterisation for this test is very similar to that of section 6.3.1, which probes the up- and down-type fermion symmetry. In this case, the free parameters are $\lambda_{lq} = \kappa_l/\kappa_q$, $\lambda_{Vq} = \kappa_V/\kappa_q$, and $\kappa_{qq} = \kappa_q \cdot \kappa_q/\kappa_H$, where the latter term is positive definite, like κ_{uu}. The quark couplings are mainly probed by the ggF process, the $H \to \gamma\gamma$ and $H \to bb$ decays, and to a lesser extent by the ttH process. The lepton couplings are probed by the $H \to \tau\tau$ decays. The results are expected, however, to be insensitive to the relative sign of the couplings, because there is no sizeable lepton-quark interference in any of the relevant Higgs boson production processes and decay modes. Only the absolute value of the λ_{lq} parameter is therefore considered in the fit.

The results of the fit are reported in table 19 and figure 22. The p-value of the compatibility between the data and the SM predictions is 79%. The likelihood scan for the λ_{lq} parameter is shown in figure 23 for the combination of ATLAS and CMS. Negative values for the parameter λ_{Vq} are excluded by more than 4σ.

JHEP08(2016)045

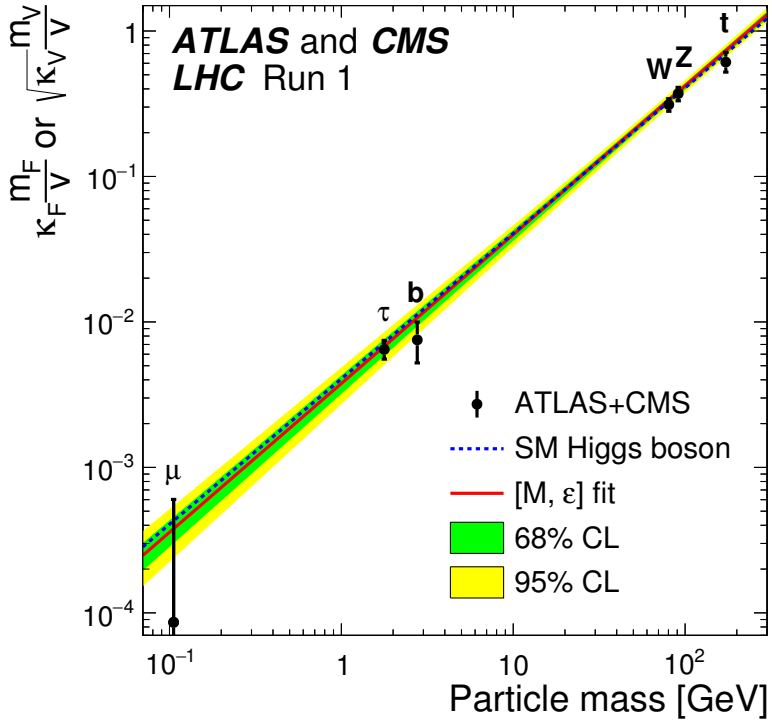

Figure 19. Best fit values as a function of particle mass for the combination of ATLAS and CMS data in the case of the parameterisation described in the text, with parameters defined as $\kappa_F \cdot m_F/v$ for the fermions, and as $\sqrt{\kappa_V} \cdot m_V/v$ for the weak vector bosons, where $v = 246\,\text{GeV}$ is the vacuum expectation value of the Higgs field. The dashed (blue) line indicates the predicted dependence on the particle mass in the case of the SM Higgs boson. The solid (red) line indicates the best fit result to the $[M, \epsilon]$ phenomenological model of ref. [129] with the corresponding 68% and 95% CL bands.

6.4 Fermion and vector boson couplings

The last and most constrained parameterisation studied in this section is motivated by the intrinsic difference between the Higgs boson couplings to weak vector bosons, which originate from the breaking of the EW symmetry, and the Yukawa couplings to the fermions. Similarly to section 6.2, it is assumed in this section that there are no new particles in the loops (ggF production process and $H \to \gamma\gamma$ decay mode) and that there are no BSM decays, i.e. $\text{B}_{\text{BSM}} = 0$. Vector and fermion coupling modifiers, κ_V and κ_F, are defined such that $\kappa_Z = \kappa_W = \kappa_V$ and $\kappa_t = \kappa_\tau = \kappa_b = \kappa_F$. These definitions can be applied either globally, yielding two parameters, or separately for each of the five decay channels, yielding ten parameters κ_V^f and κ_F^f (following the notation related to Higgs boson decays used for the signal strength parameterisation). Two fits are performed: a two-parameter fit as a function of κ_V and κ_F, and a ten-parameter fit as a function of κ_V^f and κ_F^f for each decay channel.

As explained in section 2.4 and shown explicitly in table 4, the Higgs boson production cross sections and partial decay widths are only sensitive to products of coupling modifiers and not to their absolute sign. Any sensitivity to the relative sign between κ_V and κ_F

JHEP08(2016)045

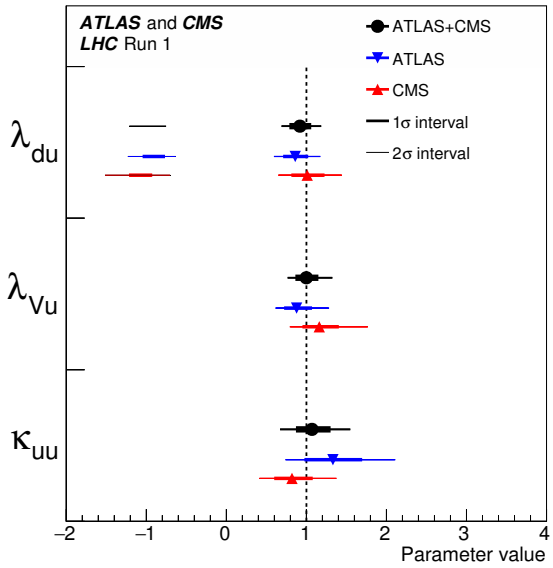

Figure 20. Best fit values of parameters for the combination of ATLAS and CMS data, and separately for each experiment, for the parameterisation testing the up- and down-type fermion coupling ratios. The error bars indicate the 1σ (thick lines) and 2σ (thin lines) intervals. The parameter κ_{uu} is positive definite since κ_H is always assumed to be positive. Negative values for the parameter λ_{Vu} are excluded by more than 4σ.

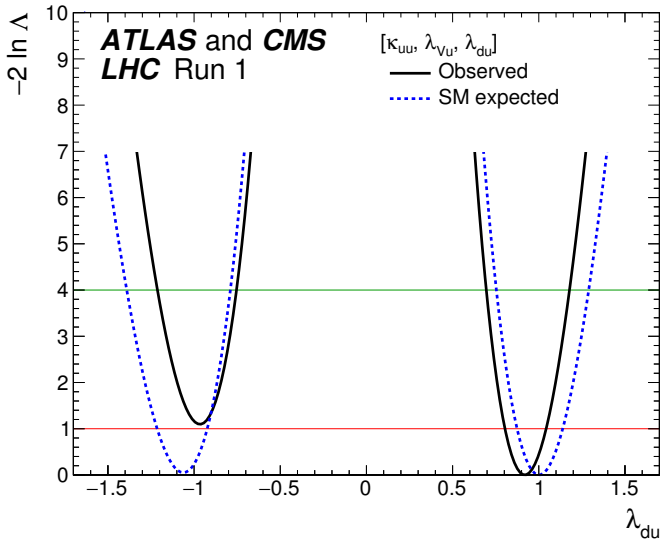

Figure 21. Observed (solid line) and expected (dashed line) negative log-likelihood scan of the λ_{du} parameter, probing the ratios of coupling modifiers for up-type versus down-type fermions for the combination of ATLAS and CMS. The other parameters of interest from the list in the legend are also varied in the minimisation procedure. The red (green) horizontal line at the $-2\Delta \ln \Lambda$ value of 1 (4) indicates the value of the profile likelihood ratio corresponding to a 1σ (2σ) CL interval for the parameter of interest, assuming the asymptotic χ^2 distribution of the test statistic.

JHEP08(2016)045

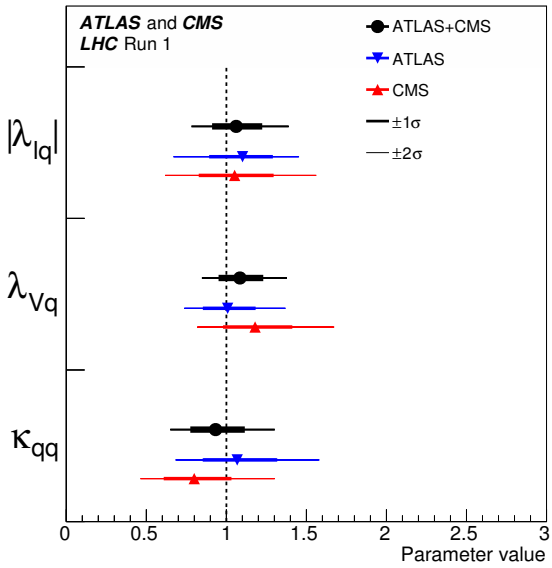

Figure 22. Best fit values of parameters for the combination of ATLAS and CMS data, and separately for each experiment, for the parameterisation testing the lepton and quark coupling ratios. The error bars indicate the 1σ (thick lines) and 2σ (thin lines) intervals. For the parameter λ_{lq}, for which there is no sensitivity to the sign, only the absolute values are shown. The parameter κ_{qq} is positive definite since κ_H is always assumed to be positive. Negative values for the parameter λ_{Vq} are excluded by more than 4σ.

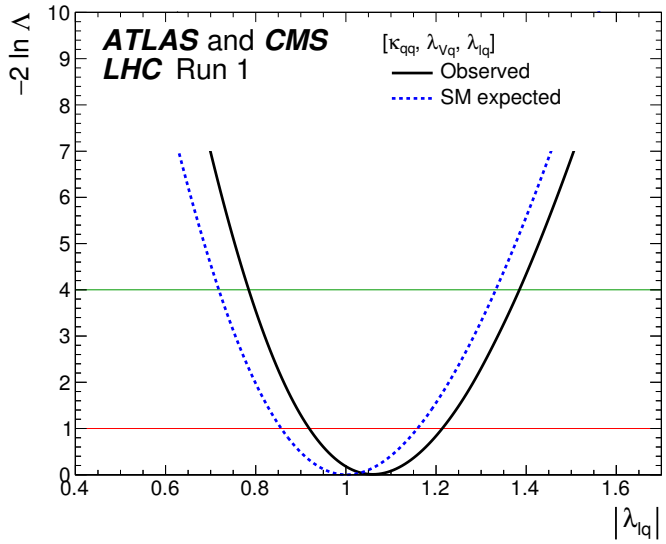

Figure 23. Observed (solid line) and expected (dashed line) negative log-likelihood scan of the λ_{lq} parameter, probing the ratios of coupling modifiers for leptons versus quarks for the combination of ATLAS and CMS. The other parameters of interest from the list in the legend are also varied in the minimisation procedure. The red (green) horizontal line at the $-2\Delta \ln \Lambda$ value of 1 (4) indicates the value of the profile likelihood ratio corresponding to a 1σ (2σ) CL interval for the parameter of interest, assuming the asymptotic χ^2 distribution of the test statistic.

Table 19. Summary of fit results for the two parameterisations probing the ratios of coupling modifiers for up-type versus down-type fermions and for leptons versus quarks. The results for the combination of ATLAS and CMS are reported together with their measured and expected uncertainties. Also shown are the results from each experiment. The parameters κ_{uu} and κ_{qq} are both positive definite since κ_H is always assumed to be positive. For the parameter λ_{du}, for which both signs are allowed, the 1σ CL intervals are shown on a second line. For the parameter λ_{lq}, for which there is no sensitivity to the sign, only the absolute values are shown. Negative values for the parameters λ_{Vu} and λ_{Vq} are excluded by more than 4σ.

can only occur through interference terms, either in the $H \to \gamma\gamma$ decays, through the t–W interference in the $\gamma\gamma$ decay loop, or in $ggZH$ or tH production. Without any loss of generality, this parameterisation assumes that one of the two coupling modifiers, namely κ_V (or κ_V^f), is positive.

The combined ATLAS and CMS results are shown in figure 24 for the individual channels and their combination. The individual decay channels are seen to be compatible with each other only for positive values of κ_F^f. The incompatibility between the channels for negative values of κ_F^f arises mostly from the $H \to \gamma\gamma$, $H \to WW$, and $H \to ZZ$ channels. Nonetheless, the best fit values for most of the individual channels correspond to negative values of κ_F^f. However, the best fit value from the global fit yields $\kappa_F \geq 0$, a result that is driven by the large asymmetry between the positive and negative coupling ratios in the case of $H \to \gamma\gamma$ decays.

The fact that, for four of the five individual channels, the best fit values correspond to $\kappa_F^f \leq 0$ is not significant, as shown by the likelihood curves in figures 25 (a-e). The $H \to bb$ decay channel displays the largest expected sensitivity, mostly arising from the contribution of the $ggZH$ process, and the best fit value of κ_F^{bb} is positive. For all other decay modes, a small sensitivity arises because of the tH process. The excess observed in the combination of the two experiments for the ttH production process induces a preference for a relative

JHEP08(2016)045

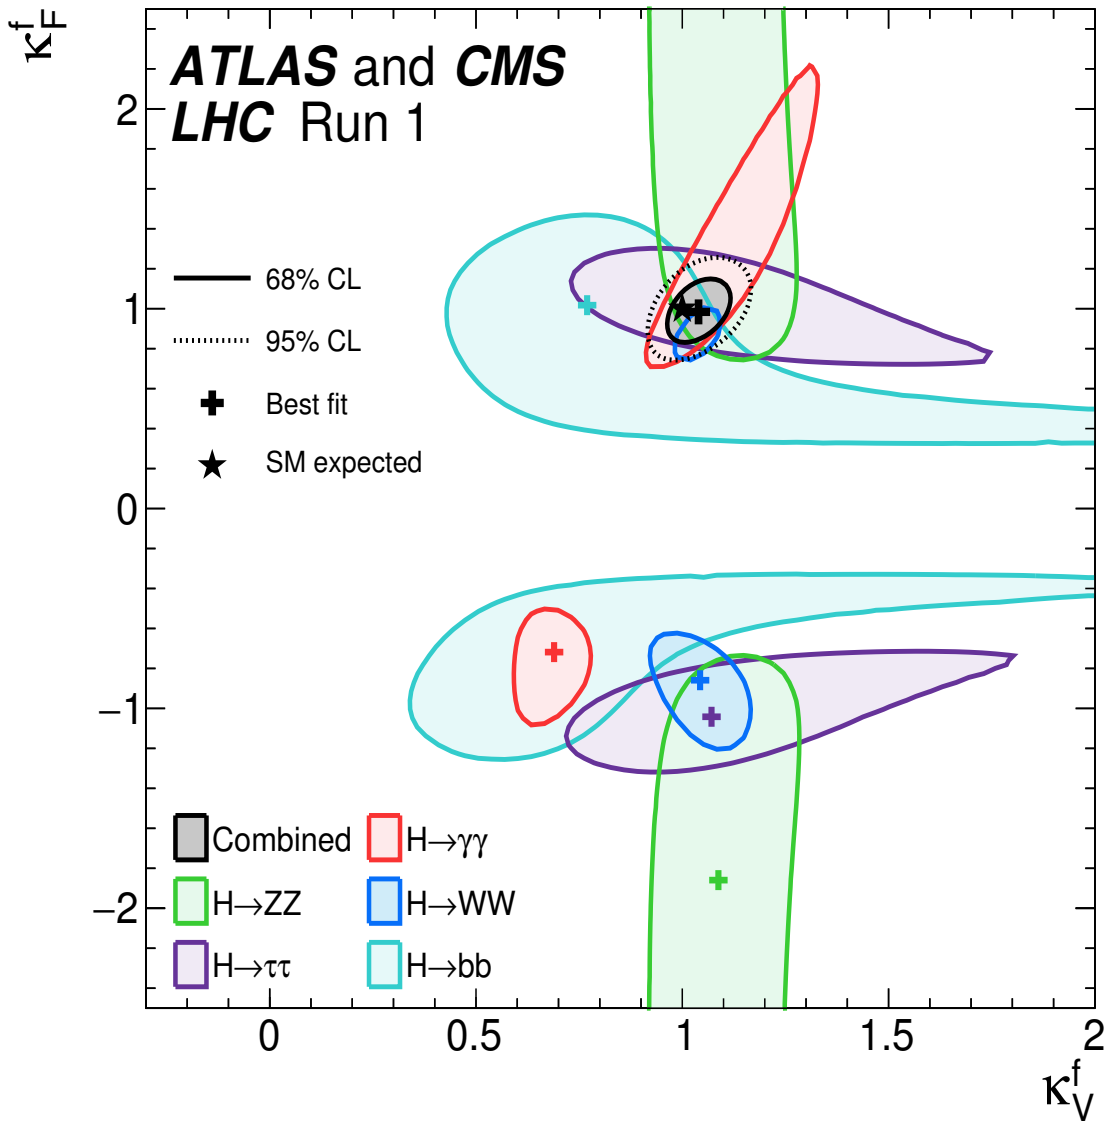

Figure 24. Negative log-likelihood contours at 68% and 95% CL in the (κ_F^f, κ_V^f) plane for the combination of ATLAS and CMS and for the individual decay channels, as well as for their combination (κ_F versus κ_V shown in black), without any assumption about the sign of the coupling modifiers. The other two quadrants (not shown) are symmetric with respect to the point (0,0).

JHEP08(2016)045

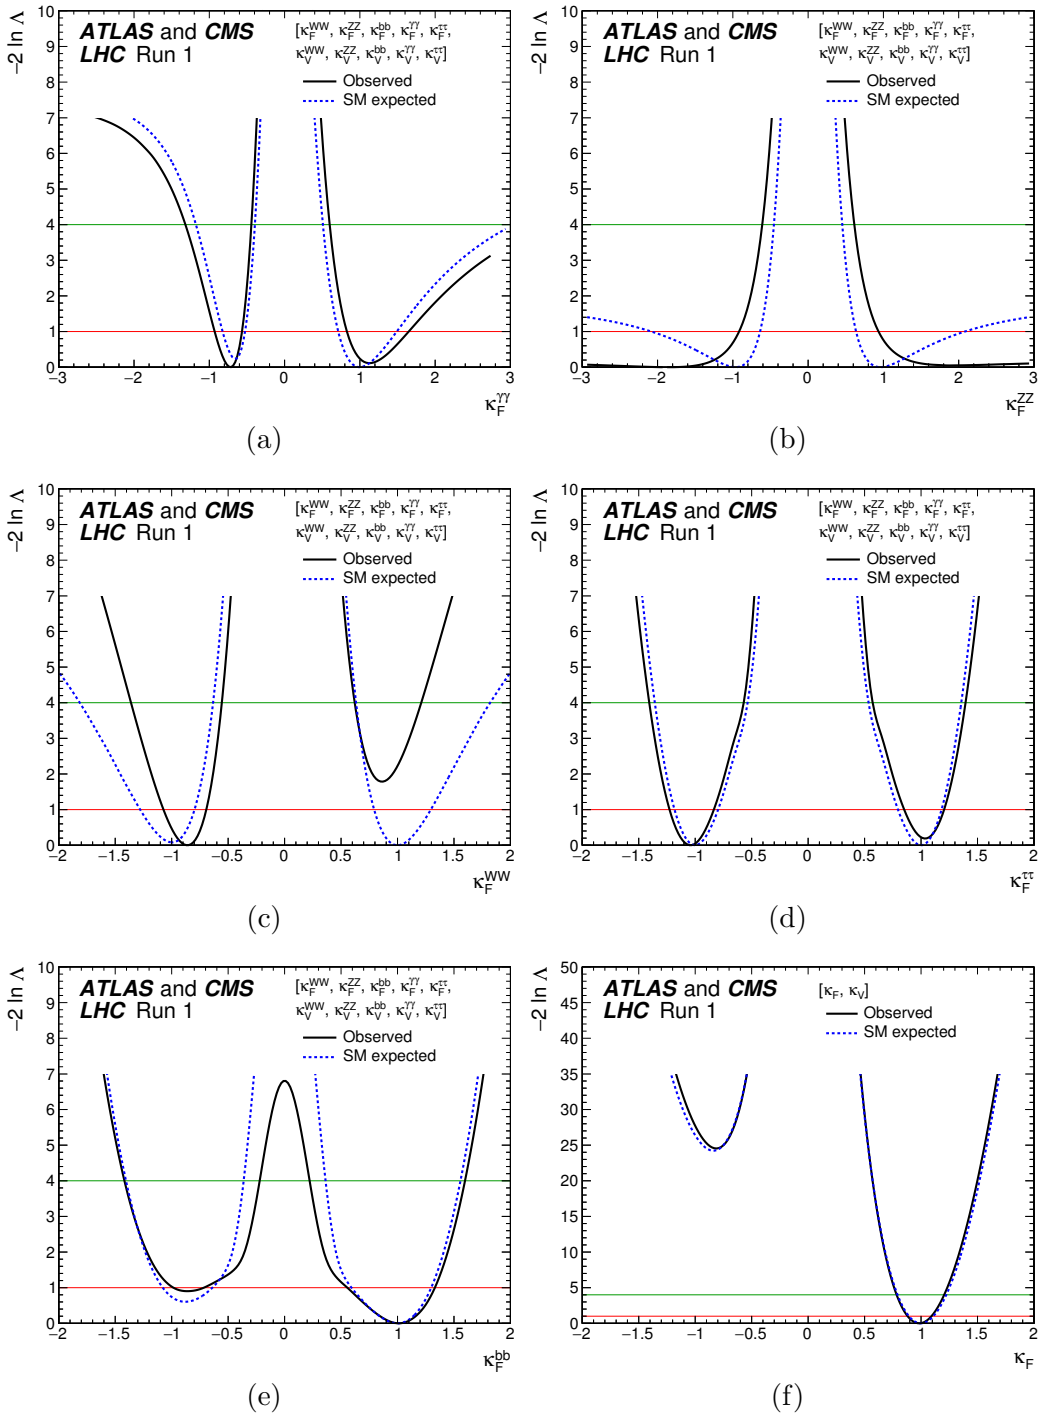

Figure 25. Observed (solid line) and expected (dashed line) negative log-likelihood scans for the five κ_F^f parameters, corresponding to each individual decay channel, and for the global κ_F parameter, corresponding to the combination of all decay channels: (a) $\kappa_F^{\gamma\gamma}$, (b) κ_F^{ZZ}, (c) κ_F^{WW}, (d) $\kappa_F^{\tau\tau}$, (e) κ_F^{bb}, and (f) κ_F. All the other parameters of interest from the list in the legends are also varied in the minimisation procedure. The red (green) horizontal lines at the $-2\Delta\ln\Lambda$ value of 1 (4) indicate the value of the profile likelihood ratio corresponding to a 1σ (2σ) CL interval for the parameter of interest, assuming the asymptotic χ^2 distribution of the test statistic.

JHEP08(2016)045

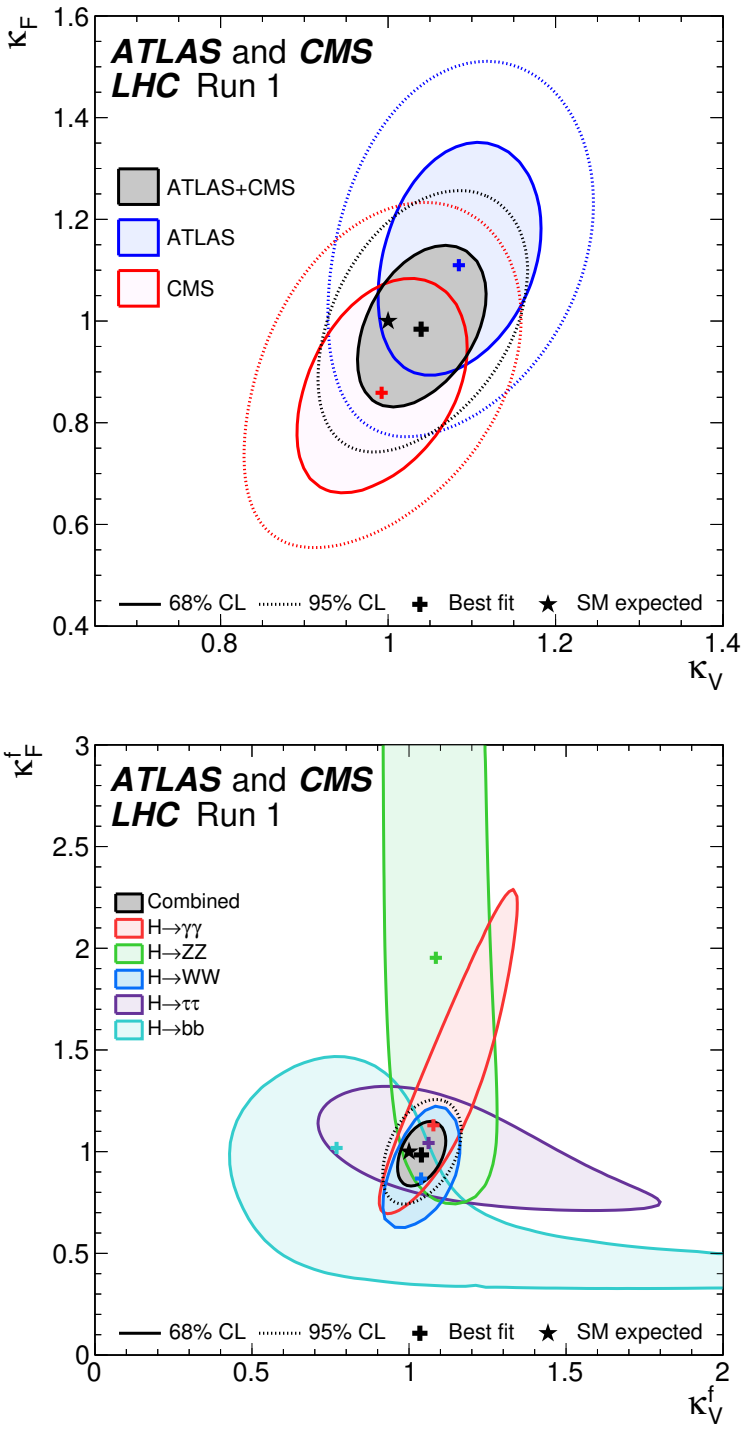

Figure 26. Top: negative log-likelihood contours at 68% and 95% CL in the (κ_F, κ_V) plane on an enlarged scale for the combination of ATLAS and CMS and for the global fit of all channels. Also shown are the contours obtained for each experiment separately. Bottom: negative log-likelihood contours at 68% CL in the (κ_F^f, κ_V^f) plane for the combination of ATLAS and CMS and for the individual decay channels as well as for their global combination (κ_F versus κ_V), assuming that all coupling modifiers are positive.

JHEP08(2016)045

negative sign between the two coupling modifiers, which increases significantly the tH cross section and thereby provides a better fit to the data. The only visible difference between the two minima at positive and negative values of κ_F^f is observed for the $H \to WW$ channel.

As stated above, the channel most affected by the relative sign of the couplings is the $H \to \gamma\gamma$ decay channel: because of the negative t–W interference in the $\gamma\gamma$ loop, the $H \to \gamma\gamma$ partial width would be much larger if the sign of $\kappa_F^{\gamma\gamma}$ were opposite to that of $\kappa_V^{\gamma\gamma}$. When combining the $H \to \gamma\gamma$ decay channel with all the other channels, the opposite sign case is excluded by almost 5σ, as can be inferred from figure 25 (f).

Figure 26 (top) presents, on an enlarged scale, the results of the scan for the global coupling modifiers as well as those obtained separately for each experiment. For completeness, additional likelihood scans are performed for the two global coupling modifiers and for those of each decay channel, assuming in all cases that κ_F and κ_V are both positive. The results of these scans are shown in figure 26 (bottom). The most precise determination of κ_F^f and κ_V^f is obtained from the $H \to WW$ decay channel because it is the only one that provides significant constraints on both parameters, through the measurements of the ggF and VBF production processes. The difference in size between the $H \to WW$ confidence regions obtained for $\kappa_F^f \geq 0$ in figure 24 and figure 26 (bottom), where it is explicitly assumed that $\kappa_F^f \geq 0$, is due to the fact that the negative log-likelihood contours are evaluated using as a reference the minima obtained from different likelihood fits. The combination of all decay modes provides significant additional constraints. All results are in agreement with the SM prediction, $\kappa_F^f = 1$ and $\kappa_V^f = 1$, and the p-value of the compatibility between the data and the SM predictions is 59%.

7 Summary

An extensive set of combined ATLAS and CMS measurements of the Higgs boson production and decay rates is presented, and a number of constraints on its couplings to vector bosons and fermions are derived based on various sets of assumptions. The combination is based on the analysis of approximately 600 categories of selected events, concerning five production processes, ggF, VBF, WH, ZH, and ttH, where ggF and VBF refer, respectively, to production through the gluon fusion and vector boson fusion processes; and six decay channels, $H \to ZZ, WW, \gamma\gamma, \tau\tau, bb$, and $\mu\mu$. All results are reported assuming a value of 125.09 GeV for the Higgs boson mass, the result of the combined Higgs boson mass measurement by the two experiments [22]. The analysis uses the LHC proton-proton collision data sets recorded by the ATLAS and CMS detectors in 2011 and 2012, corresponding to integrated luminosities per experiment of approximately 5 fb^{-1} at $\sqrt{s} = 7$ TeV and 20 fb^{-1} at $\sqrt{s} = 8$ TeV. This paper presents the final Higgs boson coupling combined results from ATLAS and CMS based on the LHC Run 1 data.

The combined analysis is sensitive to the couplings of the Higgs boson to the weak vector bosons and to the heavier fermions (top quarks, b quarks, τ leptons, and – marginally – muons). The analysis is also sensitive to the effective couplings of the Higgs boson to the photon and the gluon. At the LHC, only products of cross sections and branching fractions are measured, so the width of the Higgs boson cannot be probed without assumptions be-

JHEP08(2016)045

yond the main one used for all measurements presented here, namely that the Higgs boson production and decay kinematics are close to those predicted by the Standard Model (SM). In general, the combined analysis presented in this paper provides a significant improvement with respect to the individual combinations published by each experiment separately. The precision of the results improves in most cases by a factor of approximately $1/\sqrt{2}$, as one would expect for the combination of two largely uncorrelated measurements based on similar-size data samples. A few illustrative results are summarised below.

For the first time, results are shown for the most generic parameterisation of the observed event yields in terms of products of Higgs boson production cross sections times branching fractions, separately for each of 20 measurable (σ_i, B^f) pairs of production processes and decay modes. These measurements do not rely on theoretical predictions for the inclusive cross sections and the uncertainties are mostly dominated by their statistical component. In the context of this parameterisation, one can test whether the observed yields arise from more than one Higgs boson, all with experimentally indistinguishable masses, but possibly with different coupling structures to the SM particles. The data are compatible with the hypothesis of a single Higgs boson, yielding a p-value of 29%.

Fits to the observed event yields are also performed without any assumption about the Higgs boson width in the context of two other generic parameterisations. The first parameterisation is in terms of ratios of production cross sections and branching fractions, together with the reference cross section of the process $gg \to H \to ZZ$. All results are compatible with the SM. The best relative precision, of about 30%, is achieved for the ratio of cross sections $\sigma_{\mathrm{VBF}}/\sigma_{gg\mathrm{F}}$ and for the ratios of branching fractions $\mathrm{B}^{WW}/\mathrm{B}^{ZZ}$ and $\mathrm{B}^{\gamma\gamma}/\mathrm{B}^{ZZ}$. A relative precision of around 40% is achieved for the ratio of branching fractions $\mathrm{B}^{\tau\tau}/\mathrm{B}^{ZZ}$. The second parameterisation is in terms of ratios of coupling modifiers, together with one parameter expressing the $gg \to H \to ZZ$ reference process in terms of these modifiers. The ratios of coupling modifiers are measured with precisions of approximately 10–20%, where the improvement in precision in this second parameterisation arises because the signal yields are expressed as squares or products of these coupling modifiers.

All measurements based on the generic parameterisations are compatible between the two experiments and with the predictions of the SM. The potential presence of physics beyond the SM (BSM) is also probed using specific parameterisations. With minimal additional assumptions, the overall branching fraction of the Higgs boson into BSM decays is determined to be less than 34% at 95% CL. This constraint applies to invisible decays into BSM particles, decays into BSM particles that are not detected as such, and modifications of the decays into SM particles that are not directly measured by the experiments.

The combined signal yield relative to the SM expectation is measured to be 1.09 ± 0.07 (stat) ± 0.08 (syst), where the systematic uncertainty is dominated by the theoretical uncertainty in the inclusive cross sections. The measured (expected) significance for the direct observation of the VBF production process is at the level of 5.4σ (4.6σ), while that for the $H \to \tau\tau$ decay channel is at the level of 5.5σ (5.0σ).

A Correlation matrices

Figures 27, 28 and 29 show the correlation matrices obtained from the fits to the generic parameterisations described respectively in sections 4.1.1, 4.1.2, and 4.2. The correlation coefficients are evaluated around the best fit values, using the second derivatives of the negative log-likelihood ratio.

In the case of the parameterisation using 23 products of cross sections times branching fractions, most of the parameters are uncorrelated, as shown in figure 27. Some significant anticorrelations are present however, because of cross-contamination between different channels. These can be seen in the ggF versus VBF production processes for all decay modes, in the WH versus ZH production processes for the $H \to \gamma\gamma$ decay mode, and in the $H \to WW$ versus $H \to \tau\tau$ decay modes for the ttH production process.

In contrast, for the two parameterisations based on ratios shown in figures 28 and 29, correlations are present for all pairs of parameters. For example, in each of these parameterisations, the first parameter is anticorrelated to most of the others, which are all expressed as ratios of cross sections, branching fractions, or coupling modifiers, because it is directly correlated to the denominators of these ratios.

These correlation matrices are constructed as symmetric at the observed best fit values of the parameters of interest, and therefore are not fully representative of the asymmetric uncertainties observed in certain parameterisations, as shown for example in figure 9. The derivation of the results for a specific parameterisation, with additional assumptions compared to a more generic one, from the fit results and the covariance matrix of this more generic parameterisation, is therefore not straightforward. This is one of the reasons for quoting the best fit results in sections 5 and 6 for a wide range of parameterisations, beyond the more generic ones discussed in section 4.

B Breakdown of systematic uncertainties

The results of the generic parameterisation of section 4.1.2, in terms of ratios of cross sections and branching fractions, with $gg \to H \to ZZ$ as the reference channel, are shown with the full breakdown of the uncertainties in table 20. The corresponding results for a similar parameterisation, with $gg \to H \to WW$ as reference, are shown in table 21 and illustrated in figure 30. The parameters corresponding to ratios of cross sections are identical in each of these parameterisations, and they are included in both tables for convenience, as are the two ratios, $\mathrm{B}^{WW}/\mathrm{B}^{ZZ}$ and $\mathrm{B}^{ZZ}/\mathrm{B}^{WW}$. Finally, the results of the generic parameterisation of section 4.2, in terms of ratios of coupling modifiers, are shown with the full breakdown of the uncertainties in table 22.

JHEP08(2016)045

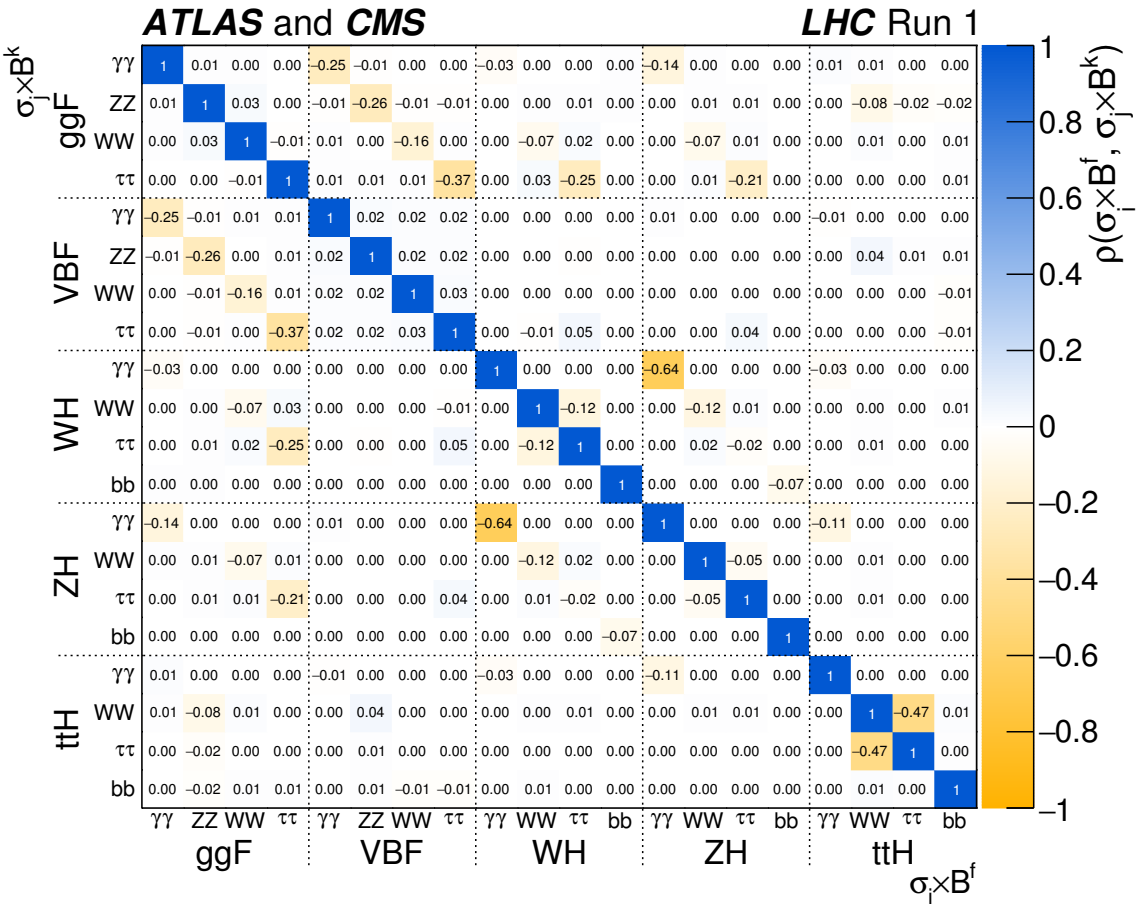

Figure 27. Correlation matrix obtained from the fit combining the ATLAS and CMS data using the generic parameterisation with 23 parameters described in section 4.1.1. Only 20 parameters are shown because the other three, corresponding to the $H \to ZZ$ decay channel for the WH, ZH, and ttH production processes, are not measured with a meaningful precision.

JHEP08(2016)045

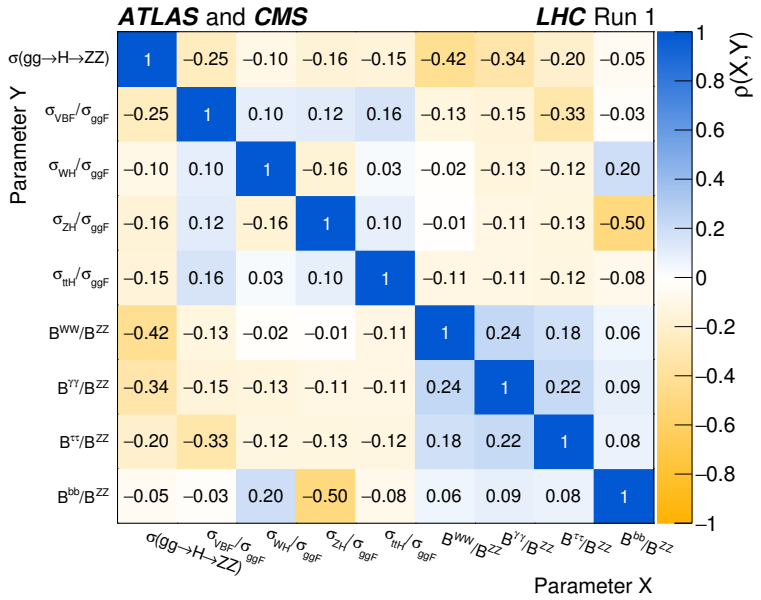

Figure 28. Correlation matrix obtained from the fit combining the ATLAS and CMS data using the generic parameterisation with nine parameters described in section 4.1.2.

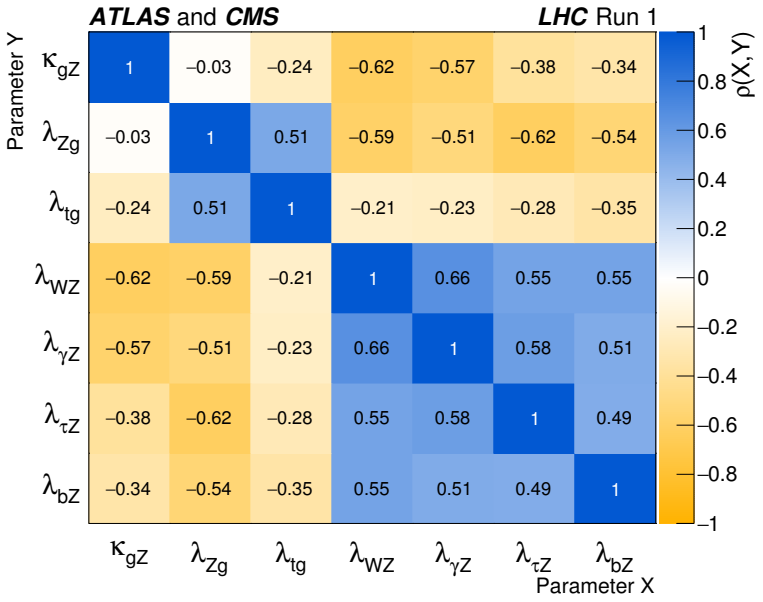

Figure 29. Correlation matrix obtained from the fit combining the ATLAS and CMS data using the generic parameterisation with seven parameters described in section 4.2.

Table 20. Best fit values of $\sigma(gg \to H \to ZZ)$, $\sigma_i/\sigma_{gg\mathrm{F}}$, and $\mathrm{B}^f/\mathrm{B}^{ZZ}$ from the combined analysis of the $\sqrt{s} = 7$ and 8 TeV data. The values involving cross sections are given for $\sqrt{s} = 8$ TeV, assuming the SM values for $\sigma_i(7\ \mathrm{TeV})/\sigma_i(8\ \mathrm{TeV})$. The results are shown for the combination of ATLAS and CMS, and also separately for each experiment, together with their total uncertainties and their breakdown into the four components described in the text. The expected total uncertainties in the measurements are also shown in parentheses. The SM predictions [32] are shown with their total uncertainties.

Table 21. Best fit values of $\sigma(gg \to H \to WW)$, $\sigma_i/\sigma_{gg\mathrm{F}}$, and $\mathrm{B}^f/\mathrm{B}^{WW}$ from the combined analysis of the $\sqrt{s} = 7$ and 8 TeV data. The values involving cross sections are given for $\sqrt{s} = 8$ TeV, assuming the SM values for $\sigma_i(7\ \mathrm{TeV})/\sigma_i(8\ \mathrm{TeV})$. The results are shown for the combination of ATLAS and CMS, and also separately for each experiment, together with their total uncertainties and their breakdown into the four components described in the text. The expected total uncertainties in the measurements are also shown in parentheses. The SM predictions [32] are shown with their total uncertainties.

JHEP08(2016)045

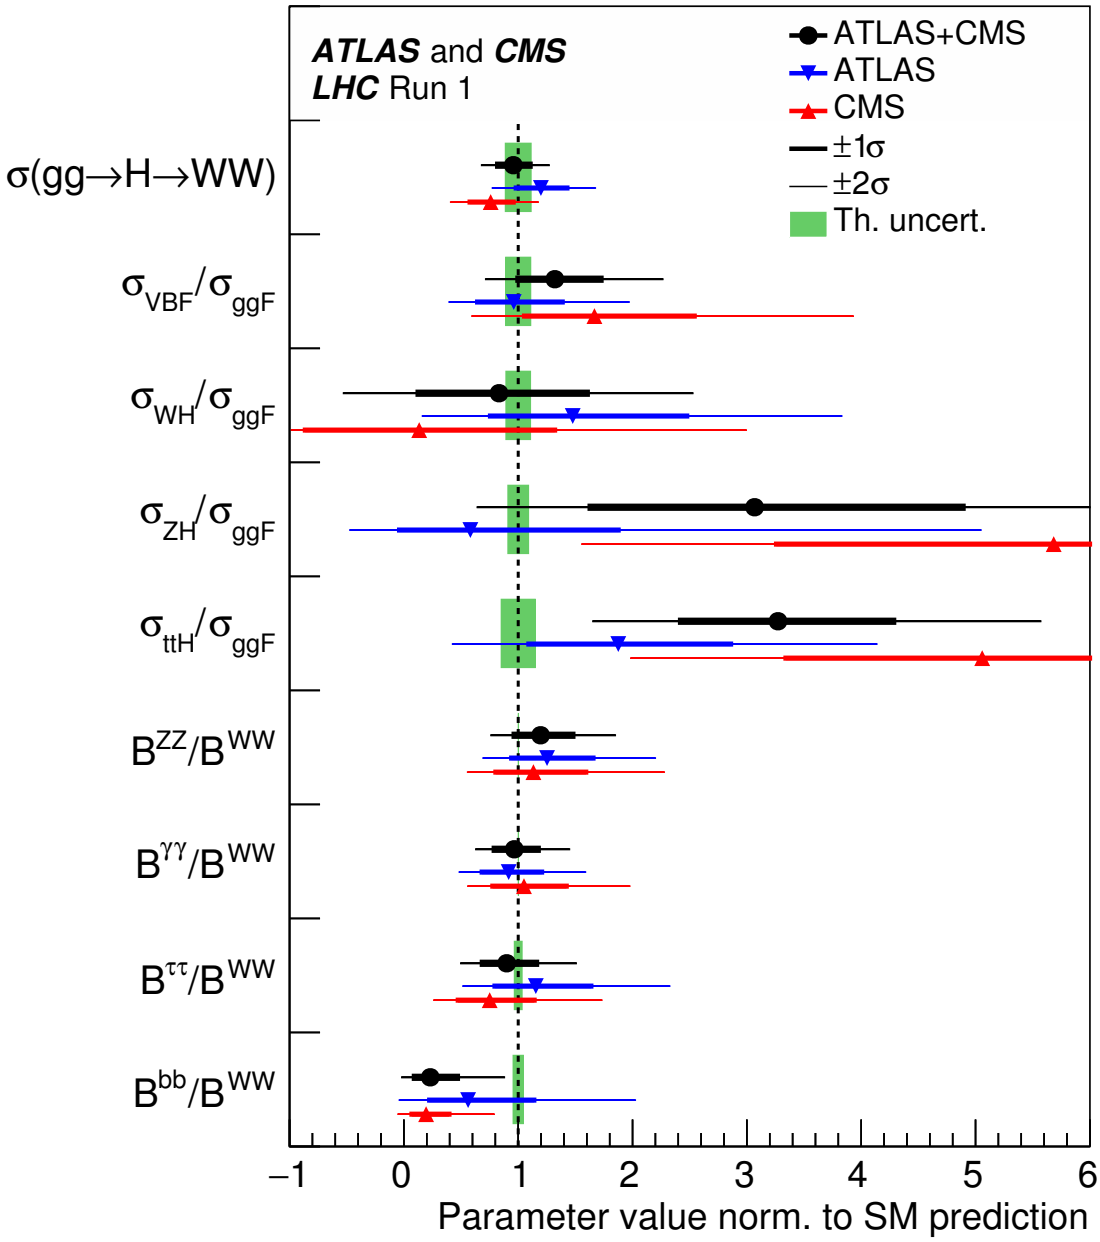

Figure 30. Best fit values of the $gg \to H \to WW$ cross section and of ratios of cross sections and branching fractions, as obtained from the generic parameterisation described in section 4.1.2 and as tabulated in table 21 for the combination of the ATLAS and CMS measurements. Also shown are the results from each experiment. The values involving cross sections are given for $\sqrt{s} = 8\,\text{TeV}$, assuming the SM values for $\sigma_i(7\ \text{TeV})/\sigma_i(8\ \text{TeV})$. The error bars indicate the 1σ (thick lines) and 2σ (thin lines) intervals. In this figure, the fit results are normalised to the SM predictions for the various parameters and the shaded bands indicate the theoretical uncertainties in these predictions.

Table 22. Best fit values of $\kappa_{gZ} = \kappa_g \cdot \kappa_Z/\kappa_H$ and of the ratios of coupling modifiers, as defined in the most generic parameterisation described in the context of the κ framework, from the combined analysis of the $\sqrt{s} = 7$ and 8 TeV data. The results are shown for the combination of ATLAS and CMS and also separately for each experiment, together with their total uncertainties and their breakdown into the four components described in the text. The uncertainties in λ_{tg} and λ_{WZ}, for which a negative solution is allowed, are calculated around the overall best fit value. The combined 1σ CL intervals are $\lambda_{tg} = [-2.00, -1.59] \cup [1.50, 2.07]$ and $\lambda_{WZ} = [-0.96, -0.82] \cup [0.80, 0.98]$. The expected total uncertainties in the measurements are also shown in parentheses. For those parameters with no sensitivity to the sign, only the absolute values are shown.

JHEP08(2016)045

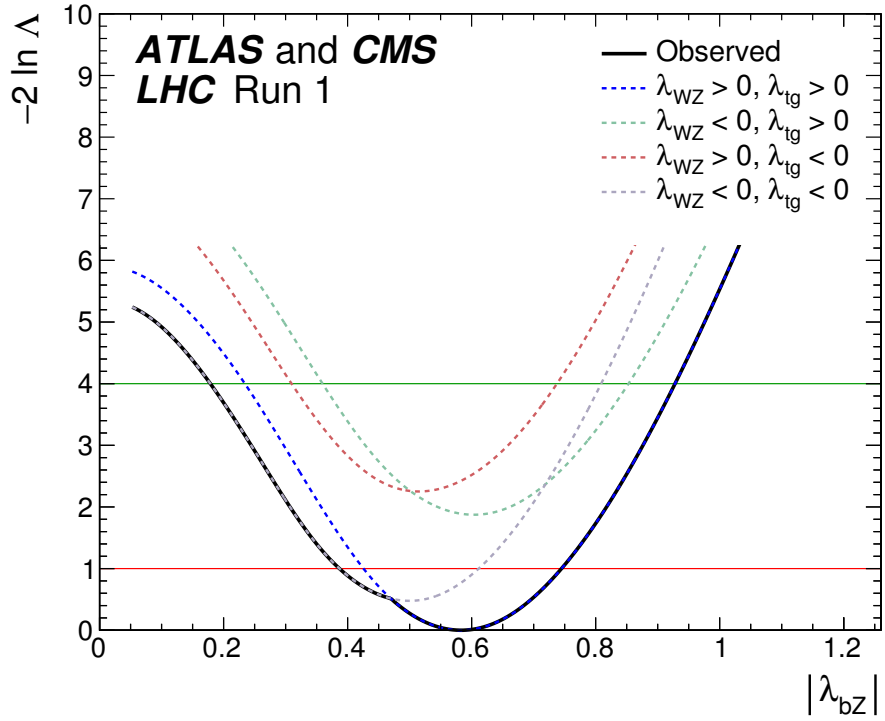

Figure 31. Negative log-likelihood scan for λ_{bZ} showing the minima obtained when considering all sign combinations (solid line) and each specific one separately (dashed lines).

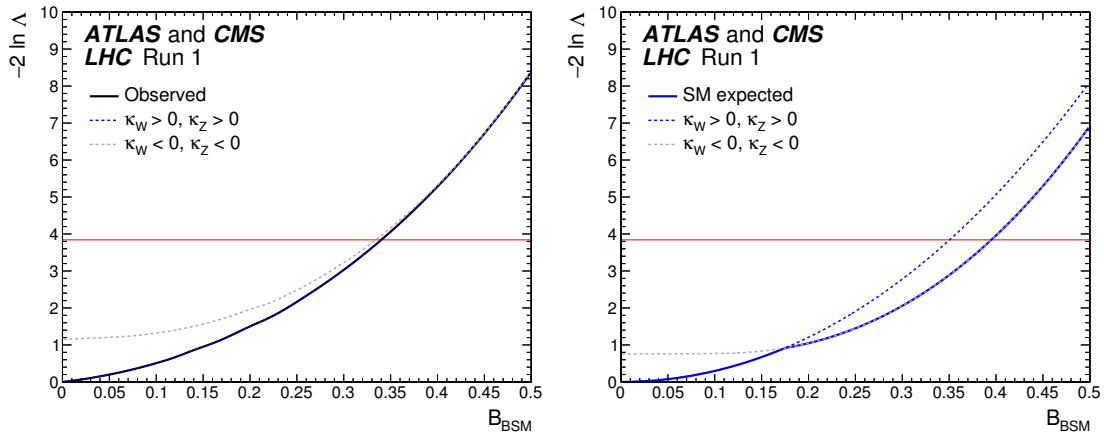

Figure 32. Observed (left) and expected (right) negative log-likelihood scan for B_{BSM}, the minima obtained when considering both sign combinations (solid line) and each specific one separately (dashed lines).

C Likelihood scans for coupling modifier parameterisations

For the results based on certain coupling modifier parameterisations described in sections 4.2 and 6, it is necessary to account for the relative signs between parameters that

JHEP08(2016)045

modify the rates of certain signal production processes and decay modes through interference effects. For example, in the generic parameterisation in terms of ratios of coupling modifiers, the signs of λ_{Zg}, λ_{WZ}, and λ_{tg} affect the rates of tH production through t–W interference, and of $ggZH$ production through t–Z interference. The parameters λ_{Zg} and, as a consequence, κ_{gZ} are assumed to be positive without loss of generality. From this follows that there are four relevant sign combinations of λ_{WZ} and λ_{tg}, which must be evaluated when performing all likelihood scans. An example is given in figure 31 for $|\lambda_{bZ}|$, with a separate curve shown for each sign combination. Each sign hypothesis gives rise to a distinct local minimum. As the negative log-likelihood for each case is determined relative to a common reference point, it is possible to identify the global minimum. For this parameterisation, the SM sign hypothesis ($\lambda_{WZ} > 0, \lambda_{tg} > 0$) corresponds to this global minimum. A new negative log-likelihood curve is defined as the envelope of the ones obtained for the different sign hypotheses, by taking the smallest value of $-2\ln\Lambda$ from the different sign hypotheses as a function of the parameter being considered in the scan. This curve, indicated by the solid line in figure 31, is used to determine the uncertainties and the confidence intervals. In the case of the example chosen here, but also more generally, this procedure results in larger confidence intervals than would be found from the ($\lambda_{WZ} > 0, \lambda_{tg} > 0$) hypothesis alone.

Another example of the effect of the different sign combinations is given in figure 32, which shows the observed and expected negative log-likelihood scans for $\mathrm{B_{BSM}}$ using the parameterisation described in section 6.1. Given that in this parameterisation, opposite signs of κ_W and κ_Z are not considered, only two sign combination hypotheses, $\kappa_W > 0, \kappa_Z > 0$ and $\kappa_W < 0, \kappa_Z < 0$, are evaluated. In the expected negative log-likelihood curve, a transition between the two hypotheses occurs at $\mathrm{B_{BSM}} \approx 0.175$. This has the effect of increasing the expected 95% CL upper limit on $\mathrm{B_{BSM}}$ from 0.35, when considering only the $\kappa_W > 0, \kappa_Z > 0$ case, to 0.39, once both sign combinations are considered.

ABSTRACT

We have developed n^+-in-p pixel sensors to obtain highly radiation tolerant sensors for extremely high radiation environments such as those found at the high-luminosity LHC. We have designed novel pixel structures to eliminate the sources of efficiency loss under the bias rails after irradiation by removing the bias rail out of the boundary region and routing the bias resistors inside the area of the pixel electrodes. After irradiation by protons with the fluence of approximately 3×10^{15} n_{eq}/cm^2, the pixel structure with the polysilicon bias resistor and the bias rails removed far away from the boundary shows an efficiency loss of <0.5% per pixel at the boundary region, which is as efficient as the pixel structure without a biasing structure. The pixel structure with the bias rails at the boundary and the widened p-stop's underneath the bias rail also exhibits an improved loss of approximately 1% per pixel at the boundary region. We have elucidated the physical mechanisms behind the efficiency loss under the bias rail with TCAD simulations. The efficiency loss is due to the interplay of the bias rail acting as a charge collecting electrode with the region of low electric field in the silicon near the surface at the boundary. The region acts as a "shield" for the electrode. After irradiation, the strong applied electric field nearly eliminates the region. The TCAD simulations have shown that wide p-stop and large Si–SiO_2 interface charge (inversion layer, specifically) act to shield the weighting potential. The pixel sensor of the old design irradiated by γ-rays at 2.4 MGy is confirmed to exhibit only a slight efficiency loss at the boundary.

1. Introduction

We have developed radiation-tolerant, planar-process, position-sensitive, silicon sensors in p-type 6-inch silicon wafers for applications in extremely high radiation environments [1–3] where radiation damage is generated by charged and neutral particles passing through the silicon sensors. Since the silicon bulk stays as p-type after irradiation, the p-type sensor requires lithographic processing only in the p–n junction side, simplifying the fabrication and leading to low device cost. Reading the signals out from the n-side enables the operation of the sensor without completely depleting the bulk and makes the sensor highly radiation tolerant. The planar silicon fabrication process is well established in the industry and is a cost-effective solution for large volume device production.

Extremely high radiation environments are found in the large hadron collider (LHC) [4]. The LHC accelerator complex is planned to be upgraded to High Luminosity LHC (HL-LHC) [5] to reach a

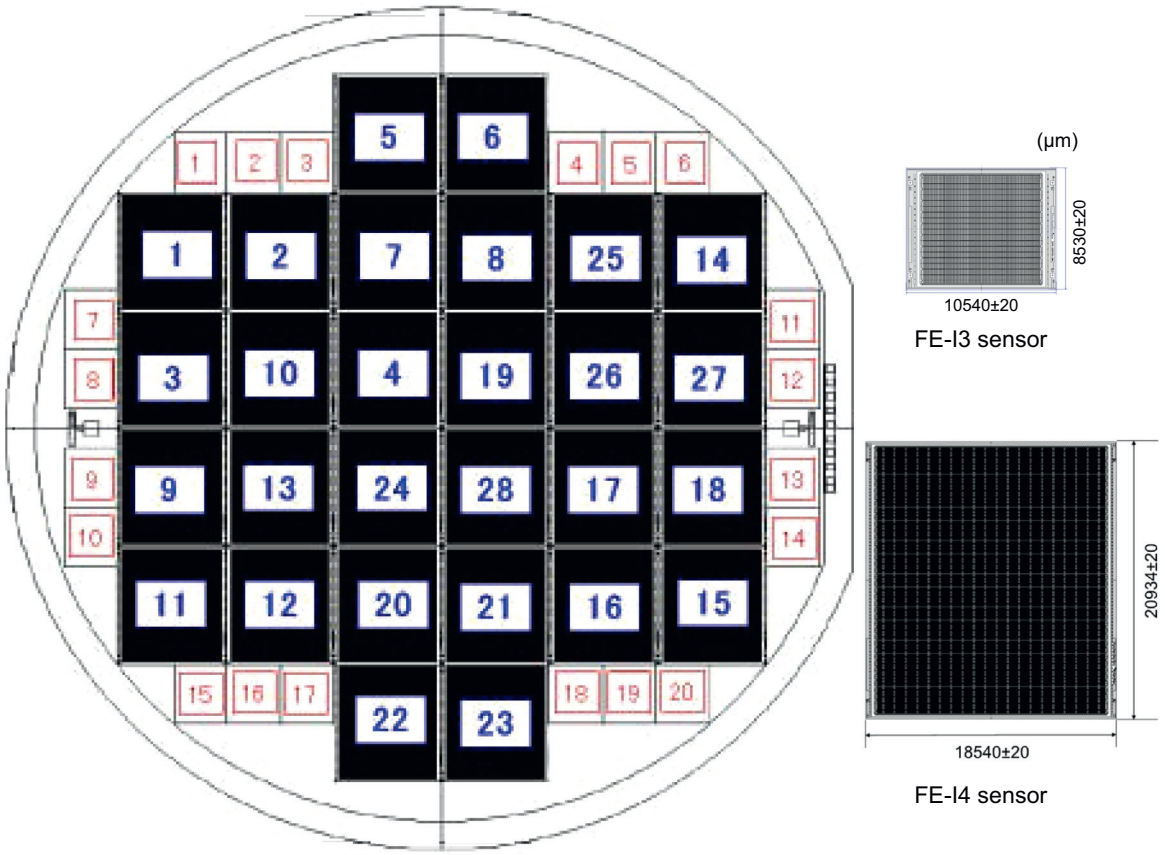

Fig. 2. Wafer layout #4 in 6-inch wafer, with 28 of ATLAS FE-I4 singles and 20 of FE-I3 singles of pixel sensors. Each FE-I4 and FE-I3 pixel sensor is 18.54×20.93 and 10.54×8.53 mm^2 in chip size, with a 336×80 and 160×18 matrix of 50×250 and 50×400 μm^2 pixels, respectively, with unique pixel structure per sensor.

higher collision rate (5×10^{34} cm^{-2}s^{-1} with "luminosity leveling") and consequently obtain an increase of one order in magnitude in the number of accumulated events (3000 fb^{-1}). The upgrade is scheduled during the LHC shutdown during the years 2024–2026. Our study primarily aims to develop a planar pixel sensor for the ATLAS detector, which is a general-purpose detector at a collision point in the LHC ring [6], that will be upgraded for the HL-LHC [7]. Considering a safety factor of 2, the sensor must cope with a radiation specified: the accumulated flow of particles ("fluence") of approximately 2×10^{16} 1 MeV-neutrons equivalent (n_{eq})/cm^2 and 3×10^{15} n_{eq}/cm^2 at a radius of 4 cm for the inner pixel layers and at 15 cm for the outer pixel layers, respectively [8].

Table 1
Specifications of wafer layout #4 of n^+-in-p pixel sensors.

Silicon wafer diameter	6 inch (150 mm)
Wafer type	p-type, float zone (FZ)
Crystal orientation	⟨100⟩
Resistivity	3–7 kΩ cm
Thickness	320 μm
Thinned	150 μm
Number FE-I4 sensors	28
Number FE-I3 sensors	20

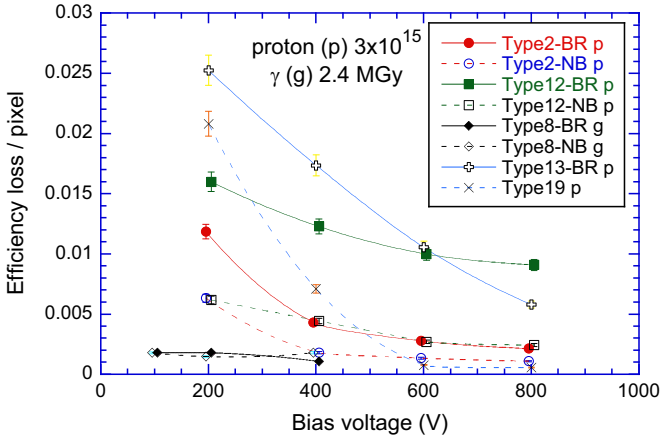

Fig. 4. Efficiency loss per pixel as a function of bias voltage in the bias rail (BR, filled) and the no bias bail (NB, open) regions, of Types 2 (Large offset, circle) and 12 (Small offset, square) pixel structures after proton irradiation of 3×10^{15} n_{eq}/cm^2, Type 8 (Old, diamond) after γ irradiation of 2.4 MGy. Those data of Types 13 (Wide p-stop, vertical cross) and 19 (No bias, cross) after proton irradiation [16] are reproduced together.

2. KEK/HPK n^+-in-p pixel sensors

2.1. Pixel structure – "Old" design (wafer layout #2)

We have previously produced n^+-in-p pixel sensors[1] in 6-inch wafers (hereafter referred to as "wafer layout #2") [2]. The sensors were bump bonded to the ATLAS pixel readout ASIC, FE-I4 [9], irradiated at a fluence of 2×10^{15} n_{eq}/cm^2 with 23 MeV protons at KIT [10], and tested by beam tests before and after the irradiation [11]. Several issues were identified on the basis of the results of these experiments.

The pixel structure of interest in the wafer layout #2 is shown in Fig. 1(a) (hereafter referred to as "Old" structure). Although the individual pixels are to be DC coupled to the readout ASIC, we have designed a connection of bias potential to the individual pixels to

[1] The superscript, +, indicates that the density of the material is higher than that of the silicon bulk.

Table 2
Parameters before and after irradiation in TCAD simulations.

Parameter	Non-irrad.	Irrad.
Fluence (n_{eq}/cm^2)	0	3×10^{15}
Effective space charge concentration (p-type), N_{eff} (cm^{-3})	2.6×10^{12}	2.5×10^{13}
Full depletion voltage, V_{dep} (V)	44	430
Applied bias voltage, V_{op} (V)	100	430
Leakage current, I_{leak} (a.u.)	1	~10^3
Surface density of interface charge, Q_f (cm^{-2})	1×10^{10}	1×10^{12}

(a.u: arbitrary unit)

Table 3
Geometry parameters used in TCAD simulations.

Parameter	Value
Silicon thickness (*tSi*)	150 μm
Bulk type	p-type
Pixel: implant type	n-type
Dopant concentration	1×10^{19} cm^{-3}
Implant width, depth (*wNsub*, *tNsub*)	50, 1 μm
Metal electrode	Al, DC-coupled
Overhang (*wEx1*)	2 μm
p-stop: implant type	p-type
Dopant concentration	1×10^{16} cm^{-3}
Implant width (*wPsub*), narrow/wide	4 / 8 μm
Implant depth (*tPsub*=*tNsub*)	1 μm
Gap to Pixel implant (*wGap*), wide/narrow	9.5/6.5 μm
Bias rail: metal, thickness	Al, 1.8 μm
Overhang, wide/narrow (*wEx1*, −2 × *wEx1*)	2/−4 μm
Insulator thickness (*tSio1*)	0.2 μm
Backplane implant, thickness (*tPback*)	p-type, 3 μm
Dopant concentration	1×10^{18} cm^{-3}

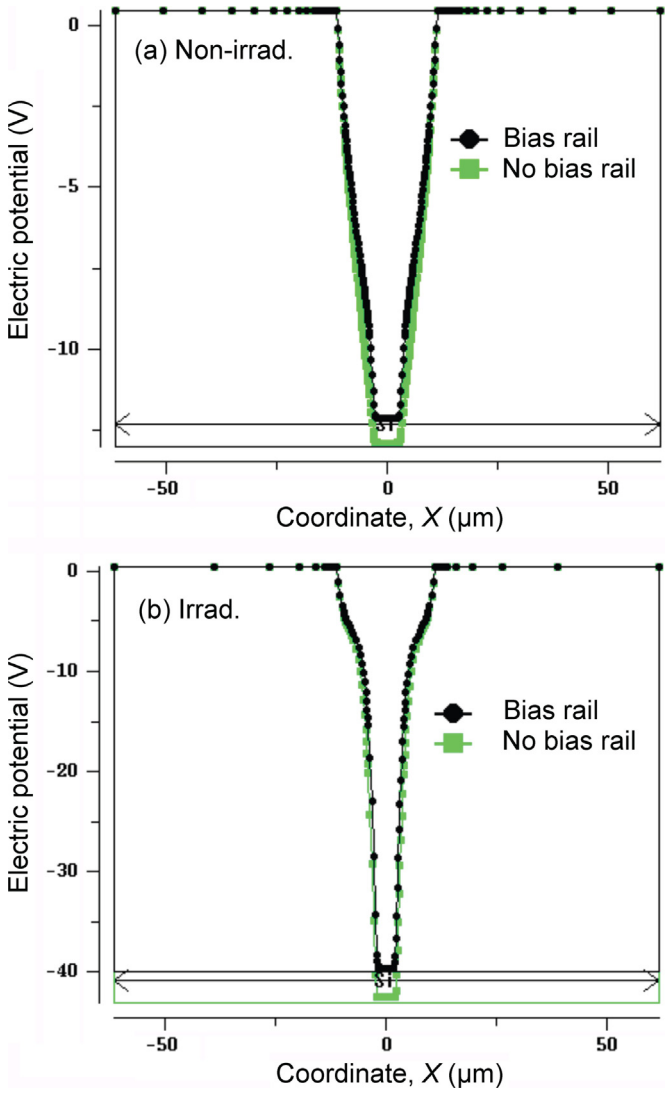

Fig. 6. Electric potential near the surface under the bias rail, with bias rail (black circle) and without bias rail (light-color square): (a) before irradiation (Non-irrad.) and (b) after irradiation (Irrad.).

test the sensor without bump bonding to the ASIC. We use a bias resistor made of polysilicon material to connect the individual pixels to a bias rail common to a row of pixel pairs. The bias rail was made of polysilicon in the design. Addition of a biasing network is a complication in the pixel structure but the quality control of the sensors would save time and cost at later assembly stages.

In the old design, the bias rail runs in the middle of the boundary of a pair of pixels, which is shown horizontally in the figure, and the bias resistors are routed to the pixel implants by encircling outside the pixels. The bias rail runs over the narrow trace of p^+ implant in the surface of silicon, called "p-stop". The p-stop is required to separate the n^+ pixel implants. The bias rail and the p-stop are separated spatially and electrically by the SiO_2 surface passivation. The width of the p-stop was chosen to be narrow according to the analysis of the designs [12]. The width of the bias rail is wider than that of the p-stop to reduce the electric field at the edge of the p-stop.

Efficiency loss was observed for this layout. The loss of efficiency was most pronounced under the bias rails, and was smaller but still noticeable under the bias resistors, compared to the loss at the pixel boundaries in the opposite side where no bias rail exists.

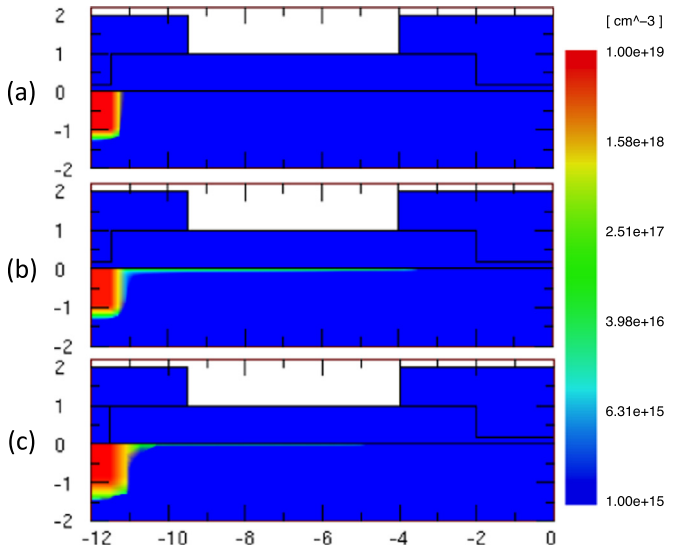

Fig. 7. Electron density in the surface of silicon simulated with TCAD: (a) before irradiation, $Q_f = 1 \times 10^{10}$ cm^{-2}, bias voltage -100 V, (b) the same as (a) but $Q_f = 1 \times 10^{12}$ cm^{-2}, and (c) after irradiation, $Q_f = 1 \times 10^{12}$ cm^{-2}, bias voltage -430 V. The color scale is in the unit of volume density (cm^{-3}). (For interpretation of the references to color in this figure caption, the reader is referred to the web version of this paper.)

In the absence of irradiation, the loss was negligible.

2.2. Optimization of pixel structures – novel design (wafer layout #4)

We have then designed novel pixel structures to optimize the pixel structures to mitigate the problems found for sensors with wafer layout #2. The structures of special interest are shown in Fig. 1, (b) Type 10 and (c) Type 13 in wafer layout #4. The physical mechanisms behind the efficiency loss, especially the difference between before and after irradiation, have been investigated and are presented in Section 4. Phenomenologically, we hypothesized that removal of the bias rails out of the boundary region and the placement of the bias rails and bias resistor traces in the area of and over the pixel implantation to shield them from the silicon underneath will mitigate the efficiency loss. In Type10 (hereafter referred to as "Large offset"), the common bias rail for a pair of rows of pixels is split into individual bias rails per a row of pixels, the bias rails are removed far away from the boundary, and the bias rails and the bias resistors are routed in the area of and over the pixel implantation. In Type13 (hereafter referred to as "Wide p-stop"), the common bias rails are kept at the boundaries, but their width is smaller and the width of the p-stop is wider, which is based on the hypothesis that the p-stop may function as a shield for the bias rail.

The novel pixel structures are laid out in wafer layout #4 as shown in Fig. 2 in two types of sensors: FE-I4 (18.54×20.93 mm^2) with a matrix of 336×80 of 50×250 μm^2 pixels [9] and FE-I3 (10.54×8.53 mm^2) with 160×18 of 50×400 μm^2 pixels [13]. The detailed description of the novel pixel designs is given in Appendix A along with relevant tables and figures. No additional cost is associated with the novel pixel structures in fabrication as the PolySi process has already been included.

Typical parameters of the wafer layout #4 are summarized in Table 1. The thickness of the raw wafers is 320 μm. After the fabrication of the front side, the thin sensors are fabricated by thinning the rear of the wafer to a thickness of 150 μm, followed by an additional process for the rear.

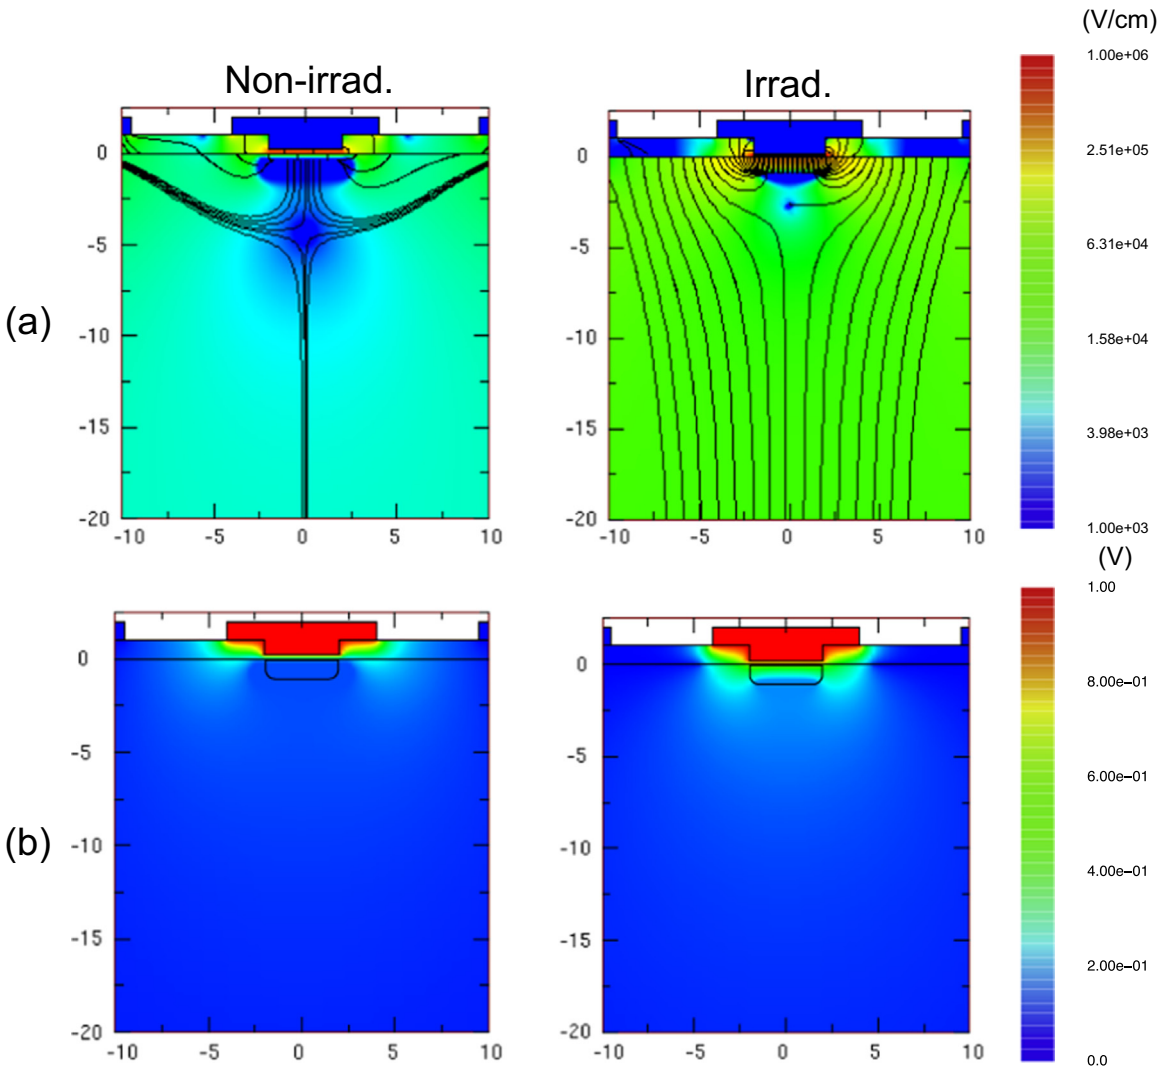

Fig. 8. 2D maps of the fields in the vicinity of bias rail, before and after irradiation in the left and right column, and in the rows of (a) electric field E overlaid with flow lines and (b) weighting potential of the bias rail V_{qA}, respectively.

3. Results with test beams

Pixel sensors with the novel pixel structures were irradiated at a fluence of 3 to 5×10^{15} n_{eq}/cm^2 with 70 MeV protons at CYRIC [14]. The samples were irradiated in an irradiation box attached to an X–Y stage to scan the beam uniformly over the samples. The samples were cooled to -15 °C during the irradiation with the cold nitrogen gas from a liquid nitrogen dewar, and after irradiation stored cold in a freezer. A pixel sensor of the old design was irradiated with γ rays at a dose of 2.4 MGy at TARRI [15]. These irradiated samples were then tested using test beams at DESY with 4 GeV electrons and/or CERN with 120 GeV π's [16,17]. Based on the energy of the beam particles, together with the distance between the telescope planes and the device under test (DUT), the pointing resolution of the beam particles at the DUT plane was approximately 30 and 8 μm at DESY and CERN, respectively.

3.1. Efficiency mapping over pixel boundaries

An example of the improvement of the novel pixel structure is illustrated in Fig. 3, using an efficiency mapping over two pixel regions projected on the long pixel side. The DUT is KEK46 and 150 μm thick with the Type 10 pixel structure, irradiated at 4.18×10^{15} n_{eq}/cm^2 and tested at DESY. The boundary of the bias rail side (Bias rail (hereafter referred to as BR)) is at 125 μm and the opposite side (No bias rail (hereafter referred to as NB)) is at 375 μm. The curves are fit to the data for guidance. The width of the efficiency loss is dominated by the pointing resolution. The efficiency losses in the BR and NB boundaries are nearly symmetric; the effect of the bias rail is nearly eliminated. In the plot, the efficiencies of the central region of the pixels are normalized to unity since the absolute efficiency was not reliable due to a technical issue in this test beam.

3.2. Efficiency loss per pixel – comparison of pixel structures

The efficiency loss at the boundary can be quantified as an "efficiency loss per pixel" by fitting a Gaussian function to the efficiency mapping over the pixel boundaries and dividing the integrated "area" of the Gaussian by the length of two pixels. The calculation of "area" eliminates the difference in the pointing resolutions at DESY and CERN. A compilation of the efficiency loss per pixel at the boundaries is shown in Fig. 4 for the DUT's of KEK84ch1 (150 μm, Type 2, p 3.03×10^{15}), KEK71ch3 (150 μm, Type 12, p 3.08×10^{15}), KEK93 (320 μm, Type 8, γ 2.4 MGy), using the CERN data and KEK49ch3 (150 μm, Type 13, p 3.20×10^{15}) and KEK53ch3 (150 μm, Type 19, p 2.35×10^{15}) using the DESY data. The letters "p" and "g" in the legend

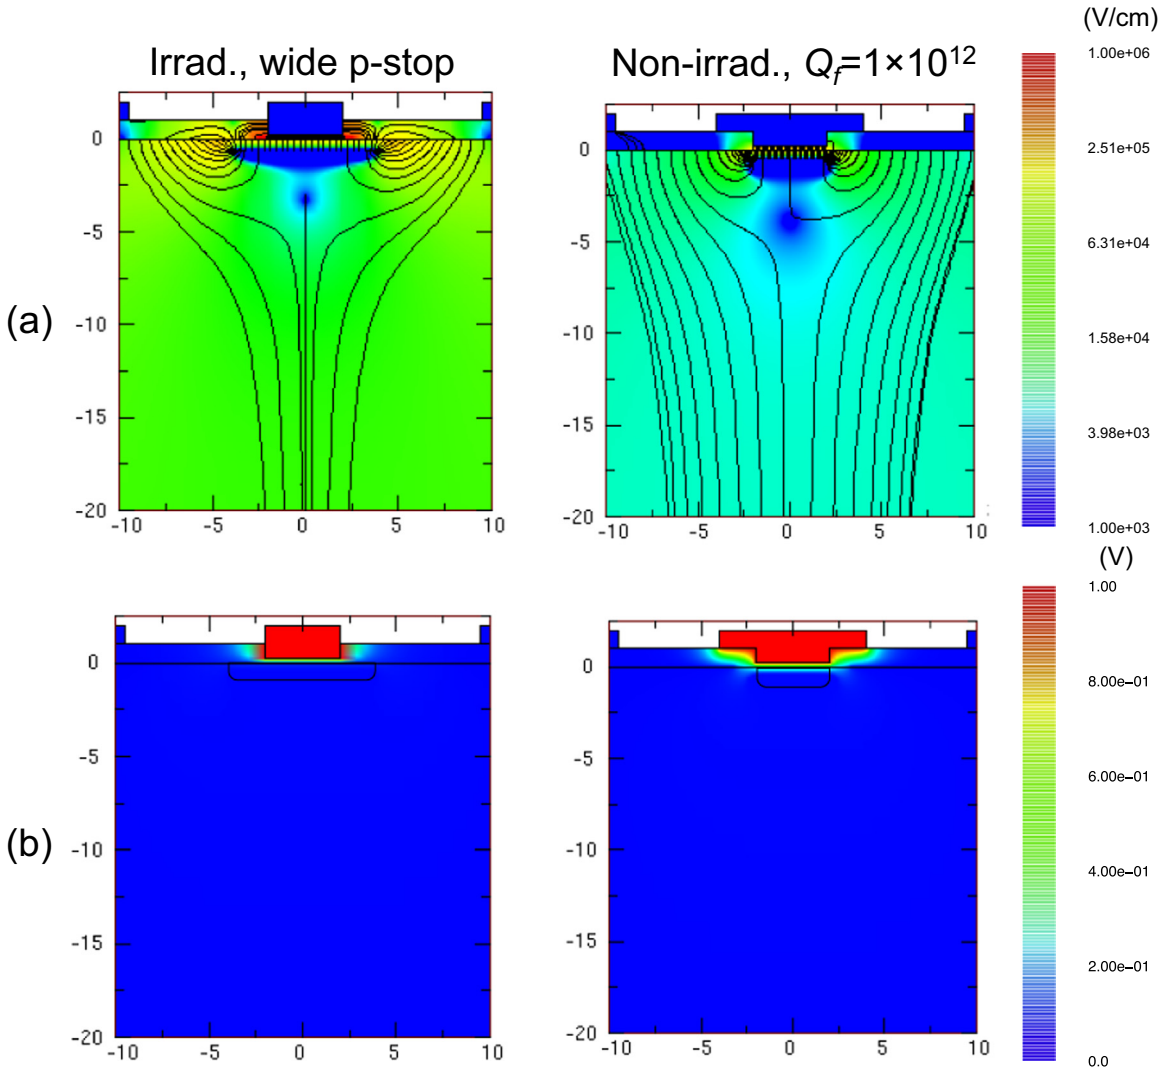

Fig. 9. 2D maps of the fields in the vicinity of bias rail of the wide p-stop geometry after irradiation and the narrow p-stop geometry before irradiation with the interface charge as that after irradiation in the left and right column, and in the rows of (a) electric field E overlaid with flow lines and (b) weighting potential of the bias rail V_{qA}, respectively.

indicate the proton and the γ irradiation, respectively. The efficiency losses at the boundary of the bias rail side or the no bias rail side are indicated with the BR (with solid line) or NB (with dashed line), respectively. The pixel structure of Type 2 is an equivalent of Type 10 but the bias rail is made from an aluminum material. Type 12 is a variation of Type 10 with the bias rails set at the edges of the pixels (hereafter referred to as "Small offset"). Type 8 is an equivalent of the old structure. Type 19 is the reference with no bias structure and represents the best case. The details of the pixel structures are presented in Appendix A.

There is a noticeable difference in bias voltage dependence between the DUT's of the CERN (Types 2 and 12) and DESY data (Types 13 and 19). The difference has been traced to the difference in the bias voltage dependence of the pulse height distribution, most likely due to different tunings of the readout ASICs at different bias voltages. This difference can be removed by normalizing the NB data points by each other because the NB side is basically the same as the no bias structure.

On the basis of Fig. 4, we have evaluated the pixel structure of the bias rail side (BR), finding that

(1) Type 2 (Large offset) is as good as NB (No bias) side, the loss is <0.5% per pixel at the bias voltage >400 V,
(2) Type 12 (Small offset) and Type 13 (Wide p-stop) are similarly good, the loss is approximately 1% at >600 V,
(3) These pixel structures exhibit greatly improved efficiency loss, compared with the ≥3% loss of the "old" design [16], and
(4) γ irradiation has no effect on the efficiency loss under the bias rail.

The result (4) especially indicates that the efficiency loss under the bias rail is not caused by the surface charge in the Si–SiO_2 interface but caused by the radiation damage in the silicon bulk.

4. Understanding the underlying physics

We have used a semiconductor technology CAD (TCAD) program, ENEXSS [18], to calculate the electric fields in detail, including the effect of trapped charges in the interface. The region of the pixel boundary with the bias rail is modeled and implemented as a 2D geometry in the TCAD simulations as shown in Fig. 5. We have approximated the conditions before and after irradiation with three parameters according to the method elaborated in Ref. [19]: effective space charge concentration (N_{eff}) and leakage current (I_{leak}) in the silicon bulk, and fixed interface charge (Q_f) at the

boundary between the silicon bulk and the surface SiO_2. After irradiation, space charge concentration, leakage current, and fixed interface charge are taken to be increased by one order, three orders, and two orders of magnitude, respectively, caused by displacement and ionization damages. The parameters before and after irradiation are summarized in Table 2, in columns of "Non-irrad." and "Irrad.", respectively (hereafter referred to as Non-irrad. and Irrad.). The values of the geometry parameters are summarized in Table 3.

4.1. Effect of electric potential of the bias rail

In the DUTs with polysilicon bias resistors, the pixel electrode is connected to the bias rail through the polysilicon resistor. The pixel electrode is connected to the virtual ground of ASIC and thus the bias rail is at the ground potential. We used TCAD simulations to determine the electric field in the boundary region near the surface of the silicon (1 μm below the surface of silicon in the TCAD geometry) with and without the bias rail. The electric

potentials before and after irradiation are shown in Fig. 6(a) and (b) for the narrow p-stop geometry (widths of bias rail and p-stop being 8 and 4 μm), with the Non-irrad. (bias voltage of −100 V) and the Irrad. (−430 V) conditions, respectively. The data obtained with and without the bias rail are shown by filled circles and squares, respectively. The existence of the ground potential induced a difference of approximately 1 V over the electric potential of 16 V before irradiation and of 2 V over 42 V after irradiation at the location of the bias rail. The differences are small and the fractions to the total potential are similar before and after irradiation. The difference of the interface charge before and after irradiation generates a subtle difference in the shape of the electric potential between the p-stop and the pixel electrode, but only slightly influences the values of the potentials with and without the bias rail. The existence or non-existence of the ground potential does not appear to be the source of efficiency loss at the boundary.

4.2. Charge induced on the bias rail

A moving charge in the presence of any number of electrodes kept at constant voltages induces a mirror charge on the electrodes according to Ramo's theorem:

$$Q_A = q \cdot V_{qA}, \tag{1}$$

where Q_A is the charge induced on an electrode A, q is the charge at a given position, and V_{qA} is the "weighting potential" of the electrode A at the position of the charge q. In a finite time, with a fast readout electronics, instantaneous induced current i_A is represented by the gradient of V_{qA} along the direction of motion multiplied by the drift velocity:

$$i_A = q \cdot \frac{dV_{qA}}{dt} = q \cdot \left(\frac{\partial V_{qA}}{\partial x}\,\frac{dx}{dt}\right) = q \cdot \vec{v} \cdot \overrightarrow{\frac{\partial V_{qA}}{\partial x}} = q \cdot \mu \vec{E} \cdot \overrightarrow{\frac{\partial V_{qA}}{\partial x}}, \tag{2}$$

where μ is the charge carrier mobility and E is the electric field. Although the current has to be integrated to evaluate the charge, an insight into the physics can be obtained qualitatively and visually from the maps of the electric field E, the flow lines of the electric field representing the drifting paths of the charge carriers, and the weighting potential V_{qA}.

Since the drifting carriers do not terminate on the bias rail, the current induced on the bias rail is bipolar. The collection time of charge carriers (electrons in n^+ electrode) is in the order of 10 ns. Since we use a fast-shaping amplifier (peaking time of approximately 20 ns), the early part of the bipolar signal will result in a finite amount of charges induced on the bias rail. Thus, it is natural to expect that charge will be lost to the bias rail, causing efficiency loss. However, it is unclear why we observe efficiency loss only after irradiation and not prior to it.

4.3. Visualization of the fields and predictions by TCAD

The weighting potential is independent of the space charge distribution and actual voltages, however, it depends on the geometry of the electrodes and the resulting electric field. In a semiconductor device the actual shape of the electrode is bias dependent due to the change in depletion volume, for instance. In the p-type device the effective extent of the n^+ electrode is bias dependent due to the existence of inversion layer in the n-side surface of silicon. The radiation damage by charged particles on the surface of device leaves positive fixed charge at the interface of $Si–SiO_2$. The inversion layer is created by the electric potential of the positive fixed charges that repels the holes from the silicon surface. The potential of the fixed interface charge is partially compensated by the potential at the surface of silicon generated by the bias voltage (see Fig. 6), thus the extent of the inversion layer is bias dependent.

Using the geometry setup and the conditions described above, we extract two-dimensional maps of fields. The inversion layer is indeed simulated in the TCAD as shown as the electron density in the surface of silicon in Fig. 7, (a) before irradiation (with Non-irrad. condition: $Q_f = 1 \times 10^{10}$ cm^{-2}, bias voltage −100 V), (b) as same as (a) but $Q_f = 1 \times 10^{12}$ cm^{-2}, and (c) after irradiation (with Irrad. condition: $Q_f = 1 \times 10^{12}$ cm^{-2}, bias voltage −430 V). There is little inversion layer before irradiation due to the low density of the interface charge. The inversion layer is visible with the interface charge density after irradiation; extends from the n^+ electrode toward the p-stop (edge at −2 μm) approximately to −3 and −5 μm with the bias voltage of −100 V and −430 V, respectively. Visual thickness of the layers in the plots should be due to the resolution of the calculation and plotting.

The weighting potential of the electrode of interest is calculated from the difference of the two maps of the electric potential: the map with the setup and that obtained by adding 1 V to the electrode of interest over the setup. The remnant is the potential where the selected electrode at unit potential, all other electrodes at zero potential. The extracted fields are shown in Fig. 8 for the narrow p-stop geometry in the rows of (a) electric field E overlaid with flow lines of the field and (b) weighting potential of the bias rail V_{qA}, in the columns of before (Non-irrad., −100 V) and after irradiation (Irrad., −430 V), respectively.

Examination of Fig. 8 shows that there are several distinctive differences between the fields before and after irradiation. Prior to irradiation, the electric field shows a large blob of low electric field region under the bias rail/p-stop, the flow lines of the electric field, i.e., the path of drifting carriers are deflected from the low electric field region toward the pixel electrodes distinctly, and the intensity of the weighing potential of the bias rail is not extending in the area and vicinity of the low electric field region. The area of low electric field region appears to function as a shield against the drift paths and the weighting potential. After irradiation, the blob of low electric field region under the bias rail becomes minute, the flow lines are not deflected very much, and the intensity of the weighting potential extends more near to the bias rail and more toward the backplane. The shrinkage of the blob is caused by the strong electric field generated by the large bias voltage applied to cope with the space charge (N_{eff}) increased by the radiation damage in the silicon bulk. The extent of the inversion layer shields the weighting potential to remain in the vicinity of the bias rail.

The charge induced on the bias rail is determined by the interplay of the weighting potential and the path of drifting carriers. By overlaying the flow lines over the weighting potentials, we observe that before irradiation the drifting carriers from most of the bulk do not pass high intensity region of the weighting potential, but after irradiation drifting carriers especially from the bulk under the bias rail pass through. On the basis of the visualization, we conclude that the charge induced on the bias rail is small (almost zero) before irradiation but finite after irradiation.

The TCAD simulations have also predicted only a slight efficiency loss in the pixel structure with the wide p-stop geometry (widths of bias rail and p-stop being 4 and 8 μm) after irradiation, and in the old pixel structure after γ irradiation. Fig. 9 shows in the rows of (a) electric field overlaid with flow lines and (b) weighting potential, in the columns of the cases of wide p-stop geometry after irradiation (Irrad., wide p-stop) and of narrow p-stop geometry before irradiation but with the interface charge as that after irradiation (Non-irrad., $Q_f = 1 \times 10^{12}$ cm^{-2}), respectively. The latter scenario corresponds to the case of γ irradiation. In both cases, the weighting potentials are very low and uniform over a wide region including under the bias rail/p-stop region. The low electric field

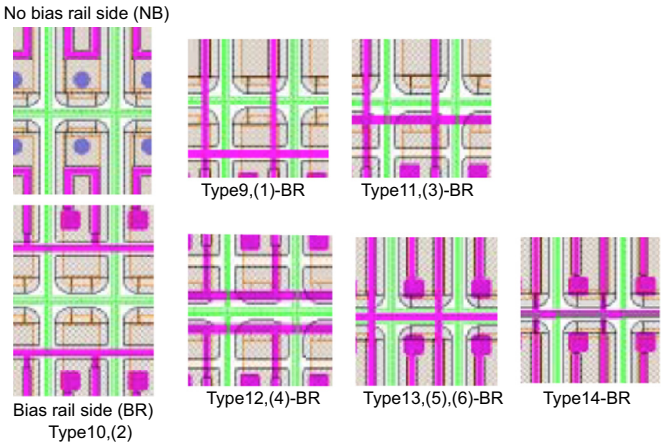

Fig. 10. Pixel structures in wafer layout #4 of Types 1–6 and 9–14 with variations of number of bias rails and their locations. Bias rail is made of polysilicon (Types 9–14) or aluminum (Types 1–6).

region under the p-stop and the extent of the inversion layer are nearly overlapping, thus seem to shield the weighting potential against extending into the silicon bulk. The γ irradiation study was motivated by the TCAD prediction.

5. Summary

We have developed n^+-in-p pixel sensors, using planar process in p-type 6-inch silicon wafers to obtain highly radiation tolerant sensors for extremely high radiation environments such those found in HL-LHC. We have designed novel pixel structures – wafer layout #4 – to eliminate the efficiency loss at the pixel boundary observed in the old pixel structure of the wafer layout #2, especially after irradiation. The new pixel sensors were irradiated with protons at a fluence of approximately 3×10^{15} n_{eq}/cm^2 at CYRIC or with γ rays at a dose of 2.4 MGy at TARRI, and evaluated with test beams at CERN and DESY.

- Among the novel pixel structures tested, the best pixel structure to retain high efficiency after irradiation is the one with "Large offset" where the bias rails removed far away from the boundary and the polysilicon biasing resistor routed inside the pixel implant region, achieving an efficiency loss of <0.5% per pixel at the boundary, as efficient as that without the bias rail.
- If offsetting the bias rail were not applicable, the one with "Wide p-stop" geometry could be an alternate solution, achieving a loss of approximately 1% per pixel at the boundary.

We have also obtained an understanding of the physics underlying the efficiency loss under the bias rail with TCAD simulations, by simulating the electric fields, especially the weighting potential of the bias rail.

- The efficiency loss is due to the loss of charge induced on the bias rail.
- The difference of the charge induced on the bias rail before and after irradiation is caused by the difference of the region of low electric field under the bias rail together with the extent of the inversion layer in the surface of silicon.
- Before irradiation, a large blob of low electric field region under the bias rail makes the weighting potential very low in the area and vicinity, deflects drifting carries out of high intensity region of the weighting potential.
- After irradiation, the blob becomes minute due to strong electric field in the radiation-damaged silicon, which together with the extent of the inversion layer makes the weighting potential to extend more into the silicon under the bias rail, makes drifting carriers especially from the region under the bias rail to pass through high intensity region of the weighting potential.
- The TCAD simulations have also shown that wide p-stop and large $Si–SiO_2$ interface charge (inversion layer, specifically) act to shield the weighting potential against extending into the silicon bulk. The pixel sensor with old pixel structures irradiated with γ rays has confirmed little efficiency loss at the boundary.

Appendix A. Pixel structures in wafer layout #4

In the wafer layout #4 (Fig. 2), we have designed several variations of the structures to investigate and evaluate the novel pixel structures in FE-I4 and FE-I3 pixel sensors. The characteristics of 28 variations in the FE-I4 pixel sensors and 20 in that of the FE-I3 pixel sensors are summarized in Tables 4 and 5, respectively. The material of the bias rail is either polysilicon (referred to as "PolySi") or aluminum (referred to as "Al"). The pixel structure with the Al bias rail is symbolized with the type number in parenthesis. The detailed views of the pixel structures are shown in Figs. 10–14. The pixel structures of bias rail side and no bias rail side are labelled with BR and NB, respectively.

A.1. FE-I4 sensors

The 19 variations from Types 1 to 19 are fabricated using a pixel size of 50 × 250 μm^2 (column "Pixel size" in the tables, Figs. 10–12). The 9 variations from Types 20 to 28 are fabricated with a pixel size of 25 × 500 μm^2, mating to the same grid of the bump pads of the FE-I4 readout ASIC, splitting the 50 μm of short pixel direction into two 25 μm pixels and merging two pixels to 500-μm-long pixels in the long pixel direction to study a finer pitch of the pixels (Figs. 13 and 14).

In the 50 × 250 μm^2 pixels, the location of the bump pads (column "Bump pad") is always at the end of pixel electrodes (referred to as "End", e.g. Fig. 10) in the NB side for Types 1–19. In the 25 × 500 μm^2 pixels, the locations of the bump pads are, (1) at the end of pixel electrodes for Type 20, etc. (Fig. 13), (2) at the center of pixel electrodes (referred to as "Center" in the tables, BP in Fig. 14) for Type 23, etc., or (3) at the center and the end alternately (referred to as "Staggered") for Type 27 (Fig. 14) to make the pixel electrodes to be staggered by half pitch in the long pixel direction. The staggered pixel layout is used to evaluate improvements in position resolution in the long pixel direction because more two-cluster hits are expected in the 25 μm pixels than in the 50 μm pixels.

The bias resistor is either formed with a resistive trace of polysilicon material, approximately 5 kΩ/μm (column "Bias type", referred to as "PolySi") or a punch-through structure with a narrow gap, approximately 18 μm between a bias dot (n^+ implant) and the pixel electrodes (n^+ implant) (referred to as "PT"). The PolySi resistor is routed (column "PolySi routing") to place the trace either "inside" the area of pixel electrode (Fig. 10) to mitigate the efficiency loss under the trace or "outside" the pixel area for Types 7 and 8 (Fig. 11) as a reference to the old design.

One approach for the removal of the bias rail out of the boundary region is to use two bias rails for a pair of pixel rows (column "Bias rail"), placing them in the pixel area largely away from the boundary (referred to as "Large offset", column "Bias rail offset", e.g. Fig. 10 Type 10) or just over the edge of the pixel electrode (referred to as "Small offset", Fig. 10 Type 12). The other is to keep one bias rail at the boundary (referred to as "None") but to increase the width of the p-stop under the bias rail while keeping the width of the bias rail narrow (referred to as "Wide", column "p-stop width", Fig. 10 Type 13), otherwise narrow (referred to as "Narrow", Fig. 10 Type 14).

In the case of PT structures, one PT dot is shared by four pixels in a pair of pixel rows to which one bias rail is placed [20]. The bias rail is either straight (referred to as "Straight", column "Bias rail") with the wide p-stop under the bias rail ("Wide", column "p-stop width") or zigzags ("Zigzag", column "Bias rail") by passing through the bias dot and then being largely removed away from the boundary region ("Large offset", column "Bias rail offset") or just over the edge of the pixel electrode ("Small offset", Fig. 12).

The material of the bias rail is listed in the column "Bias rail material". Historically, Al has been used. The resistance of the biasing network is a source of electrical noise (parallel noise). Larger resistance gives smaller noise, leading to our preference to "PolySi".

The similar structures of PolySi and PT are implemented in the 25 × 500 μm^2 pixels (Types 20–28, Figs. 13 and 14). The pixel structure without the biasing network ("None", column "Bias type") is used as the reference due to it showing the best performance (Type 19, Fig. 12 for the 50 × 250 μm^2 and Type 28, Fig. 13 for the 25 × 500 μm^{2}pixels).

A.2. FE-I3 sensors

The characteristics of the variations in the FE-I3 pixel sensors

are summarized in Table 5. The pixel structures are limited to 20 variations due to the available space in the wafer layout. The 13 variations from Type 1 to 13 used $50 \times 400\ \mu m^2$ pixels. The 7 variations from Type 14 to 20 used $25 \times 800\ \mu m^2$ pixels. The basic structures are copied from the FE-I4 pixel structures. The pixel structures equivalent to the FE-I4 sensors are listed in the "FE-I4 sensor equivalent" column in Table 5.

Combined Measurement of the Higgs Boson Mass in pp Collisions at $\sqrt{s} = 7$ and 8 TeV with the ATLAS and CMS Experiments

G. Aad *et al.*[*]

(ATLAS Collaboration)[†]
(CMS Collaboration)[‡]

(Received 25 March 2015; published 14 May 2015)

A measurement of the Higgs boson mass is presented based on the combined data samples of the ATLAS and CMS experiments at the CERN LHC in the $H \to \gamma\gamma$ and $H \to ZZ \to 4\ell$ decay channels. The results are obtained from a simultaneous fit to the reconstructed invariant mass peaks in the two channels and for the two experiments. The measured masses from the individual channels and the two experiments are found to be consistent among themselves. The combined measured mass of the Higgs boson is $m_H = 125.09 \pm 0.21\,(\text{stat}) \pm 0.11\,(\text{syst})$ GeV.

DOI: 10.1103/PhysRevLett.114.191803 PACS numbers: 14.80.Bn, 13.85.Qk

The study of the mechanism of electroweak symmetry breaking is one of the principal goals of the CERN LHC program. In the standard model (SM), this symmetry breaking is achieved through the introduction of a complex doublet scalar field, leading to the prediction of the Higgs boson H [1–6], whose mass m_H is, however, not predicted by the theory. In 2012, the ATLAS and CMS Collaborations at the LHC announced the discovery of a particle with Higgs-boson-like properties and a mass of about 125 GeV [7–9]. The discovery was based primarily on mass peaks observed in the $\gamma\gamma$ and $ZZ \to \ell^+\ell^-\ell'^+\ell'^-$ (denoted $H \to ZZ \to 4\ell$ for simplicity) decay channels, where one or both of the Z bosons can be off shell and where ℓ and ℓ' denote an electron or muon. With m_H known, all properties of the SM Higgs boson, such as its production cross section and partial decay widths, can be predicted. Increasingly precise measurements [10–13] have established that all observed properties of the new particle, including its spin, parity, and coupling strengths to SM particles are consistent within the uncertainties with those expected for the SM Higgs boson.

The ATLAS and CMS Collaborations have independently measured m_H using the samples of proton-proton collision data collected in 2011 and 2012, commonly referred to as LHC Run 1. The analyzed samples correspond to approximately 5 fb^{-1} of integrated luminosity at $\sqrt{s} = 7$ TeV, and 20 fb^{-1} at $\sqrt{s} = 8$ TeV, for each experiment. Combined results in the context of the separate experiments, as well as those in the individual channels, are presented in Refs. [12,14–16].

This Letter describes a combination of the Run 1 data from the two experiments, leading to improved precision for m_H. Besides its intrinsic importance as a fundamental parameter, improved knowledge of m_H yields more precise predictions for the other Higgs boson properties. Furthermore, the combined mass measurement provides a first step towards combinations of other quantities, such as the couplings. In the SM, m_H is related to the values of the masses of the W boson and top quark through loop-induced effects. Taking into account other measured SM quantities, the comparison of the measurements of the Higgs boson, W boson, and top quark masses can be used to directly test the consistency of the SM [17] and thus to search for evidence of physics beyond the SM.

The combination is performed using only the $H \to \gamma\gamma$ and $H \to ZZ \to 4\ell$ decay channels, because these two channels offer the best mass resolution. Interference between the Higgs boson signal and the continuum background is expected to produce a downward shift of the signal peak relative to the true value of m_H. The overall effect in the $H \to \gamma\gamma$ channel [18–20] is expected to be a few tens of MeV for a Higgs boson with a width near the SM value, which is small compared to the current precision. The effect in the $H \to ZZ \to 4\ell$ channel is expected to be much smaller [21]. The effects of the interference on the mass spectra are neglected in this Letter.

The ATLAS and CMS detectors [22,23] are designed to precisely reconstruct charged leptons, photons, hadronic jets, and the imbalance of momentum transverse to the direction of the beams. The two detectors are based on different technologies requiring different reconstruction and calibration methods. Consequently, they are subject to different sources of systematic uncertainty.

The $H \to \gamma\gamma$ channel is characterized by a narrow resonant signal peak containing several hundred events per experiment above a large falling continuum background. The overall signal-to-background ratio is a few

percent. Both experiments divide the $H \to \gamma\gamma$ events into different categories depending on the signal purity and mass resolution, as a means to improve sensitivity. While CMS uses the same analysis procedure for the measurement of the Higgs boson mass and couplings [15], ATLAS implements separate analyses for the couplings [24] and for the mass [14]; the latter analysis classifies events in a manner that reduces the expected systematic uncertainties in m_H.

The $H \to ZZ \to 4\ell$ channel yields only a few tens of signal events per experiment, but has very little background, resulting in a signal-to-background ratio larger than 1. The events are analyzed separately depending on the flavor of the lepton pairs. To extract m_H, ATLAS employs a two-dimensional (2D) fit to the distribution of the four-lepton mass and a kinematic discriminant introduced to reject the main background, which arises from ZZ continuum production. The CMS procedure is based on a three-dimensional fit, utilizing the four-lepton mass distribution, a kinematic discriminant, and the estimated event-by-event uncertainty in the four-lepton mass. Both analyses are optimized for the mass measurement and neither attempts to distinguish between different Higgs boson production mechanisms.

There are only minor differences in the parametrizations used for the present combination compared to those used for the combination of the two channels by the individual experiments. These differences have almost no effect on the results.

The measurement of m_H, along with its uncertainty, is based on the maximization of profile-likelihood ratios $\Lambda(\boldsymbol{\alpha})$ in the asymptotic regime [25,26]:

$$\Lambda(\boldsymbol{\alpha}) = \frac{L(\boldsymbol{\alpha}, \hat{\hat{\boldsymbol{\theta}}}(\boldsymbol{\alpha}))}{L(\hat{\boldsymbol{\alpha}}, \hat{\boldsymbol{\theta}})}, \tag{1}$$

where L represents the likelihood function, $\boldsymbol{\alpha}$ the parameters of interest, and $\boldsymbol{\theta}$ the nuisance parameters. There are three types of nuisance parameters: those corresponding to systematic uncertainties, the fitted parameters of the background models, and any unconstrained signal model parameters not relevant to the particular hypothesis under test. Systematic uncertainties are discussed below. The other two types of nuisance parameters are incorporated into the statistical uncertainty. The $\boldsymbol{\theta}$ terms are profiled, i.e., for each possible value of a parameter of interest (e.g., m_H), all nuisance parameters are refitted to maximize L. The $\hat{\boldsymbol{\alpha}}$ and $\hat{\boldsymbol{\theta}}$ terms denote the unconditional maximum likelihood estimates of the best-fit values for the parameters, while $\hat{\hat{\boldsymbol{\theta}}}(\boldsymbol{\alpha})$ is the conditional maximum likelihood estimate for given parameter values $\boldsymbol{\alpha}$.

The likelihood functions L are constructed using signal and background probability density functions (PDFs) that depend on the discriminating variables: for the $H \to \gamma\gamma$ channel, the diphoton mass, and, for the $H \to ZZ \to 4\ell$ channel, the four-lepton mass (for CMS, also its uncertainty) and the kinematic discriminant. The signal PDFs are derived from samples of Monte Carlo (MC) simulated events. For the $H \to ZZ \to 4\ell$ channel, the background PDFs are determined using a combination of simulation and data control regions. For the $H \to \gamma\gamma$ channel, the background PDFs are obtained directly from the fit to the data. The profile-likelihood fits to the data are performed as a function of m_H and the signal-strength scale factors defined below. The fitting framework is implemented independently by ATLAS and CMS, using the ROOFIT [27], ROOSTATS [28], and HISTFACTORY [29] data modeling and handling packages.

Despite the current agreement between the measured Higgs boson properties and the SM predictions, it is pertinent to perform a mass measurement that is as independent as possible of SM assumptions. For this purpose, three signal-strength scale factors are introduced and profiled in the fit, thus reducing the dependence of the results on assumptions about the Higgs boson couplings and about the variation of the production cross section (σ) times branching fraction (BF) with the mass. The signal strengths are defined as $\mu = (\sigma_{\text{expt}} \times \text{BF}_{\text{expt}})/(\sigma_{\text{SM}} \times \text{BF}_{\text{SM}})$, representing the ratio of the cross section times branching fraction in the experiment to the corresponding SM expectation for the different production and decay modes. Two factors, $\mu^{\gamma\gamma}_{ggF+t\bar{t}H}$ and $\mu^{\gamma\gamma}_{\text{VBF}+VH}$, are used to scale the signal strength in the $H \to \gamma\gamma$ channel. The production processes involving Higgs boson couplings to fermions, namely gluon fusion (ggF) and associated production with a top quark-antiquark pair ($t\bar{t}H$), are scaled with the $\mu^{\gamma\gamma}_{ggF+t\bar{t}H}$ factor. The production processes involving couplings to vector bosons, namely vector boson fusion (VBF) and associated production with a vector boson (VH), are scaled with the $\mu^{\gamma\gamma}_{\text{VBF}+VH}$ factor. The third factor $\mu^{4\ell}$ is used to scale the signal strength in the $H \to ZZ \to 4\ell$ channel. Only a single signal-strength parameter is used for $H \to ZZ \to 4\ell$ events because the m_H measurement in this case is found to exhibit almost no sensitivity to the different production mechanisms.

The procedure based on the two scale factors $\mu^{\gamma\gamma}_{ggF+t\bar{t}H}$ and $\mu^{\gamma\gamma}_{\text{VBF}+VH}$ for the $H \to \gamma\gamma$ channel was previously employed by CMS [15] but not by ATLAS. Instead, ATLAS relied on a single $H \to \gamma\gamma$ signal-strength scale factor. The additional degree of freedom introduced by ATLAS for the present study results in a shift of about 40 MeV in the ATLAS $H \to \gamma\gamma$ result, leading to a shift of 20 MeV in the ATLAS combined mass measurement.

The individual signal strengths $\mu^{\gamma\gamma}_{ggF+t\bar{t}H}$, $\mu^{\gamma\gamma}_{\text{VBF}+VH}$, and $\mu^{4\ell}$ are assumed to be the same for ATLAS and CMS, and are profiled in the combined fit for m_H. The corresponding profile-likelihood ratio is

$$\Lambda(m_H) = \frac{L[m_H, \hat{\hat{\mu}}^{\gamma\gamma}_{ggF+t\bar{t}H}(m_H), \hat{\hat{\mu}}^{\gamma\gamma}_{\text{VBF}+VH}(m_H), \hat{\hat{\mu}}^{4\ell}(m_H), \hat{\hat{\boldsymbol{\theta}}}(m_H)]}{L(\hat{m}_H, \hat{\mu}^{\gamma\gamma}_{ggF+t\bar{t}H}, \hat{\mu}^{\gamma\gamma}_{\text{VBF}+VH}, \hat{\mu}^{4\ell}, \hat{\boldsymbol{\theta}})}. \tag{2}$$

Slightly more complex fit models are used, as described below, to perform additional compatibility tests between the different decay channels and between the results from ATLAS and CMS.

Combining the ATLAS and CMS data for the $H \to \gamma\gamma$ and $H \to ZZ \to 4\ell$ channels according to the above procedure, the mass of the Higgs boson is determined to be

$$m_H = 125.09 \pm 0.24 \text{ GeV} = 125.09 \pm 0.21\,(\text{stat}) \pm 0.11\,(\text{syst}) \text{ GeV}, \quad (3)$$

where the total uncertainty is obtained from the width of a negative log-likelihood ratio scan with all parameters profiled. The statistical uncertainty is determined by fixing all nuisance parameters to their best-fit values, except for the three signal-strength scale factors and the $H \to \gamma\gamma$ background function parameters, which are profiled. The systematic uncertainty is determined by subtracting in quadrature the statistical uncertainty from the total uncertainty. Equation (3) shows that the uncertainties in the m_H measurement are dominated by the statistical term, even when the Run 1 data sets of ATLAS and CMS are combined. Figure 1 shows the negative log-likelihood ratio scans as a function of m_H, with all nuisance parameters profiled (solid curves), and with the nuisance parameters fixed to their best-fit values (dashed curves).

The signal strengths at the measured value of m_H are found to be $\mu^{\gamma\gamma}_{ggF+t\bar{t}H} = 1.15^{+0.28}_{-0.25}$, $\mu^{\gamma\gamma}_{\text{VBF}+VH} = 1.17^{+0.58}_{-0.53}$, and $\mu^{4\ell} = 1.40^{+0.30}_{-0.25}$. The combined overall signal strength

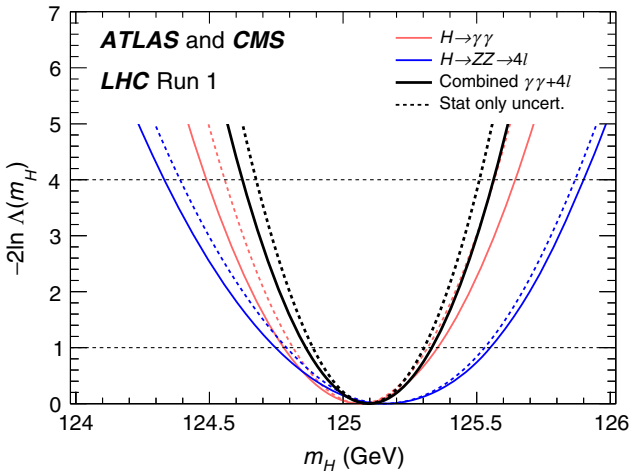

FIG. 1 (color online). Scans of twice the negative log-likelihood ratio $-2\ln\Lambda(m_H)$ as functions of the Higgs boson mass m_H for the ATLAS and CMS combination of the $H \to \gamma\gamma$ (red), $H \to ZZ \to 4\ell$ (blue), and combined (black) channels. The dashed curves show the results accounting for statistical uncertainties only, with all nuisance parameters associated with systematic uncertainties fixed to their best-fit values. The 1 and 2 standard deviation limits are indicated by the intersections of the horizontal lines at 1 and 4, respectively, with the log-likelihood scan curves.

μ (with $\mu^{\gamma\gamma}_{ggF+t\bar{t}H} = \mu^{\gamma\gamma}_{\text{VBF}+VH} = \mu^{4\ell} \equiv \mu$) is $\mu = 1.24^{+0.18}_{-0.16}$. The results reported here for the signal strengths are not expected to have the same sensitivity, nor exactly the same values, as those that would be extracted from a combined analysis optimized for the coupling measurements.

The combined ATLAS and CMS results for m_H in the separate $H \to \gamma\gamma$ and $H \to ZZ \to 4\ell$ channels are

$$m^{\gamma\gamma}_H = 125.07 \pm 0.29 \text{ GeV} = 125.07 \pm 0.25\,(\text{stat}) \pm 0.14\,(\text{syst}) \text{ GeV} \quad (4)$$

and

$$m^{4\ell}_H = 125.15 \pm 0.40 \text{ GeV} = 125.15 \pm 0.37\,(\text{stat}) \pm 0.15\,(\text{syst}) \text{ GeV}. \quad (5)$$

The corresponding likelihood ratio scans are shown in Fig. 1. For the $H \to ZZ \to 4\ell$ channel, the systematic uncertainty is dominated by the absolute scale uncertainty in the momentum measurement for the muons and in the momentum and energy measurements for the electrons. Large samples ($> 10^7$ events) of dilepton decays of the J/ψ, $\Upsilon(nS)$, and Z resonances are used by both experiments to evaluate the absolute scales and to correct for residual misalignments in the inner tracker systems [14,16]. The systematic uncertainty in the ATLAS m_H result from $H \to ZZ \to 4\ell$ decays was conservatively set to 60 MeV in Ref. [14] to account for the limited numerical precision in its estimate. A more precise procedure, resulting in a reduced systematic uncertainty of 40 MeV, is used here. For CMS, conservative systematic uncertainties of 0.1% for the $H \to ZZ \to 4\mu$ and $2\mu 2e$ channels, and 0.3% for the $H \to ZZ \to 4e$ channel, were obtained in Ref. [16] and are used here.

A summary of the results from the individual analyses and their combination is presented in Fig. 2.

The observed uncertainties in the combined measurement can be compared with expectations. The latter are evaluated by generating two Asimov data sets [26], where an Asimov data set is a representative event sample that provides both the median expectation for an experimental result and its expected statistical variation, in the asymptotic approximation, without the need for an extensive MC-based calculation. The first Asimov data set is a "prefit" sample, generated using $m_H = 125.0$ GeV and the SM predictions for the couplings, with all nuisance parameters fixed to their nominal values. The second Asimov data set is a "postfit" sample, in which m_H, the three signal strengths $\mu^{\gamma\gamma}_{ggF+t\bar{t}H}$, $\mu^{\gamma\gamma}_{\text{VBF}+VH}$, and $\mu^{4\ell}$, and all nuisance parameters are fixed to their best-fit estimates from the data. The expected uncertainties for the combined mass are

$$\delta m_{H\,\text{prefit}} = \pm 0.24 \text{ GeV} = \pm 0.22\,(\text{stat}) \pm 0.10\,(\text{syst}) \text{ GeV} \quad (6)$$

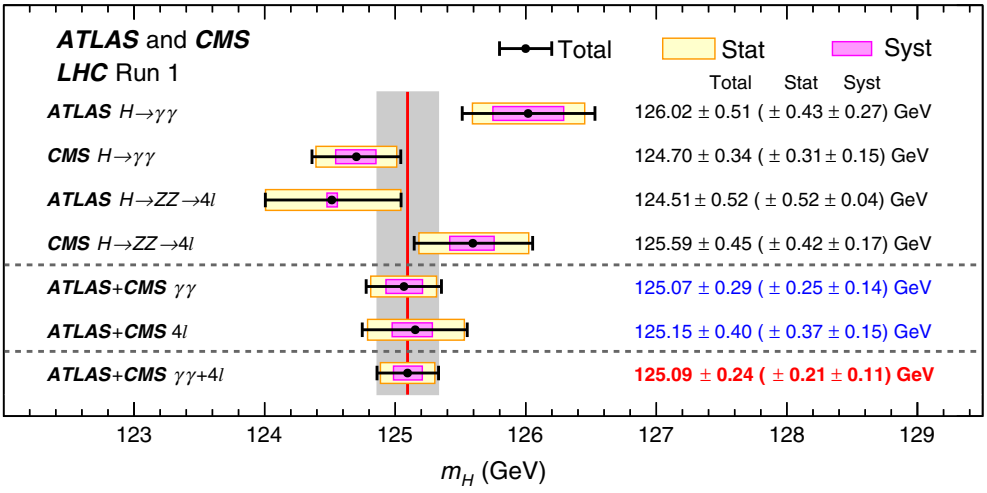

FIG. 2 (color online). Summary of Higgs boson mass measurements from the individual analyses of ATLAS and CMS and from the combined analysis presented here. The systematic (narrower, magenta-shaded bands), statistical (wider, yellow-shaded bands), and total (black error bars) uncertainties are indicated. The (red) vertical line and corresponding (gray) shaded column indicate the central value and the total uncertainty of the combined measurement, respectively.

for the prefit case and

$$\delta m_{H\,\mathrm{postfit}} = \pm 0.22\ \mathrm{GeV} = \pm 0.19\,(\mathrm{stat}) \pm 0.10\,(\mathrm{syst})\ \mathrm{GeV} \quad (7)$$

for the postfit case, which are both very similar to the observed uncertainties reported in Eq. (3).

Constraining all signal yields to their SM predictions results in an m_H value that is about 70 MeV larger than the nominal result with a comparable uncertainty. The increase in the central value reflects the combined effect of the higher-than-expected $H \to ZZ \to 4\ell$ measured signal strength and the increase of the $H \to ZZ$ branching fraction with m_H. Thus, the fit assuming SM couplings forces the mass to a higher value in order to accommodate the value $\mu = 1$ expected in the SM.

Since the discovery, both experiments have improved their understanding of the electron, photon, and muon measurements [16,30–34], leading to a significant reduction of the systematic uncertainties in the mass measurement. Nevertheless, the treatment and understanding of systematic uncertainties is an important aspect of the individual measurements and their combination. The combined analysis incorporates approximately 300 nuisance parameters. Among these, approximately 100 are fitted parameters describing the shapes and normalizations of the background models in the $H \to \gamma\gamma$ channel, including a number of discrete parameters that allow the functional form in each of the CMS $H \to \gamma\gamma$ analysis categories to be changed [35]. Of the remaining almost 200 nuisance parameters, most correspond to experimental or theoretical systematic uncertainties.

Based on the results from the individual experiments, the dominant systematic uncertainties for the combined m_H result are expected to be those associated with the energy or momentum scale and its resolution: for the photons in the $H \to \gamma\gamma$ channel and for the electrons and muons in the $H \to ZZ \to 4\ell$ channel [14–16]. These uncertainties are assumed to be uncorrelated between the two experiments since they are related to the specific characteristics of the detectors as well as to the calibration procedures, which are fully independent except for negligible effects due to the use of the common Z boson mass [36] to specify the absolute energy and momentum scales. Other experimental systematic uncertainties [14–16] are similarly assumed to be uncorrelated between the two experiments. Uncertainties in the theoretical predictions and in the measured integrated luminosities are treated as fully and partially correlated, respectively.

To evaluate the relative importance of the different sources of systematic uncertainty, the nuisance parameters are grouped according to their correspondence to three broad classes of systematic uncertainty: (1) uncertainties in the energy or momentum scale and resolution for photons, electrons, and muons ("scale"), (2) theoretical uncertainties, e.g., uncertainties in the Higgs boson cross section and branching fractions, and in the normalization of SM background processes ("theory"), (3) other experimental uncertainties ("other").

First, the total uncertainty is obtained from the full profile-likelihood scan, as explained above. Next, parameters associated with the scale terms are fixed and a new scan is performed. Then, in addition to the scale terms, the parameters associated with the theory terms are fixed and a scan performed. Finally, in addition, the other parameters are fixed and a scan performed. Thus the fits are performed iteratively, with the different classes of nuisance parameters cumulatively held fixed to their best-fit values. The uncertainties associated with the different classes of nuisance parameters are defined by the difference in quadrature

between the uncertainties resulting from consecutive scans. The statistical uncertainty is determined from the final scan, with all nuisance parameters associated with systematic terms held fixed, as explained above. The result is

$$m_H = 125.09 \pm 0.21\,(\text{stat}) \pm 0.11\,(\text{scale}) \pm 0.02\,(\text{other}) \pm 0.01\,(\text{theory})\ \text{GeV}, \quad (8)$$

from which it is seen that the systematic uncertainty is indeed dominated by the energy and momentum scale terms. The result in Eq. (8) is consistent with the values of m_H derived from the less precise WW and $\tau\tau$ Higgs boson decay modes [37–40].

The relative importance of the various sources of systematic uncertainty is further investigated by dividing the nuisance parameters into yet-finer groups, with each group associated with a specific underlying effect, and evaluating the impact of each group on the overall mass uncertainty. The matching of nuisance parameters to an effect is not strictly rigorous because nuisance parameters in the two experiments do not always represent exactly the same effect and in some cases multiple effects are related to the same nuisance parameter. Nevertheless, the relative impact of the different effects can be explored. A few experiment-specific groups of nuisance parameters are defined. For example, ATLAS includes a group of nuisance parameters to account for the inaccuracy of the background modeling for the $H \to \gamma\gamma$ channel. To model this background, ATLAS uses specific analytic functions in each category [14] while CMS simultaneously considers different background parametrizations [35]. The systematic uncertainty in m_H related to the background modeling in CMS is estimated to be negligible [15].

The impact of groups of nuisance parameters is evaluated starting from the contribution of each individual nuisance parameter to the total uncertainty. This contribution is defined as the mass shift δm_H observed when reevaluating the profile-likelihood ratio after fixing the nuisance parameter in question to its best-fit value increased or decreased by 1 standard deviation (σ) in its distribution. For a nuisance parameter whose PDF is a Gaussian distribution, this shift corresponds to the contribution of that particular nuisance parameter to the final uncertainty. The impact of a group of nuisance parameters is estimated by summing in quadrature the contributions from the individual parameters.

The impacts δm_H due to each of the considered effects are listed in Table I. The results are reported for the four individual channels, both for the data and (in parentheses) the prefit Asimov data set. The row labeled "Systematic uncertainty (sum in quadrature)" shows the total sums in quadrature of the individual terms in the table. The row labeled "Systematic uncertainty (nominal)" shows the corresponding total systematic uncertainties derived using the subtraction in quadrature method discussed in connection with Eq. (3). The two methods to evaluate the total systematic uncertainty are seen to agree within 10 MeV, which is comparable with the precision of the estimates. The two rightmost columns of Table I list the contribution of each group of nuisance parameters to the uncertainties in the combined mass measurement, for ATLAS and CMS separately.

The statistical and total uncertainties are summarized in the bottom section of Table I. Since the weight of a channel in the final combination is determined by the inverse of the squared uncertainty, the approximate relative weights for the combined result are 19% ($H \to \gamma\gamma$) and 18% ($H \to ZZ \to 4\ell$) for ATLAS, and 40% ($H \to \gamma\gamma$) and 23% ($H \to ZZ \to 4\ell$) for CMS. These weights are reported in the last row of Table I, along with the expected values.

Figure 3 presents the impact of each group of nuisance parameters on the total systematic uncertainty in the mass measurement of ATLAS, CMS, and the combination. For the individual ATLAS and CMS measurements, the results in Fig. 3 are approximately equivalent to the sum in quadrature of the respective δm_H terms in Table I multiplied by their analysis weights, after normalizing these weights to correspond to either ATLAS only or CMS only. The ATLAS and CMS combined results in Fig. 3 are the sum in quadrature of the combined results in Table I.

The results in Table I and Fig. 3 establish that the largest systematic effects for the mass uncertainty are those related to the determination of the energy scale of the photons, followed by those associated with the determination of the electron and muon momentum scales. Since the CMS $H \to \gamma\gamma$ channel has the largest weight in the combination, its impact on the systematic uncertainty of the combined result is largest.

The mutual compatibility of the m_H results from the four individual channels is tested using a likelihood ratio with four masses in the numerator and a common mass in the denominator, and thus three degrees of freedom. The three signal strengths are profiled in both the numerator and denominator as in Eq. (1). The resulting compatibility, defined as the asymptotic p value of the fit, is 10%. Allowing the ATLAS and CMS signal strengths to vary independently yields a compatibility of 7%. This latter fit results in an m_H value that is 40 MeV larger than the nominal result.

The compatibility of the combined ATLAS and CMS mass measurement in the $H \to \gamma\gamma$ channel with the combined measurement in the $H \to ZZ \to 4\ell$ channel is evaluated using the variable $\Delta m_{\gamma Z} \equiv m_H{}^{\gamma\gamma} - m_H{}^{4\ell}$ as the parameter of interest, with all other parameters, including m_H, profiled. Similarly, the compatibility of the ATLAS combined mass measurement in the two channels with the CMS combined measurement in the two channels is evaluated using the variable $\Delta m^{\text{expt}} \equiv m_H^{\text{ATLAS}} - m_H^{\text{CMS}}$. The observed results, $\Delta m_{\gamma Z} = -0.1 \pm 0.5$ GeV and $\Delta m^{\text{expt}} = 0.4 \pm 0.5$ GeV, are both consistent with zero within 1σ. The difference between the mass values in

TABLE I. Systematic uncertainties δm_H (see text) associated with the indicated effects for each of the four input channels, and the corresponding contributions of ATLAS and CMS to the systematic uncertainties of the combined result. "ECAL" refers to the electromagnetic calorimeters. The numbers in parentheses indicate expected values obtained from the prefit Asimov data set discussed in the text. The uncertainties for the combined result are related to the values of the individual channels through the relative weight of the individual channel in the combination, which is proportional to the inverse of the respective uncertainty squared. The top section of the table divides the sources of systematic uncertainty into three classes, which are discussed in the text. The bottom section of the table shows the total systematic uncertainties estimated by adding the individual contributions in quadrature, the total systematic uncertainties evaluated using the nominal method discussed in the text, the statistical uncertainties, the total uncertainties, and the analysis weights, illustrative of the relative weight of each channel in the combined m_H measurement.

the two experiments is $\Delta m_{\gamma\gamma}^{\text{expt}} = 1.3 \pm 0.6$ GeV (2.1σ) for the $H \to \gamma\gamma$ channel and $\Delta m_{4\ell}^{\text{expt}} = -0.9 \pm 0.7$ GeV (1.3σ) for the $H \to ZZ \to 4\ell$ channel. The combined results exhibit a greater degree of compatibility than the results from the individual decay channels because the Δm^{expt} value has opposite signs in the two channels.

The compatibility of the signal strengths from ATLAS and CMS is evaluated through the ratios $\lambda^{\text{expt}} = \mu^{\text{ATLAS}}/\mu^{\text{CMS}}$, $\lambda_F^{\text{expt}} = \mu_{ggF+t\bar{t}H}^{\gamma\gamma\text{ATLAS}}/\mu_{ggF+t\bar{t}H}^{\gamma\gamma\text{CMS}}$, and $\lambda_{4\ell}^{\text{expt}} = \mu^{4\ell\text{ATLAS}}/\mu^{4\ell\text{CMS}}$. For this purpose, each ratio is individually taken to be the parameter of interest, with all other nuisance parameters profiled, including the remaining two ratios for the first two tests. We find $\lambda^{\text{expt}} = 1.21^{+0.30}_{-0.24}$, $\lambda_F^{\text{expt}} = 1.3^{+0.8}_{-0.5}$, and $\lambda_{4\ell}^{\text{expt}} = 1.3^{+0.5}_{-0.4}$, all of which are consistent with unity within 1σ. The ratio $\lambda_V^{\text{expt}} = \mu_{\text{VBF}+VH}^{\gamma\gamma\text{ATLAS}}/\mu_{\text{VBF}+VH}^{\gamma\gamma\text{CMS}}$ is omitted because the ATLAS mass measurement in the $H \to \gamma\gamma$ channel is not sensitive to $\mu_{\text{VBF}+VH}^{\gamma\gamma}/\mu_{ggF+t\bar{t}H}^{\gamma\gamma}$.

The correlation between the signal strength and the measured mass is explored with 2D likelihood scans as functions of μ and m_H. The three signal strengths are assumed to be the same: $\mu_{ggF+t\bar{t}H}^{\gamma\gamma} = \mu_{\text{VBF}+VH}^{\gamma\gamma} = \mu^{4\ell} \equiv \mu$, and thus the ratios of the production cross sections times branching fractions are constrained to the SM

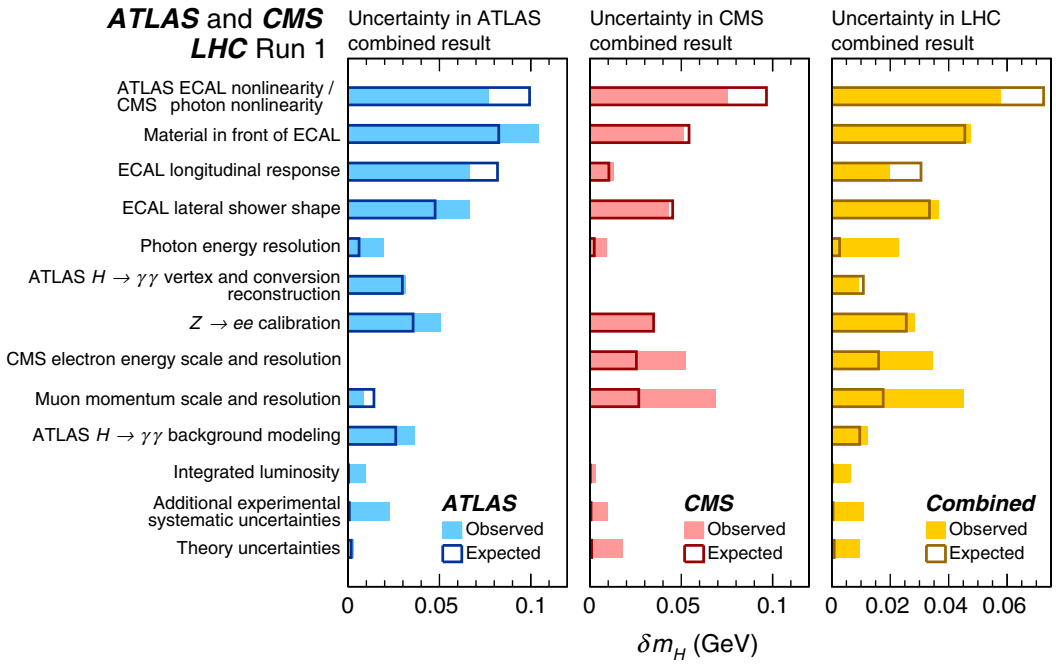

FIG. 3 (color online). The impacts δm_H (see text) of the nuisance parameter groups in Table I on the ATLAS (left), CMS (center), and combined (right) mass measurement uncertainty. The observed (expected) results are shown by the solid (empty) bars.

predictions. Assuming that the negative log-likelihood ratio $-2\ln\Lambda(\mu, m_H)$ is distributed as a χ^2 variable with two degrees of freedom, the 68% confidence level (C.L.) confidence regions are shown in Fig. 4 for each individual measurement, as well as for the combined result.

In summary, a combined measurement of the Higgs boson mass is performed in the $H \to \gamma\gamma$ and $H \to ZZ \to 4\ell$ channels using the LHC Run 1 data sets of the ATLAS and CMS experiments, with minimal reliance on the assumption that the Higgs boson behaves as predicted by the SM.

The result is

$$m_H = 125.09 \pm 0.24 \text{ GeV} = 125.09 \pm 0.21\,(\text{stat}) \pm 0.11\,(\text{syst}) \text{ GeV}, \quad (9)$$

where the total uncertainty is dominated by the statistical term, with the systematic uncertainty dominated by effects related to the photon, electron, and muon energy or momentum scales and resolutions. Compatibility tests are performed to ascertain whether the measurements are consistent with each other, both between the different decay channels and between the two experiments. All tests on the combined results indicate consistency of the different measurements within 1σ, while the four Higgs boson mass measurements in the two channels of the two experiments agree within 2σ. The combined measurement of the Higgs boson mass improves upon the results from the individual experiments and is the most precise measurement to date of this fundamental parameter of the newly discovered particle.

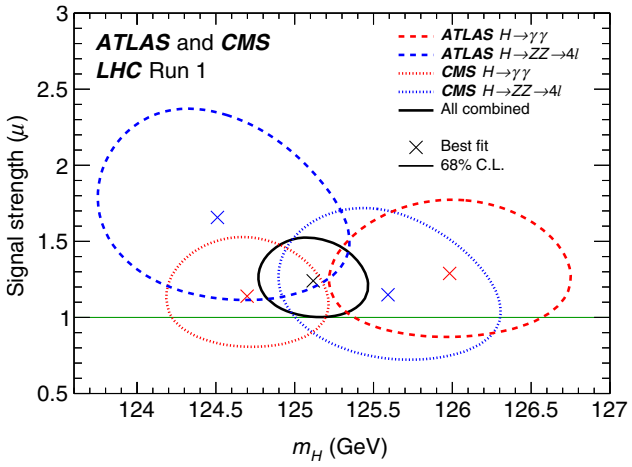

FIG. 4 (color online). Summary of likelihood scans in the 2D plane of signal strength μ versus Higgs boson mass m_H for the ATLAS and CMS experiments. The 68% C.L. confidence regions of the individual measurements are shown by the dashed curves and of the overall combination by the solid curve. The markers indicate the respective best-fit values. The SM signal strength is indicated by the horizontal line at $\mu = 1$.

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS and CMS could not be operated efficiently. We acknowledge the support of ANPCyT (Argentina); YerPhI (Armenia); ARC (Australia); BMWFW and FWF (Austria); ANAS (Azerbaijan); SSTC (Belarus); FNRS and FWO (Belgium); CNPq, CAPES, FAPERJ, and FAPESP (Brazil); MES

[a]Deceased.
[b]Also at Department of Physics, King's College London, London, United Kingdom.
[c]Also at Institute of Physics, Azerbaijan Academy of Sciences, Baku, Azerbaijan.
[d]Also at Novosibirsk State University, Novosibirsk, Russia.
[e]Also at TRIUMF, Vancouver, BC, Canada.
[f]Also at Department of Physics, California State University, Fresno, CA, USA.
[g]Also at Department of Physics, University of Fribourg, Fribourg, Switzerland.
[h]Also at Departamento de Fisica e Astronomia, Faculdade de Ciencias, Universidade do Porto, Portugal.
[i]Also at Tomsk State University, Tomsk, Russia.
[j]Also at CPPM, Aix-Marseille Université and CNRS/IN2P3, Marseille, France.
[k]Also at Università di Napoli Parthenope, Napoli, Italy.
[l]Also at Institute of Particle Physics (IPP), Canada.
[m]Also at Particle Physics Department, Rutherford Appleton Laboratory, Didcot, United Kingdom.
[n]Also at Department of Physics, St. Petersburg State Polytechnical University, St. Petersburg, Russia.
[o]Also at Louisiana Tech University, Ruston, LA, USA.
[p]Also at Institucio Catalana de Recerca i Estudis Avancats, ICREA, Barcelona, Spain.
[q]Also at Department of Physics, National Tsing Hua University, Taiwan.
[r]Also at Department of Physics, The University of Texas at Austin, Austin, TX, USA.
[s]Also at Institute of Theoretical Physics, Ilia State University, Tbilisi, Georgia.
[t]Also at CERN, Geneva, Switzerland.
[u]Also at Georgian Technical University (GTU),Tbilisi, Georgia.
[v]Also at Ochadai Academic Production, Ochanomizu University, Tokyo, Japan.
[w]Also at Manhattan College, New York, NY, USA.
[x]Also at Institute of Physics, Academia Sinica, Taipei, Taiwan.
[y]Also at LAL, Université Paris-Sud and CNRS/IN2P3, Orsay, France.
[z]Also at Academia Sinica Grid Computing, Institute of Physics, Academia Sinica, Taipei, Taiwan.
[aa]Also at School of Physics, Shandong University, Shandong, China.
[bb]Also at Moscow Institute of Physics and Technology State University, Dolgoprudny, Russia.
[cc]Also at Section de Physique, Université de Genève, Geneva, Switzerland.
[dd]Also at International School for Advanced Studies (SISSA), Trieste, Italy.
[ee]Also at Department of Physics and Astronomy, University of South Carolina, Columbia, SC, USA.
[ff]Also at School of Physics and Engineering, Sun Yat-sen University, Guangzhou, China.
[gg]Also at Faculty of Physics, M.V.Lomonosov Moscow State University, Moscow, Russia.
[hh]Also at National Research Nuclear University MEPhI, Moscow, Russia.
[ii]Also at Department of Physics, Stanford University, Stanford, CA, USA.
[jj]Also at Institute for Particle and Nuclear Physics, Wigner Research Centre for Physics, Budapest, Hungary.
[kk]Also at Department of Physics, The University of Michigan, Ann Arbor, MI, USA.
[ll]Also at Discipline of Physics, University of KwaZulu-Natal, Durban, South Africa.
[mm]Also at University of Malaya, Department of Physics, Kuala Lumpur, Malaysia.
[nn]Also at Vienna University of Technology, Vienna, Austria.
[oo]Also at CERN, European Organization for Nuclear Research, Geneva, Switzerland.
[pp]Also at State Key Laboratory of Nuclear Physics and Technology, Peking University, Beijing, China.
[qq]Also at Institut Pluridisciplinaire Hubert Curien, Université de Strasbourg, Université de Haute Alsace Mulhouse, CNRS/IN2P3, Strasbourg, France.
[rr]Also at National Institute of Chemical Physics and Biophysics, Tallinn, Estonia.
[ss]Also at Skobeltsyn Institute of Nuclear Physics, Lomonosov Moscow State University, Moscow, Russia.
[tt]Also at Universidade Estadual de Campinas, Campinas, Brazil.
[uu]Also at Centre National de la Recherche Scientifique (CNRS)–IN2P3, Paris, France.
[vv]Also at Laboratoire Leprince-Ringuet, Ecole Polytechnique, IN2P3–CNRS, Palaiseau, France.
[ww]Also at Joint Institute for Nuclear Research, Dubna, Russia.
[xx]Also at Ain Shams University, Cairo, Egypt.

[yy]Also at British University in Egypt, Cairo, Egypt.
[zz]Also at Helwan University, Cairo, Egypt.
[aaa]Also at Suez University, Suez, Egypt.
[bbb]Also at Cairo University, Cairo, Egypt.

Evidence for the Higgs-boson Yukawa coupling to tau leptons with the ATLAS detector

The ATLAS collaboration

E-mail: atlas.publications@cern.ch

Abstract: Results of a search for $H \to \tau\tau$ decays are presented, based on the full set of proton-proton collision data recorded by the ATLAS experiment at the LHC during 2011 and 2012. The data correspond to integrated luminosities of $4.5\,\text{fb}^{-1}$ and $20.3\,\text{fb}^{-1}$ at centre-of-mass energies of $\sqrt{s} = 7\,\text{TeV}$ and $\sqrt{s} = 8\,\text{TeV}$ respectively. All combinations of leptonic ($\tau \to \ell\nu\bar{\nu}$ with $\ell = e, \mu$) and hadronic ($\tau \to$ hadrons ν) tau decays are considered. An excess of events over the expected background from other Standard Model processes is found with an observed (expected) significance of 4.5 (3.4) standard deviations. This excess provides evidence for the direct coupling of the recently discovered Higgs boson to fermions. The measured signal strength, normalised to the Standard Model expectation, of $\mu = 1.43\ ^{+0.43}_{-0.37}$ is consistent with the predicted Yukawa coupling strength in the Standard Model.

1 Introduction

The investigation of the origin of electroweak symmetry breaking and, related to this, the experimental confirmation of the Brout-Englert-Higgs mechanism [1–6] is one of the prime goals of the physics programme at the Large Hadron Collider (LHC) [7]. With the discovery of a Higgs boson with a mass of approximately 125 GeV by the ATLAS [8] and CMS [9] collaborations, an important milestone has been reached. More precise measurements of the properties of the discovered particle [10, 11] as well as tests of the spin-parity quantum numbers [12–14] continue to be consistent with the predictions for the Standard Model (SM) Higgs boson.

These measurements rely predominantly on studies of the bosonic decay modes, $H \to \gamma\gamma$, $H \to ZZ^*$ and $H \to WW^*$. To establish the mass generation mechanism for fermions as implemented in the SM, it is of prime importance to demonstrate the direct coupling of the Higgs boson to fermions and the proportionality of its strength to mass [15]. The most promising candidate decay modes are the decays into tau leptons, $H \to \tau\tau$, and bottom quarks (b-quarks), $H \to b\bar{b}$. Due to the high background, the search for decays to $b\bar{b}$ is restricted to Higgs bosons produced in modes which have a more distinct signature but a lower cross-section, such as H production with an associated vector boson. The smaller rate of these processes in the presence of still large background makes their detection challenging. More favourable signal-to-background conditions are expected for $H \to \tau\tau$ decays. Recently, the CMS Collaboration published evidence for $H \to \tau\tau$ decays at a significance in terms of standard deviations of 3.2σ [16], and an excess corresponding to a significance of 2.1σ in the search for $H \to b\bar{b}$ decays [17]. The combination of channels provides evidence for fermionic couplings with a significance of 3.8σ [18]. The yield of events in the search for $H \to b\bar{b}$ decays observed by the ATLAS Collaboration has a signal significance of 1.4σ [19]. The Tevatron experiments have observed an excess corresponding to 2.8σ in the $H \to b\bar{b}$ search [20].

In this paper, the results of a search for $H \to \tau\tau$ decays are presented, based on the full proton-proton dataset collected by the ATLAS experiment during the 2011 and 2012 data-taking periods, corresponding to integrated luminosities of 4.5 fb^{-1} at a centre-of-mass energy of $\sqrt{s} = 7$ TeV and 20.3 fb^{-1} at $\sqrt{s} = 8$ TeV. These results supersede the earlier upper limits on the cross section times the branching ratio obtained with the 7 TeV data [21]. All combinations of leptonic ($\tau \to \ell\nu\bar{\nu}$ with $\ell = e, \mu$) and hadronic ($\tau \to$ hadrons ν) tau decays are considered.[1] The corresponding three analysis channels are denoted by $\tau_{\text{lep}}\tau_{\text{lep}}$, $\tau_{\text{lep}}\tau_{\text{had}}$, and $\tau_{\text{had}}\tau_{\text{had}}$ in the following. The search is designed to be sensitive to the major production processes of a SM Higgs boson, i.e. production via gluon fusion (ggF) [22], vector-boson fusion (VBF) [23], and associated production (VH) with $V = W$ or Z. These production processes lead to different final-state signatures, which are exploited by defining an event categorisation. Two dedicated categories are considered to achieve both a good signal-to-background ratio and good resolution for the reconstructed $\tau\tau$ invariant mass. The VBF category, enriched in events produced via vector-boson fusion,

[1] Throughout this paper the inclusion of charge-conjugate decay modes is implied.

JHEP04(2015)117

is defined by the presence of two jets with a large separation in pseudorapidity.[2] The boosted category contains events where the reconstructed Higgs boson candidate has a large transverse momentum. It is dominated by events produced via gluon fusion with additional jets from gluon radiation. In view of the signal-to-background conditions, and in order to exploit correlations between final-state observables, a multivariate analysis technique, based on boosted decision trees (BDTs) [24–26], is used to extract the final results. As a cross-check, a separate analysis where cuts on kinematic variables are applied is carried out.

2 The ATLAS detector and object reconstruction

The ATLAS detector [27] is a multi-purpose detector with a cylindrical geometry. It comprises an inner detector (ID) surrounded by a thin superconducting solenoid, a calorimeter system and an extensive muon spectrometer in a toroidal magnetic field. The ID tracking system consists of a silicon pixel detector, a silicon microstrip detector (SCT), and a transition radiation tracker (TRT). It provides precise position and momentum measurements for charged particles and allows efficient identification of jets containing b-hadrons (b-jets) in the pseudorapidity range $|\eta| < 2.5$. The ID is immersed in a 2 T axial magnetic field and is surrounded by high-granularity lead/liquid-argon (LAr) sampling electromagnetic calorimeters which cover the pseudorapidity range $|\eta| < 3.2$. A steel/scintillator tile calorimeter provides hadronic energy measurements in the central pseudorapidity range ($|\eta| < 1.7$). In the forward regions ($1.5 < |\eta| < 4.9$), the system is complemented by two end-cap calorimeters using LAr as active material and copper or tungsten as absorbers. The muon spectrometer (MS) surrounds the calorimeters and consists of three large superconducting eight-coil toroids, a system of tracking chambers, and detectors for triggering. The deflection of muons is measured within $|\eta| < 2.7$ by three layers of precision drift tubes, and cathode strip chambers in the innermost layer for $|\eta| > 2.0$. The trigger chambers consist of resistive plate chambers in the barrel ($|\eta| < 1.05$) and thin-gap chambers in the end-cap regions ($1.05 < |\eta| < 2.4$).

A three-level trigger system [28] is used to select events. A hardware-based Level-1 trigger uses a subset of detector information to reduce the event rate to a value to 75 kHz or less. The rate of accepted events is then reduced to about 400 Hz by two software-based trigger levels, Level-2 and the Event Filter.

The reconstruction of the basic physics objects used in this analysis is described in the following. The primary vertex referenced below is chosen as the proton-proton vertex candidate with the highest sum of the squared transverse momenta of all associated tracks.

Electron candidates are reconstructed from energy clusters in the electromagnetic calorimeters matched to a track in the ID. They are required to have a transverse en-

[2]The ATLAS experiment uses a right-handed coordinate system with its origin at the nominal interaction point (IP) in the centre of the detector and the z-axis along the beam direction. The x-axis points from the IP to the centre of the LHC ring, and the y-axis points upward. Cylindrical coordinates (r, ϕ) are used in the transverse (x, y) plane, ϕ being the azimuthal angle around the beam direction. The pseudorapidity is defined in terms of the polar angle θ as $\eta = -\ln\tan(\theta/2)$. The distance ΔR in the η–ϕ space is defined as $\Delta R = \sqrt{(\Delta\eta)^2 + (\Delta\phi)^2}$.

JHEP04(2015)117

ergy, $E_{\mathrm{T}} = E \sin\theta$, greater than 15 GeV, to be within the pseudorapidity range $|\eta| < 2.47$, and to satisfy the medium shower shape and track selection criteria defined in ref. [29]. Candidates found in the transition region between the end-cap and barrel calorimeters ($1.37 < |\eta| < 1.52$) are not considered. Typical reconstruction and identification efficiencies for electrons satisfying these selection criteria range between 80% and 90% depending on E_{T} and η.

Muon candidates are reconstructed using an algorithm [30] that combines information from the ID and the MS. The distance between the z-position of the point of closest approach of the muon inner-detector track to the beam-line and the z-coordinate of the primary vertex is required to be less than 1 cm. This requirement reduces the contamination due to cosmic-ray muons and beam-induced backgrounds. Muon quality criteria such as inner detector hit requirements are applied to achieve a precise measurement of the muon momentum and reduce the misidentification rate. Muons are required to have a momentum in the transverse plane $p_{\mathrm{T}} > 10$ GeV and to be within $|\eta| < 2.5$. Typical efficiencies for muons satisfying these selection criteria are above 95% [30].

Jets are reconstructed using the anti-k_t jet clustering algorithm [31, 32] with a radius parameter $R = 0.4$, taking topological energy clusters [33] in the calorimeters as inputs. Jet energies are corrected for the contribution of multiple interactions using a technique based on jet area [34] and are calibrated using p_{T}- and η-dependent correction factors determined from data and simulation [35–37]. Jets are required to be reconstructed in the range $|\eta| < 4.5$ and to have $p_{\mathrm{T}} > 30$ GeV. To reduce the contamination of jets by additional interactions in the same or neighbouring bunch crossings (pile-up), tracks originating from the primary vertex must contribute a large fraction of the p_{T} when summing the scalar p_{T} of all tracks in the jet. This jet vertex fraction (JVF) is required to be at least 75% (50%) for jets with $|\eta| < 2.4$ in the 7 TeV (8 TeV) dataset. Moreover, for the 8 TeV dataset, the JVF selection is applied only to jets with $p_{\mathrm{T}} < 50$ GeV. Jets with no associated tracks are retained.

In the pseudorapidity range $|\eta| < 2.5$, b-jets are selected using a tagging algorithm [38]. The b-jet tagging algorithm has an efficiency of 60–70% for b-jets in simulated $t\bar{t}$ events. The corresponding light-quark jet misidentification probability is 0.1–1%, depending on the jet's p_{T} and η.

Hadronically decaying tau leptons are reconstructed starting from clusters of energy in the electromagnetic and hadronic calorimeters. The τ_{had}[3] reconstruction is seeded by the anti-k_t jet finding algorithm with a radius parameter $R = 0.4$. Jet-specific cleaning selection such as the JVF requirement is not needed for the tau candidate seeds, due to stricter vertex requirements. Tracks with $p_{\mathrm{T}} > 1$ GeV within a cone of radius 0.2 around the cluster barycentre are matched to the τ_{had} candidate, and the τ_{had} charge is determined from the sum of the charges of its associated tracks. The rejection of jets is provided in a separate identification step using discriminating variables based on tracks with $p_{\mathrm{T}} > 1$ GeV and the energy deposited in calorimeter cells found in the core region ($\Delta R < 0.2$) and in the region $0.2 < \Delta R < 0.4$ around the τ_{had} candidate's direction. Such discriminating variables

[3]In the following, the τ_{had} symbol always refers to the visible decay products of the τ hadronic decay.

JHEP04(2015)117

are combined in a boosted decision tree and three working points, labelled tight, medium and loose [39], are defined, corresponding to different τ_{had} identification efficiency values.

In this analysis, τ_{had} candidates with $p_{\text{T}} > 20$ GeV and $|\eta| < 2.47$ are used. The τ_{had} candidates are required to have charge ± 1, and must be 1- or 3-track (prong) candidates. In addition, a sample without the charge and track multiplicity requirements is retained for background modelling in the $\tau_{\text{had}}\tau_{\text{had}}$ channel, as described in section 6.2. The identification efficiency for τ_{had} candidates satisfying the medium criteria is of the order of 55–60%. Dedicated criteria [39] to separate τ_{had} candidates from misidentified electrons are also applied, with a selection efficiency for true τ_{had} decays of 95%. The probability to misidentify a jet with $p_{\text{T}} > 20$ GeV as a τ_{had} candidate is typically 1–2%.

Following their reconstruction, candidate leptons, hadronically decaying taus and jets may point to the same energy deposits in the calorimeters (within $\Delta R < 0.2$). Such overlaps are resolved by selecting objects in the following order of priority (from highest to lowest): muons, electrons, τ_{had}, and jet candidates. For all channels, the leptons that are considered in overlap removal with τ_{had} candidates need to only satisfy looser criteria than those defined above, to reduce misidentified τ_{had} candidates from leptons. The p_{T} threshold of muons considered in overlap removal is also lowered to 4 GeV.

The missing transverse momentum (with magnitude $E_{\text{T}}^{\text{miss}}$) is reconstructed using the energy deposits in calorimeter cells calibrated according to the reconstructed physics objects (e, γ, τ_{had}, jets and μ) with which they are associated [40]. The transverse momenta of reconstructed muons are included in the $E_{\text{T}}^{\text{miss}}$ calculation, with the energy deposited by these muons in the calorimeters taken into account. The energy from calorimeter cells not associated with any physics objects is scaled by a soft-term vertex fraction and also included in the $E_{\text{T}}^{\text{miss}}$ calculation. This fraction is the ratio of the summed scalar p_{T} of tracks from the primary vertex not matched with objects to the summed scalar p_{T} of all tracks in the event also not matched to objects. This method allows to achieve a more accurate reconstruction of the $E_{\text{T}}^{\text{miss}}$ in high pile-up conditions [41].

3 Data and simulated samples

After data quality requirements, the integrated luminosities of the samples used are 4.5 fb^{-1} at $\sqrt{s} = 7$ TeV and 20.3 fb^{-1} at $\sqrt{s} = 8$ TeV.

Samples of signal and background events were simulated using various Monte Carlo (MC) generators, as summarised in table 1. The generators used for the simulation of the hard-scattering process and the model used for the simulation of the parton shower, of the hadronisation and of the underlying-event activity are listed. In addition, the cross section values to which the simulation is normalised and the perturbative order in QCD of the respective calculations are provided.

The signal contributions considered include the three main processes for Higgs boson production at the LHC: ggF, VBF, and associated VH production processes. The contributions from the associated $t\bar{t}H$ production process are found to be small and are neglected. The ggF and VBF production processes are simulated with Powheg [42–45] interfaced to Pythia8 [46]. In the Powheg event generator, the CT10 [47] parameter-

JHEP04(2015)117

isation of the parton distribution functions (PDFs) is used. The overall normalisation of the ggF process is taken from a calculation at next-to-next-to-leading-order (NNLO) [48–53] in QCD, including soft-gluon resummation up to next-to-next-to-leading logarithm terms (NNLL) [54]. Next-to-leading order (NLO) electroweak (EW) corrections are also included [55, 56]. Production by VBF is normalised to a cross section calculated with full NLO QCD and EW corrections [57–59] with an approximate NNLO QCD correction applied [60]. The associated VH production process is simulated with Pythia8. The Cteq6L1 [61] parameterisation of PDFs is used for the Pythia8 event generator. The predictions for VH production are normalised to cross sections calculated at NNLO in QCD [62], with NLO EW radiative corrections [63] applied.

Additional corrections to the shape of the generated p_{T} distribution of Higgs bosons produced via ggF are applied to match the distribution from a calculation at NNLO including the NNLL corrections provided by the HRes2.1 [64] program. In this calculation, the effects of finite masses of the top and bottom quarks [64, 65] are included and dynamical renormalisation and factorisation scales, $\mu_{\mathrm{R}}, \mu_{\mathrm{F}} = \sqrt{m_H^2 + p_{\mathrm{T}}^2}$, are used. A reweighting is performed separately for events with no more than one jet at particle level and for events with two or more jets. In the latter case, the Higgs boson p_{T} spectrum is reweighted to match the MinLo HJJ predictions [66]. The reweighting is derived such that the inclusive Higgs boson p_{T} spectrum and the p_{T} spectrum of events with at least two jets match the HRes2.1 and MinLo HJJ predictions respectively, and that the jet multiplicities are in agreement with (N)NLO calculations from JetVHeto [67–69].

The NLO EW corrections for VBF production depend on the p_{T} of the Higgs boson, varying from a few percent at low p_{T} to $\sim 20\%$ at $p_{\mathrm{T}} = 300$ GeV [70]. The p_{T} spectrum of the VBF-produced Higgs boson is therefore reweighted, based on the difference between the Powheg+Pythia calculation and the Hawk [57, 58] calculation which includes these corrections.

The main and largely irreducible $Z/\gamma^* \to \tau\tau$ background is modelled using $Z/\gamma^* \to \mu\mu$ events from data,[4] where the muon tracks and associated energy depositions in the calorimeters are replaced by the corresponding simulated signatures of the final-state particles of the tau decay. In this approach, essential features such as the modelling of the kinematics of the produced boson, the modelling of the hadronic activity of the event (jets and underlying event) as well as contributions from pile-up are taken from data. Thereby the dependence on the simulation is minimised and only the τ decays and the detector response to the tau-lepton decay products are based on simulation. By requiring two isolated, high-energy muons with opposite charge and a dimuon invariant mass $m_{\mu\mu} > 40$ GeV, $Z \to \mu\mu$ events can be selected from the data with high efficiency and purity. To replace the muons in the selected events, all tracks associated with the muons are removed and calorimeter cell energies associated with the muons are corrected by subtracting the corresponding energy depositions in a single simulated $Z \to \mu\mu$ event with the same kinematics. Finally, both the track information and the calorimeter cell energies from a simulated $Z \to \tau\tau$ decay are

[4] These processes are hereafter for simplicity denoted by $Z \to \tau\tau$ and $Z \to \mu\mu$ respectively, even though the whole continuum above and below the Z peak is considered.

JHEP04(2015)117

added to the data event. The decays of the tau leptons are simulated by TAUOLA [71]. The tau lepton kinematics are matched to the kinematics of the muons they are replacing, including polarisation and spin correlations [72], and the mass difference between the muons and the tau leptons is accounted for. This hybrid sample is referred to as embedded data in the following.

Other background processes are simulated using different generators, each interfaced to PYTHIA [46, 73] or HERWIG [74, 75] to provide the parton shower, hadronisation and the modelling of the underlying event, as indicated in table 1. For the HERWIG samples, the decays of tau leptons are also simulated using TAUOLA [71]. Photon radiation from charged leptons for all samples is provided by PHOTOS [76]. The samples for W/Z+jets production are generated with ALPGEN [77], employing the MLM matching scheme [78] between the hard process (calculated with LO matrix elements for up to five partons) and the parton shower. For WW production, the loop-induced $gg \to WW$ process is also generated, using the GG2WW [79] program. In the ACERMC [80], ALPGEN, and HERWIG event generators, the CTEQ6L1 parameterisation of the PDFs is used, while the CT10 parameterisation is used for the generation of events with GG2WW. The normalisation of these background contributions is either estimated from control regions using data, as described in section 6, or the cross sections quoted in table 1 are used.

For all samples, a full simulation of the ATLAS detector response [81] using the GEANT4 program [82] was performed. In addition, events from minimum-bias interactions were simulated using the AU2 [83] parameter tuning of PYTHIA8. The AU2 tune includes the set of optimized parameters for the parton shower, hadronisation, and multiple parton interactions. They are overlaid on the simulated signal and background events according to the luminosity profile of the recorded data. The contributions from these pile-up interactions are simulated both within the same bunch crossing as the hard-scattering process and in neighbouring bunch crossings. Finally, the resulting simulated events are processed through the same reconstruction programs as the data.

4 Event selection and categorisation

4.1 Event selection

Single lepton, dilepton and di-τ_{had} triggers were used to select the events for the analysis. A summary of the triggers used by each channel at the two centre-of-mass energies is reported in table 2. Due to the increasing luminosity and the different pile-up conditions, the online p_{T} thresholds increased during data-taking in 2011 and again for 2012, and more stringent identification requirements were applied for the data-taking in 2012. The p_{T} requirements on the objects in the analysis are usually 2 GeV higher than the trigger requirements, to ensure that the trigger is fully efficient.

In addition to applying criteria to ensure that the detector was functioning properly, requirements to increase the purity and quality of the data sample are applied by rejecting non-collision events such as cosmic rays and beam-halo events. At least one reconstructed vertex is required with at least four associated tracks with $p_{\text{T}} > 400$ MeV and a posi-

Table 1. Monte Carlo generators used to model the signal and the background processes at $\sqrt{s} = 8$ TeV. The cross sections times branching fractions ($\sigma \times \mathcal{B}$) used for the normalisation of some processes (many of these are subsequently normalised to data) are included in the last column together with the perturbative order of the QCD calculation. For the signal processes the $H \to \tau\tau$ SM branching ratio is included, and for the W and Z/γ^* background processes the branching ratios for leptonic decays ($\ell = e, \mu, \tau$) of the bosons are included. For all other background processes, inclusive cross sections are quoted (marked with a †).

tion consistent with the beam spot. It has been verified that, after object selection cuts, contributions from other primary vertices are negligible.

With respect to the object identification requirements described in section 2, tighter criteria are applied to address the different background contributions and compositions in the different analysis channels. Higher p_{T} thresholds are applied to electrons, muons, and τ_{had} candidates according to the trigger conditions satisfied by the event, as listed in table 2. For the channels involving leptonic tau decays, $\tau_{\mathrm{lep}}\tau_{\mathrm{lep}}$ and $\tau_{\mathrm{lep}}\tau_{\mathrm{had}}$, additional isolation criteria for electrons and muons, based on tracking and calorimeter information, are used to suppress the background from misidentified jets or from semileptonic decays of charm and bottom hadrons. The calorimeter isolation variable $I(E_{\mathrm{T}}, \Delta R)$ is defined

Table 3. Summary of isolation requirements applied for the selection of isolated electrons and muons at the two centre-of-mass energies. The isolation variables are defined in the text.

as the sum of the total transverse energy in the calorimeter in a cone of size ΔR around the electron cluster or the muon track, divided by the E_{T} of the electron cluster or the p_{T} of the muon respectively. The track-based isolation $I(p_{\text{T}}, \Delta R)$ is defined as the sum of the transverse momenta of tracks within a cone of ΔR around the electron or muon track, divided by the E_{T} of the electron cluster or the muon p_{T} respectively. The isolation requirements applied are slightly different for the two centre-of-mass energies and are listed in table 3.

In the $\tau_{\text{had}}\tau_{\text{had}}$ channel, isolated taus are selected by requiring that there are no tracks with $p_{\text{T}} > 0.5$ GeV in an isolation region of $0.2 < \Delta R < 0.6$ around the tau direction. This requirement leads to a 12% (4%) efficiency loss for hadronic taus, while 30% (10%) of contamination from jets is rejected in 8 (7) TeV data.

After the basic lepton selection, further channel-dependent cuts are applied, as detailed in the following. The full event selection is summarised in table 4.

The $\tau_{\text{lep}}\tau_{\text{lep}}$ channel: exactly two isolated leptons with opposite-sign (OS) electric charges, passing the p_{T} threshold listed in table 2, are required. Events containing a τ_{had} candidate are vetoed. For the τ_{had} candidates considered, the criteria used to reject electrons misidentified as τ_{had} candidates are tightened to a working-point of 85% signal efficiency [39].

In addition to the irreducible $Z \to \tau\tau$ background, sizeable background contributions from $Z \to \ell\ell$ and from $t\bar{t}$ production are expected in this channel. Background contributions from Z decays, but also from low mass resonances (charmonium and bottomonium), are rejected by requirements on the invariant mass $m_{\tau\tau}^{\text{vis}}$ of the visible tau decay products, on the angle $\Delta\phi_{\ell\ell}$ between the two leptons in the transverse plane and on $E_{\text{T}}^{\text{miss}}$. To reject the large $Z \to \ell\ell$ contribution in events with same-flavour (SF) leptons ($ee, \mu\mu$), more stringent cuts on the visible mass and on $E_{\text{T}}^{\text{miss}}$ are applied for these events than for events with different-flavour (DF) leptons ($e\mu$). For SF final states, an additional variable named *high-p_{T} objects* $E_{\text{T}}^{\text{miss}}$ ($E_{\text{T}}^{\text{miss,HPTO}}$) is also used to reject background from Z/γ^* production. It is calculated from the high-p_{T} objects in the event, i.e. from the two leptons and from jets with $p_{\text{T}} > 25$ GeV. Due to the presence of real neutrinos, the two $E_{\text{T}}^{\text{miss}}$ variables

JHEP04(2015)117

are strongly correlated for signal events but only loosely correlated for background from $Z \to ee$ and $Z \to \mu\mu$ decays.

To further suppress background contributions from misidentified leptons[5] a minimum value of the scalar sum of the transverse momenta of the two leptons is required. Contributions from $t\bar{t}$ events are further reduced by rejecting events with a b-jet with $p_{\mathrm{T}} > 25$ GeV.

Within the collinear approximation [99], i.e. assuming that the tau directions are given by the directions of the visible tau decay products and that the momenta of the neutrinos constitute the missing transverse momentum, the tau momenta can be reconstructed. For tau decays, the fractions of the tau momenta carried by the visible decay products,[6] $x_{\tau,i} = p_{\mathrm{vis},i}/(p_{\mathrm{vis},i} + p_{\mathrm{mis},i})$, with $i = 1, 2$, are expected to lie in the interval $0 < x_{\tau,i} < 1$, and hence corresponding requirements are applied to further reject non-tau background contributions.

Finally, to avoid overlap between this analysis and the search for $H \to WW^* \to \ell\nu\ell\nu$ decays, the $\tau\tau$ mass in the collinear approximation is required to satisfy the condition $m_{\tau\tau}^{\mathrm{coll}} > m_Z - 25$ GeV.

The $\tau_{\mathrm{lep}}\tau_{\mathrm{had}}$ channel: exactly one isolated lepton and one τ_{had} candidate with OS charges, passing the p_{T} thresholds listed in table 2, are required. The criteria used to reject electrons misidentified as τ_{had} are also tightened in this channel to a working-point of 85% signal efficiency [39].

The production of W+jets and of top quarks constitute the dominant reducible background in this channel. To substantially reduce the W+jets contribution, a cut on the transverse mass[7] constructed from the lepton and the missing transverse momentum is applied and events with $m_{\mathrm{T}} > 70$ GeV are rejected. Contributions from $t\bar{t}$ events are reduced by rejecting events with a b-jet with $p_{\mathrm{T}} > 30$ GeV.

The $\tau_{\mathrm{had}}\tau_{\mathrm{had}}$ channel: one isolated medium τ_{had} candidate and one isolated tight τ_{had} candidate with OS charges are required. Events with electron or muon candidates are rejected. For all data, the missing transverse momentum must satisfy $E_{\mathrm{T}}^{\mathrm{miss}} > 20$ GeV and its direction must either be between the two visible τ_{had} candidates in ϕ or within $\Delta\phi < \pi/4$ of the nearest τ_{had} candidate. To further reduce the background from multijet production, additional cuts on the ΔR and pseudorapidity separation $\Delta\eta$ between the two τ_{had} candidates are applied.

With these selections, there is no overlap between the individual channels.

4.2 Analysis categories

To exploit signal-sensitive event topologies, two analysis categories are defined in an exclusive way.

[5] Misidentified leptons and τ_{had} candidates are also referred to as "fake" in this paper.

[6] The variable p_{vis} is defined as the total momentum of the visible decay products of the tau lepton while p_{mis} is defined as the momentum of the neutrino system reconstructed using the collinear approximation.

[7] $m_{\mathrm{T}} = \sqrt{2p_{\mathrm{T}}^{\ell} \, E_{\mathrm{T}}^{\mathrm{miss}} \cdot (1 - \cos\Delta\phi)}$, where $\Delta\phi$ is the azimuthal separation between the directions of the lepton and the missing transverse momentum.

JHEP04(2015)117

Channel	Preselection cuts
$\tau_{\text{lep}}\tau_{\text{lep}}$	Exactly two isolated opposite-sign leptons Events with τ_{had} candidates are rejected 30 GeV $< m_{\tau\tau}^{\text{vis}} <$ 100 (75) GeV for DF (SF) events $\Delta\phi_{\ell\ell} < 2.5$ $E_{\text{T}}^{\text{miss}} > 20$ (40) GeV for DF (SF) events $E_{\text{T}}^{\text{miss,HPTO}} > 40$ GeV for SF events $p_{\text{T}}^{\ell_1} + p_{\text{T}}^{\ell_2} > 35$ GeV Events with a b-tagged jet with $p_{\text{T}} > 25$ GeV are rejected $0.1 < x_{\tau_1}, x_{\tau_2} < 1$ $m_{\tau\tau}^{\text{coll}} > m_Z - 25$ GeV
$\tau_{\text{lep}}\tau_{\text{had}}$	Exactly one isolated lepton and one medium τ_{had} candidate with opposite charges $m_{\text{T}} < 70$ GeV Events with a b-tagged jet with $p_{\text{T}} > 30$ GeV are rejected
$\tau_{\text{had}}\tau_{\text{had}}$	One isolated medium and one isolated tight opposite-sign τ_{had}-candidate Events with leptons are vetoed $E_{\text{T}}^{\text{miss}} > 20$ GeV $E_{\text{T}}^{\text{miss}}$ points between the two visible taus in ϕ, or $\min[\Delta\phi(\tau, E_{\text{T}}^{\text{miss}})] < \pi/4$ $0.8 < \Delta R(\tau_{\text{had}_1}, \tau_{\text{had}_2}) < 2.4$ $\Delta\eta(\tau_{\text{had}_1}, \tau_{\text{had}_2}) < 1.5$
Channel	VBF category selection cuts
$\tau_{\text{lep}}\tau_{\text{lep}}$	At least two jets with $p_{\text{T}}^{j_1} > 40$ GeV and $p_{\text{T}}^{j_2} > 30$ GeV $\Delta\eta(j_1, j_2) > 2.2$
$\tau_{\text{lep}}\tau_{\text{had}}$	At least two jets with $p_{\text{T}}^{j_1} > 50$ GeV and $p_{\text{T}}^{j_2} > 30$ GeV $\Delta\eta(j_1, j_2) > 3.0$ $m_{\tau\tau}^{\text{vis}} > 40$ GeV
$\tau_{\text{had}}\tau_{\text{had}}$	At least two jets with $p_{\text{T}}^{j_1} > 50$ GeV and $p_{\text{T}}^{j_2} > 30$ GeV $p_{\text{T}}^{j_2} > 35$ GeV for jets with $\lvert\eta\rvert > 2.4$ $\Delta\eta(j_1, j_2) > 2.0$
Channel	Boosted category selection cuts
$\tau_{\text{lep}}\tau_{\text{lep}}$	At least one jet with $p_{\text{T}} > 40$ GeV
All	Failing the VBF selection $p_{\text{T}}^{H} > 100$ GeV

Table 4. Summary of the event selection for the three analysis channels. The requirements used in both the preselection and for the definition of the analysis categories are given. The labels (1) and (2) refer to the leading (highest p_{T}) and subleading final-state objects (leptons, τ_{had}, jets). The variables are defined in the text.

- The VBF category targets events with a Higgs boson produced via vector boson fusion and is characterised by the presence of two high-p_{T} jets with a large pseudorapidity separation (see table 4). The $\Delta\eta(j_1, j_2)$ requirement is applied to the two highest-p_{T} jets in the event. In the $\tau_{\text{lep}}\tau_{\text{had}}$ channel, there is an additional requirement that $m_{\tau\tau}^{\text{vis}} > 40$ GeV, to eliminate low-mass Z/γ^* events. Although this category is dominated by VBF events, it also includes smaller contributions from ggF and VH production.

- The boosted category targets events with a boosted Higgs boson produced via ggF.

JHEP04(2015)117

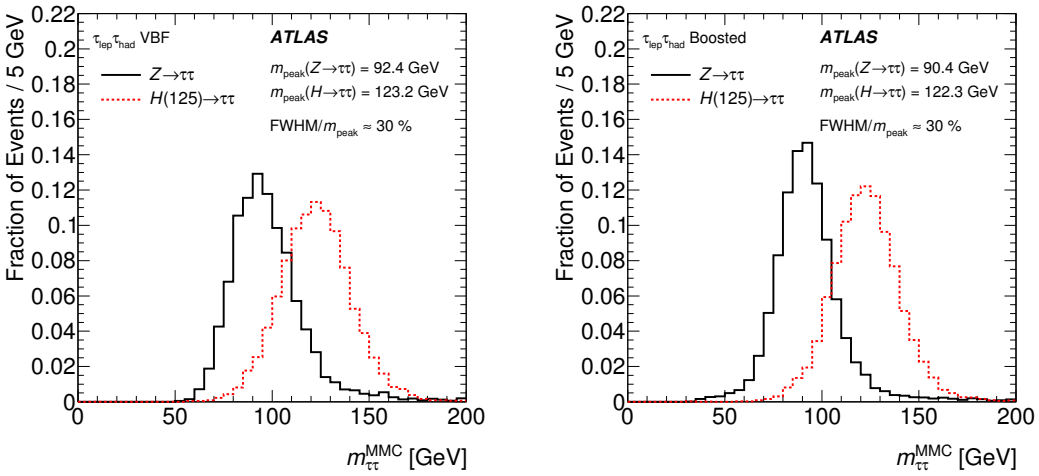
Higgs boson candidates are therefore required to have large transverse momentum, $p_{\mathrm{T}}^{H} > 100$ GeV. The p_{T}^{H} is reconstructed using the vector sum of the missing transverse momentum and the transverse momentum of the visible tau decay products. In the $\tau_{\mathrm{lep}}\tau_{\mathrm{lep}}$ channel, at least one jet with $p_{\mathrm{T}} > 40$ GeV is required. The jet requirement selects a region of the phase space where the $E_{\mathrm{T}}^{\mathrm{miss}}$ of same-flavour events is well modelled by simulation. In order to define an orthogonal category, events passing the VBF category selection are not considered. This category also includes small contributions from VBF and VH production.

While these categories are conceptually identical across the three channels, differences in the dominant background contributions require different selection criteria. For both categories, the requirement on jets is inclusive and additional jets, apart from those passing the category requirements, are allowed.

For the $\tau_{\mathrm{had}}\tau_{\mathrm{had}}$ channel, the so-called *rest category* is used as a control region. In this category, events passing the preselection requirements but not passing the VBF or boosted category selections are considered. This category is used to constrain the $Z \to \tau\tau$ and multijet background contributions. The signal contamination in this category is negligible.

4.3 Higgs boson candidate mass reconstruction

The di-tau invariant mass ($m_{\tau\tau}^{\mathrm{MMC}}$) is reconstructed using the missing mass calculator (MMC) [100]. This requires solving an underconstrained system of equations for six to eight unknowns, depending on the number of neutrinos in the $\tau\tau$ final state. These unknowns include the x-, y-, and z-components of the momentum carried by the neutrinos for each of the two tau leptons in the event, and the invariant mass of the two neutrinos from any leptonic tau decays. The calculation uses the constraints from the measured x- and y-components of the missing transverse momentum, and the visible masses of both tau candidates. A scan is performed over the two components of the missing transverse momentum vector and the yet undetermined variables. Each scan point is weighted by its probability according to the $E_{\mathrm{T}}^{\mathrm{miss}}$ resolution and the tau decay topologies. The estimator for the $\tau\tau$ mass is defined as the most probable value of the scan points.



The MMC algorithm provides a solution for ∼99% of the $H \to \tau\tau$ and $Z \to \tau\tau$ events. This is a distinct advantage compared to the mass calculation using the collinear approximation where the failure rate is higher due to the implicit collinearity assumptions. The small loss rate of about 1% for signal events is due to large fluctuations of the $E_{\mathrm{T}}^{\mathrm{miss}}$ measurement or other scan variables.

Figure 1 shows reconstructed $m_{\tau\tau}^{\mathrm{MMC}}$ mass distributions for $H \to \tau\tau$ and $Z \to \tau\tau$ events in the $\tau_{\mathrm{lep}}\tau_{\mathrm{had}}$ VBF and boosted categories. The mass resolution, defined as the ratio between the full width at half maximum (FWHM) and the peak value of the mass distribution (m_{peak}), is found to be $\approx 30\%$ for all categories and channels.

5 Boosted decision trees

Boosted decision trees are used in each category to extract the Higgs boson signal from the large number of background events. Decision trees [24] recursively partition the parameter

JHEP04(2015)117

(a) (b)

Figure 1. The reconstructed invariant $\tau\tau$ mass, $m_{\tau\tau}^{\mathrm{MMC}}$ for $H \to \tau\tau$ ($m_H = 125$ GeV) and $Z \to \tau\tau$ events in MC simulation and embedding respectively, for events passing (a) the VBF category selection and (b) the boosted category selection in the $\tau_{\mathrm{lep}}\tau_{\mathrm{had}}$ channel.

space into multiple regions where signal or background purities are enhanced. Boosting is a method which improves the performance and stability of decision trees and involves the combination of many trees into a single final discriminant [25, 26]. After boosting, the final score undergoes a transformation to map the scores on the interval -1 to $+1$. The most signal-like events have scores near 1 while the most background-like events have scores near -1.

Separate BDTs are trained for each analysis category and channel with signal and background samples, described in section 6, at $\sqrt{s} = 8$ TeV. They are then applied to the analysis of the data at both centre-of-mass energies. The separate training naturally exploits differences in event kinematics between different Higgs boson production modes. It also allows different discriminating variables to be used to address the different background compositions in each channel. A large set of potential variables was investigated, in each channel separately, and only those variables which led to an improved discrimination performance of the BDT were kept. For the training in the VBF category, only a VBF Higgs production signal sample is used, while training in the boosted category uses ggF, VBF, and VH signal samples. The Higgs boson mass is chosen to be $m_H = 125$ GeV for all signal samples. The BDT input variables used at both centre-of-mass energies are listed in table 5. Most of these variables have straightforward definitions, and the more complex ones are defined in the following.

- $\Delta R(\tau_1, \tau_2)$: the distance ΔR between the two leptons, between the lepton and τ_{had}, or between the two τ_{had} candidates, depending on the decay mode.

- $p_{\mathrm{T}}^{\mathrm{Total}}$: magnitude of the vector sum of the transverse momenta of the visible tau decay products, the two leading jets, and $E_{\mathrm{T}}^{\mathrm{miss}}$.

JHEP04(2015)117

- Sum p_{T}: scalar sum of the p_{T} of the visible components of the tau decay products and of the jets.

- $E_{\mathrm{T}}^{\mathrm{miss}}\phi$ centrality: a variable that quantifies the relative angular position of the missing transverse momentum with respect to the visible tau decay products in the transverse plane. The transverse plane is transformed such that the direction of the tau decay products are orthogonal, and that the smaller ϕ angle between the tau decay products defines the positive quadrant of the transformed plane. The $E_{\mathrm{T}}^{\mathrm{miss}}\phi$ centrality is defined as the sum of the x- and y-components of the $E_{\mathrm{T}}^{\mathrm{miss}}$ unit vector in this transformed plane.

- Sphericity: a variable that describes the isotropy of the energy flow in the event [101]. It is based on the quadratic momentum tensor

$$S^{\alpha\beta} = \frac{\sum_i p_i^\alpha p_i^\beta}{\sum_i |\vec{p}_i^{\,2}|}. \tag{5.1}$$

  In this equation, α and β are the indices of the tensor. The summation is performed over the momenta of the selected leptons and jets in the event. The sphericity of the event (S) is then defined in terms of the two smallest eigenvalues of this tensor, λ_2 and λ_3,

$$S = \frac{3}{2}(\lambda_2 + \lambda_3). \tag{5.2}$$

- $\min(\Delta\eta_{\ell_1\ell_2,\mathrm{jets}})$: the minimum $\Delta\eta$ between the dilepton system and either of the two jets.

- Object η centrality: a variable that quantifies the η position of an object (an isolated lepton, a τ_{had} candidate or a jet) with respect to the two leading jets in the event. It is defined as

$$C_{\eta_1,\eta_2}(\eta) = \exp\left[\frac{-4}{(\eta_1-\eta_2)^2}\left(\eta - \frac{\eta_1+\eta_2}{2}\right)^2\right], \tag{5.3}$$

  where η, η_1 and η_2 are the pseudorapidities of the object and the two leading jets respectively. This variable has a value of 1 when the object is halfway in η between the two jets, 1/e when the object is aligned with one of the jets, and $< 1/\mathrm{e}$ when the object is not between the jets in η. In the $\tau_{\mathrm{lep}}\tau_{\mathrm{lep}}$ channel the η centrality of a third jet in the event, $C_{\eta_1,\eta_2}(\eta_{j_3})$, and the product of the η centralities of the two leptons are used as BDT input variables, while in the $\tau_{\mathrm{lep}}\tau_{\mathrm{had}}$ channel the η centrality of the lepton, $C_{\eta_1,\eta_2}(\eta_\ell)$, is used, and in the $\tau_{\mathrm{had}}\tau_{\mathrm{had}}$ channel the η centrality of each τ, $C_{\eta_1,\eta_2}(\eta_{\tau_1})$ and $C_{\eta_1,\eta_2}(\eta_{\tau_2})$, is used. Events with only two jets are assigned a dummy value of -0.5 for $C_{\eta_1,\eta_2}(\eta_{j_3})$.

Among these variables the most discriminating ones include $m_{\tau\tau}^{\mathrm{MMC}}$, $\Delta R(\tau_1,\tau_2)$ and $\Delta\eta(j_1,j_2)$. Figures 2 and 3 show the distributions of selected BDT input variables. For the VBF category, the distributions of $\Delta\eta(j_1,j_2)$ and centrality variables are shown for all three channels. For the boosted category, the distributions of $\Delta R(\tau_1,\tau_2)$ and $E_{\mathrm{T}}^{\mathrm{miss}}\phi$

Table 5. Discriminating variables used in the training of the BDT for each channel and category at $\sqrt{s} = 8$ TeV. The more complex variables are described in the text. The filled circles indicate which variables are used in each case.

centrality are shown for the $\tau_{\text{lep}}\tau_{\text{had}}$ and $\tau_{\text{had}}\tau_{\text{had}}$ channels, and the distribution of the p_{T} of the leading jet and the sphericity are shown for the $\tau_{\text{lep}}\tau_{\text{lep}}$ channel. For all distributions, the data are compared to the predicted SM backgrounds at $\sqrt{s} = 8$ TeV. The corresponding uncertainties are indicated by the shaded bands. All input distributions are well described, giving confidence that the background models (from simulation and data) describe well the relevant input variables of the BDT. Similarly, good agreement is found for the distributions at $\sqrt{s} = 7$ TeV.

JHEP04(2015)117

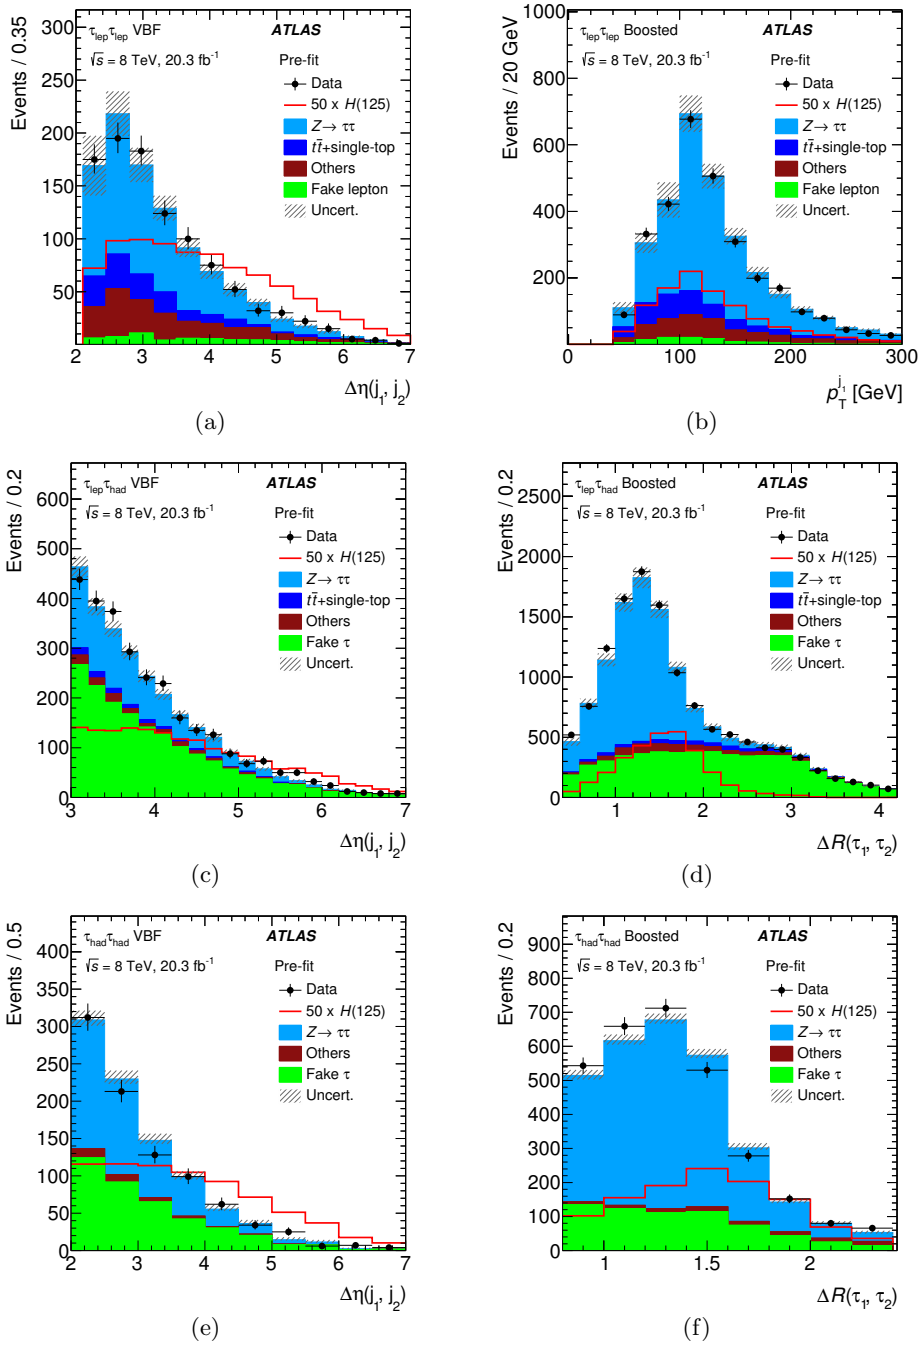

Figure 2. Distributions of important BDT input variables for the three channels and the two categories (VBF, left) and (boosted, right) for data collected at $\sqrt{s} = 8$ TeV. The distributions are shown for (a) the separation in pseudorapidity of the jets, $\Delta\eta(j_1, j_2)$, and (b) the transverse momentum of the leading jet $p_{\mathrm{T}}^{j_1}$ in the $\tau_{\mathrm{lep}}\tau_{\mathrm{lep}}$ channel, for (c) $\Delta\eta(j_1, j_2)$ and (d) $\Delta R(\tau_1, \tau_2)$, the distance ΔR between the lepton and τ_{had}, in the $\tau_{\mathrm{lep}}\tau_{\mathrm{had}}$ channel and for (e) $\Delta\eta(j_1, j_2)$ and (f) $\Delta R(\tau_1, \tau_2)$, the distance ΔR between the two τ_{had} candidates, in the $\tau_{\mathrm{had}}\tau_{\mathrm{had}}$ channel. The contributions from a Standard Model Higgs boson with $m_H = 125$ GeV are superimposed, multiplied by a factor of 50. These figures use background predictions made without the global fit defined in section 8. The error band includes statistical and pre-fit systematic uncertainties.

JHEP04(2015)117

These figures use background predictions made without the global fit defined in section 8. The error band includes statistical and pre-fit systematic uncertainties.

JHEP04(2015)117

6 Background estimation

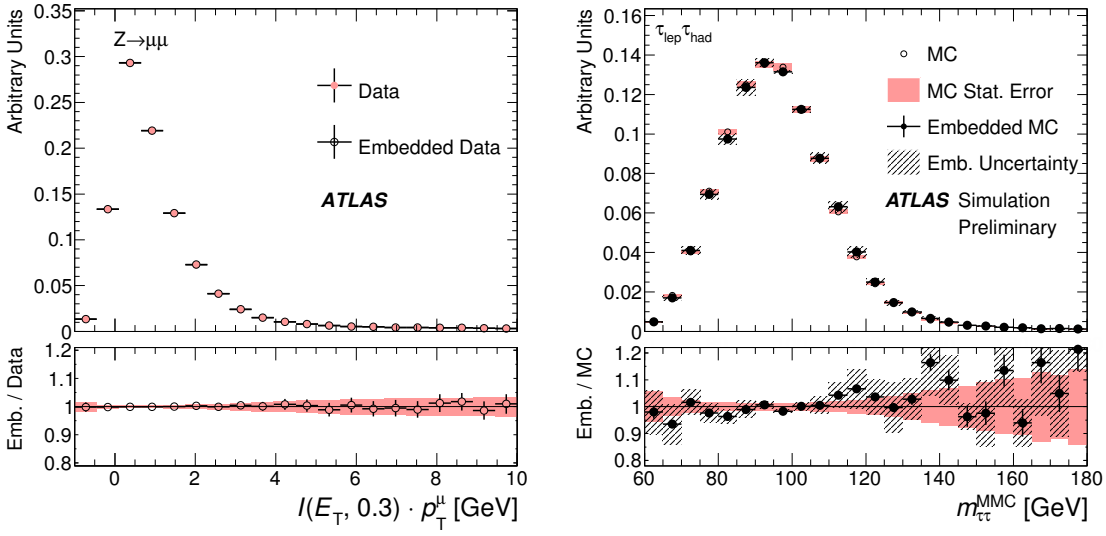
The different final-state topologies of the three analysis channels have different background compositions which necessitate different strategies for the background estimation. In general, the number of expected background events and the associated kinematic distributions are derived from a mixture of data-driven methods and simulation. The normalisation of several important background contributions is performed by comparing the simulated samples of individual background sources to data in regions which only have a small or negligible contamination from signal or other background events. The control regions used in the analysis are summarised in table 6.

Common to all channels is the dominant $Z \to \tau\tau$ background, for which the kinematic distributions are taken from data by employing the embedding technique, as described in section 3. Background contributions from jets that are misidentified as hadronically decaying taus (fake backgrounds) are estimated by using either a *fake-factor* method or samples of non-isolated τ_{had} candidates. Likewise, samples of non-isolated leptons are used to estimate fake-lepton contributions from jets or hadronically decaying taus and leptons from other sources, such as heavy-quark decays.[8]

Contributions from various other physics processes with leptons and/or τ_{had} candidates in the final state are estimated using the simulation, normalised to the theoretical cross sections, as given in table 1. A more detailed discussion of the estimation of the various background components in the different channels is given in the following.

6.1 Background from $Z \to \tau\tau$ production

A reliable modelling of the irreducible $Z \to \tau\tau$ background is an important ingredient of the analysis. It has been shown in other ATLAS analyses that existing Z+jets Monte Carlo simulation needs to be reweighted to model data correctly [102–104]. Additionally, it is not possible to select a sufficiently pure and signal-free $Z \to \tau\tau$ control sample from data to model the background in the signal region. Therefore this background is estimated using embedded data, as described in section 3. This procedure was extensively validated using both data and simulation. To validate the subtraction procedure of the muon cell energies and tracks from data and the subsequent embedding of the corresponding information from simulation, the muons in $Z \to \mu\mu$ events are replaced by simulated muons. The calorimeter isolation energy in a cone of $\Delta R = 0.3$ around the muons from data before and after embedding is compared in figure 4(a). Good agreement is found, which indicates that no deterioration (e.g. possible energy biases) in the muon environment is introduced. Another important test validates the embedding of more complex $Z \to \tau\tau$ events, which can only be performed in the simulation. To achieve a meaningful validation, the same MC generator with identical settings was used to simulate both the $Z \to \mu\mu$ and $Z \to \tau\tau$ events. The sample of embedded events is corrected for the bias due to the trigger, reconstruction and acceptance of the original muons. These corrections are determined from data as a function of p_{T}^{μ} and $\eta(\mu)$, and allow the acceptance of the original selection to be corrected. The tau decay products are treated like any other objects obtained from the simulation, with one



[8] For simplicity, leptons from heavy-quark decays are considered as fake leptons in the following.

JHEP04(2015)117

Process	$\tau_{\text{lep}}\tau_{\text{lep}}$	$\tau_{\text{lep}}\tau_{\text{had}}$	$\tau_{\text{had}}\tau_{\text{had}}$
$Z \to \ell\ell$-enriched	$80 < m_{\tau\tau}^{\text{vis}} < 100$ GeV (same-flavour)		
Top control region	Invert b-jet veto	Invert b-jet veto and $m_{\text{T}} > 40$ GeV	
Rest category			Pass preselection, Fail VBF and Boosted selections
$Z \to \tau\tau$-enriched	$m_{\tau\tau}^{\text{HPTO}} < 100$ GeV	$m_{\text{T}} < 40$ GeV and $m_{\tau\tau}^{\text{MMC}} < 110$ GeV	
Fake-enriched	Same sign τ decay products	Same sign τ decay products	
W-enriched		$m_{\text{T}} > 70$ GeV	
Mass sideband			$m_{\tau\tau}^{\text{MMC}} < 110$ GeV or $m_{\tau\tau}^{\text{MMC}} > 150$ GeV

Table 6. Summary and definition of the control regions used in the analysis. The requirements shown represent modifications to the signal region requirements. All other selections are applied as for the corresponding signal regions. The variable $m_{\tau\tau}^{\text{HPTO}}$ is the invariant mass of the $\tau\tau$-system obtained using the collinear approximation and the same objects as used in $E_{\text{T}}^{\text{miss,HPTO}}$. Each control region listed is actually two control regions, corresponding to the VBF or boosted categories, with the exception of the rest category. The first three control regions listed are used in the global fit defined in section 8.

(a) (b)

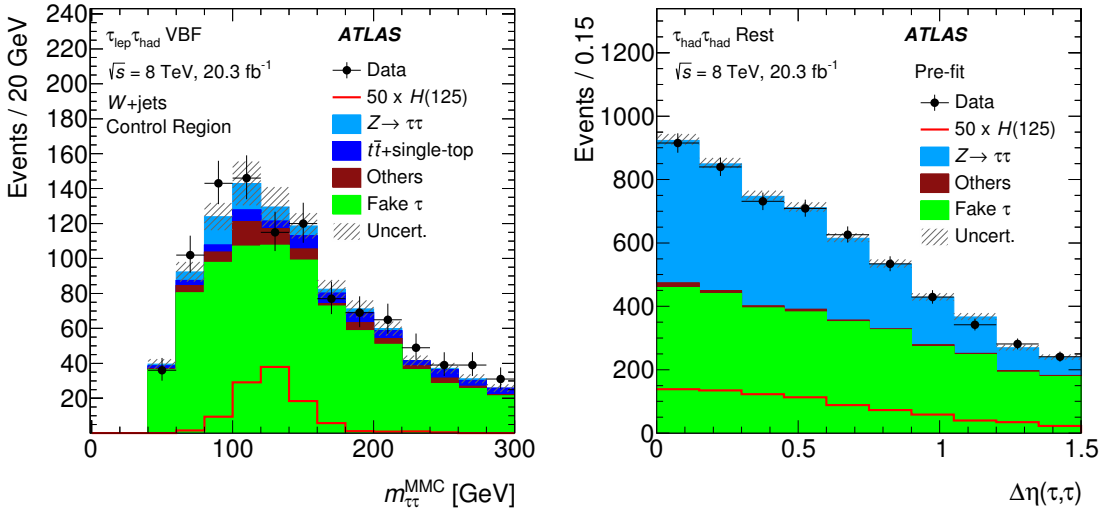
Figure 4. (a) The distribution of the calorimeter isolation energy $I(E_{\mathrm{T}}, 0.3) \cdot p_{\mathrm{T}}^{\mu}$ within a cone of radius $\Delta R = 0.3$ around the muons in $Z \to \mu\mu$ events from data, before and after the embedding of simulated muons. (b) The distribution of the reconstructed invariant $\tau\tau$ mass, $m_{\tau\tau}^{\mathrm{MMC}}$, in the $\tau_{\mathrm{lep}}\tau_{\mathrm{had}}$ final state, for simulated $Z \to \tau\tau$ events, compared to the one obtained from simulated $Z \to \mu\mu$ events after tau embedding. The ratios of the values before and after the embedding and between the embedded $Z \to \mu\mu$ and $Z \to \tau\tau$ events are given in (a) and (b) respectively. The errors in (a) and (b) on the ratios (points) represent the statistical uncertainties, while the systematic uncertainties are indicated by the hatched bands in (b). The shaded bands represent the statistical uncertainties from the $Z \to \mu\mu$ data events in (a) and from the $Z \to \tau\tau$ simulation in (b).

important difference due to the absence of trigger simulation in this sample. Trigger effects are parameterised from the simulation as a function of the tau decay product p_{T}. After replacing the muons with simulated taus, kinematic distributions of the embedded sample can be directly compared to the fully simulated ones. As an example, the reconstructed invariant mass, $m_{\tau\tau}^{\mathrm{MMC}}$, is shown in figure 4(b), for the $\tau_{\mathrm{lep}}\tau_{\mathrm{had}}$ final state. Good agreement is found and the observed differences are covered by the systematic uncertainties. Similarly, good agreement is found for other variables, such as the missing transverse momentum, the kinematic variables of the hadronically decaying tau lepton or of the associated jets in the event. A direct comparison of the $Z \to \tau\tau$ background in data and the modelling using the embedding technique also shows good agreement. This can be seen in several kinematic quantity distributions, which are dominated by $Z \to \tau\tau$ events, shown in figure 2.

The normalisation of this background process is taken from the final fit described in section 8. The normalisation is independent for the $\tau_{\mathrm{lep}}\tau_{\mathrm{lep}}$, $\tau_{\mathrm{lep}}\tau_{\mathrm{had}}$, and $\tau_{\mathrm{had}}\tau_{\mathrm{had}}$ analysis channels.

6.2 Background from misidentified leptons or hadronically decaying taus

For the $\tau_{\mathrm{lep}}\tau_{\mathrm{lep}}$ channel, all background sources resulting from misidentified leptons are treated together. In this approach, contributions from multijet and W+jets production,



JHEP04(2015)117

as well as the part of the $t\bar{t}$ background resulting from decays to leptons and hadrons ($t\bar{t} \to \ell\nu b\, qqb$) are included. A control sample is defined in data by inverting the isolation requirements for one of the two leptons, while applying all other signal region requirements. The contributions from other background channels (dileptonic $t\bar{t}$ decays ($t\bar{t} \to \ell\nu b\, \ell\nu b$), $Z \to ee$, $Z \to \mu\mu$, and diboson production) are obtained from the simulation and are subtracted. From this control sample a template is created. The normalisation factor is obtained by fitting the p_{T} distribution of the subleading lepton at an early stage of the preselection.

For the $\tau_{\mathrm{lep}}\tau_{\mathrm{had}}$ channel, the fake-factor method is used to derive estimates for the multijet, W+jets, Z+jets, and semileptonic $t\bar{t}$ background events that pass the $\tau_{\mathrm{lep}}\tau_{\mathrm{had}}$ selection due to a misidentified τ_{had} candidate. The fake factor is defined as the ratio of the number of jets identified as medium τ_{had} candidates to the number satisfying the loose, but not the medium, criteria. Since the fake factor depends on the type of parton initiating the jet and on the p_{T} of the jet, it is determined as a function of p_{T} separately for samples enriched in quark- and gluon-initiated jets. In addition, the fake factor is found to be different for 1-track and 3-track candidates. Three different, quark-jet dominated samples are used separately for the W+jets, $t\bar{t}$ and Z+jets background components. They are defined by selecting the high-m_{T} region ($m_{\mathrm{T}} > 70$ GeV), by inverting the b-jet veto and by requiring two leptons with an invariant mass consistent with m_Z (80 GeV $< m_{\ell\ell} <$ 100 GeV) respectively. In addition, a multijet sample dominated by gluon-initiated jets is selected by relaxing the lepton identification and requiring it to satisfy the loose identification criteria. The derived fake factors are found to vary from 0.124 (0.082) for $p_{\mathrm{T}} = 20$ GeV to 0.088 (0.038) for $p_{\mathrm{T}} = 150$ GeV for 1-track (3-track) candidates in the VBF category. The corresponding values for the boosted category are 0.146 (0.084) for $p_{\mathrm{T}} = 20$ GeV and 0.057 (0.033) for $p_{\mathrm{T}} = 150$ GeV. To obtain the fake-background estimate for the VBF and boosted signal regions, these factors are then applied, weighted by the expected relative W+jets, Z+jets, multijet, and $t\bar{t}$ fractions, to the events in regions defined by applying the selections of the corresponding signal region, except that the τ_{had} candidate is required to pass the loose and to fail the medium τ_{had} identification. As an example, the good agreement between data and background estimates is shown in figure 5(a) for the reconstructed $\tau\tau$ mass for events in the high-m_{T} region, which is dominated by W+jets production.

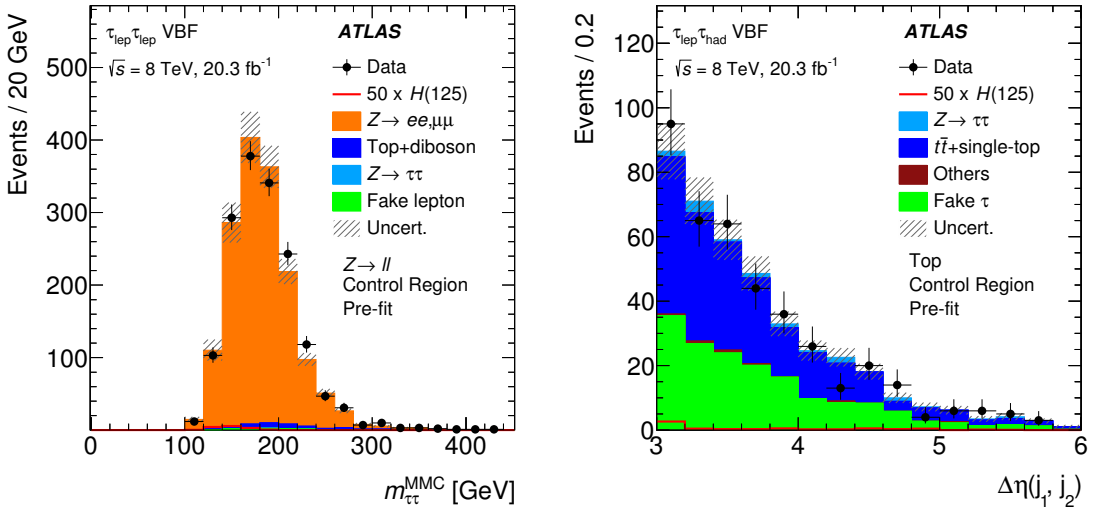
For the $\tau_{\mathrm{had}}\tau_{\mathrm{had}}$ channel, the multijet background is modelled using a template extracted from data that pass the VBF or boosted category selection, where, however, the taus fail the isolation and opposite-sign charge requirements (the number-of-tracks requirement is not enforced). The normalisation of the multijet background is first determined by performing a simultaneous fit of the multijet (modelled by the data sample just mentioned) and $Z \to \tau\tau$ (modelled by embedding) templates after the preselection cuts. The fit is performed for the distribution of the difference in pseudorapidity between the two hadronic tau candidates, $\Delta\eta(\tau_{\mathrm{had}}, \tau_{\mathrm{had}})$. The signal contribution is expected to be small in this category. The agreement between data and the background estimate for this distribution is shown in figure 5(b) for the rest category defined in section 4. The preselection normalisation is used as a reference point and starting value for the global fit (see below) and is used for validation plots. The final normalisations of the two important background components,

JHEP04(2015)117

(a) (b)

Figure 5. (a) The distribution of the reconstructed invariant $\tau\tau$ mass, $m_{\tau\tau}^{\mathrm{MMC}}$, for events in the W+jets control region, for the $\tau_{\mathrm{lep}}\tau_{\mathrm{had}}$ channel. (b) The separation in pseudorapidity of the τ_{had} candidates, $\Delta\eta(\tau_{\mathrm{had}}, \tau_{\mathrm{had}})$, for the $\tau_{\mathrm{had}}\tau_{\mathrm{had}}$ channel in the rest control region. The expected SM Higgs boson signal contribution is superimposed, multiplied by a factor 50. These figures use background predictions made without the global fit defined in section 8. The error band includes statistical and pre-fit systematic uncertainties.

from multijet and $Z \to \tau\tau$ events, are extracted from the final global fit, as described in section 8, in which the $\Delta\eta(\tau_{\mathrm{had}}, \tau_{\mathrm{had}})$ distribution for the rest category is included.



6.3 $Z \to ee$ and $Z \to \mu\mu$ background

The Drell-Yan $Z/\gamma^* \to ee$ and $Z/\gamma^* \to \mu\mu$ background channels are important contributions to the final states with two same-flavour leptons. They also contribute to the other channels. As described below, a simulation based on Alpgen is used to estimate these background sources. Correction factors are applied to account for differences between data and simulation.

In the $\tau_{\mathrm{lep}}\tau_{\mathrm{lep}}$ channel, the Alpgen simulation is normalised to the data in the Z-mass control region, 80 GeV $< m_{\ell\ell} <$ 100 GeV, for each category, and separately for $Z \to ee$ and $Z \to \mu\mu$ events. The normalisation factors are determined from the final fit described in section 8. The distribution of the reconstructed $\tau\tau$ mass for events in this control region is shown in figure 6(a).

In the $\tau_{\mathrm{lep}}\tau_{\mathrm{had}}$ channel, the $Z \to ee$ and $Z \to \mu\mu$ background estimates are also based on simulation. The corrections applied for a τ_{had} candidate depend on whether it originates from a lepton from the Z boson decay or from a jet. In the first case, corrections from data, derived from dedicated tag-and-probe studies, are applied to account for the difference in the rate of misidentified τ_{had} candidates resulting from leptons [21, 105]. This is particularly important for $Z \to ee$ events with a misidentified τ_{had} candidate originating from a true electron. In the second case, the fake-factor method described in section 6.2 is applied.

JHEP04(2015)117

(a) (b)

Figure 6. (a) The distribution of the reconstructed invariant $\tau\tau$ mass, $m_{\tau\tau}^{\mathrm{MMC}}$, for events in the $Z \rightarrow \ell\ell$ control region, for the $\tau_{\mathrm{lep}}\tau_{\mathrm{lep}}$ channel. (b) The distribution of the separation in pseudorapidity of the two leading jets, $\Delta\eta(j_1, j_2)$, for events in the top control region, for the $\tau_{\mathrm{lep}}\tau_{\mathrm{had}}$ channel. This figure uses background predictions made without the global fit defined in section 8. The error band includes statistical and pre-fit systematic uncertainties.

In the $\tau_{\mathrm{had}}\tau_{\mathrm{had}}$ channel, the contribution of this background is very small and is taken from simulation.

6.4 W+jets background

Events with W bosons and jets constitute a background to all channels since leptonic W decays can feed into all signatures when the true lepton is accompanied by a jet which is falsely identified as a τ_{had} or a lepton candidate. This process can also contribute via semileptonic heavy quark decays that provide identified leptons.

As stated in section 6.2, for the $\tau_{\mathrm{lep}}\tau_{\mathrm{lep}}$ and $\tau_{\mathrm{lep}}\tau_{\mathrm{had}}$ channels, the W+jets contributions are determined with data-driven methods. For the $\tau_{\mathrm{had}}\tau_{\mathrm{had}}$ channel, the $W \rightarrow \tau_{\mathrm{had}}\nu$ background is estimated from simulation. A correction is applied to account for differences in the τ_{had} misidentification probability between data and simulation.

6.5 Background from top-quark production

Background contributions from $t\bar{t}$ and single top-quark production, where leptons or hadronically decaying taus appear in decays of top quarks, are estimated from simulation in the $\tau_{\mathrm{lep}}\tau_{\mathrm{lep}}$ and $\tau_{\mathrm{lep}}\tau_{\mathrm{had}}$ channels. The normalisation is obtained from data control regions defined by requiring a b-jet instead of a b-veto. In the $\tau_{\mathrm{lep}}\tau_{\mathrm{had}}$ channel, a large value of the transverse mass m_{T} is also required, to enhance the background from top-quark production and to suppress the signal contribution. This background is also found to be small for the $\tau_{\mathrm{had}}\tau_{\mathrm{had}}$ channel and it is estimated using simulation. The distribution of $\Delta\eta(j_1, j_2)$ for events in the top control region, for the $\tau_{\mathrm{lep}}\tau_{\mathrm{had}}$ channel, is shown in figure 6(b).

JHEP04(2015)117

Channel	Background	Scale factors (CR) VBF	Boosted
$\tau_{\text{lep}}\tau_{\text{lep}}$	Top	0.99 ± 0.07	1.01 ± 0.05
	$Z \to ee$	0.91 ± 0.16	0.98 ± 0.10
	$Z \to \mu\mu$	0.97 ± 0.13	0.96 ± 0.08
$\tau_{\text{lep}}\tau_{\text{had}}$	Top	0.84 ± 0.08	0.96 ± 0.04

Table 7. The scale factors calculated in control regions (CR) for background normalisation. Only the statistical uncertainties are given. The background contributions shown in validation plots use the normalisation predicted from simulation multiplied by the corresponding scale factor. Final normalisations are taken from the global fit, described in section 8.

6.6 Diboson background

The production of pairs of vector bosons (W^+W^-, ZZ and $W^\pm Z$), with subsequent decays to leptons or jets, contributes especially to the background in the $\tau_{\text{lep}}\tau_{\text{lep}}$ channel. For all analysis channels, these contributions are estimated from simulation, normalised to the NLO cross sections indicated in table 1.

6.7 Contributions from other Higgs boson decays

In the $\tau_{\text{lep}}\tau_{\text{lep}}$ channel, a non-negligible contribution from $H \to WW \to \ell\nu\ell\nu$ exists and this process is considered as background. Its contribution is estimated for $m_H = 125$ GeV using simulation. The corresponding signal cross section is assumed to be the SM value and is indicated in table 1.

6.8 Validation of background estimates

As described above, the normalisation for important background sources that are modelled with simulation are determined by fitting to data in control regions. These normalisations are compared in table 7 to predictions based on the theoretical cross sections for the 8 TeV analysis. In most cases, the values obtained are compatible with unity within the statistical uncertainties shown. For the top control region in the VBF category of the $\tau_{\text{lep}}\tau_{\text{had}}$ channel, the value is also in agreement with unity if the experimental and theoretical systematic uncertainties are included. The control-region normalisations are used for validation plots, and they are used as starting values in the final global fit described in section 8. The global fit does not change any of these normalisations by more than 2%.

It is important to verify that the BDT output distributions in data control regions are well described after the various background determinations. Figure 7 shows distributions from important control regions for the $\sqrt{s} = 8$ TeV dataset, i.e. the Z-enriched control regions for the $\tau_{\text{lep}}\tau_{\text{lep}}$ and $\tau_{\text{lep}}\tau_{\text{had}}$ channels, and the reconstructed $\tau\tau$ invariant mass sideband control region (defined as $m_{\tau\tau}^{\text{MMC}} < 100$ GeV or $m_{\tau\tau}^{\text{MMC}} > 150$ GeV) for the $\tau_{\text{had}}\tau_{\text{had}}$ channel. The distributions are shown for both the VBF and the boosted categories. All distributions are found to be well described, within the systematic uncertainties.

JHEP04(2015)117

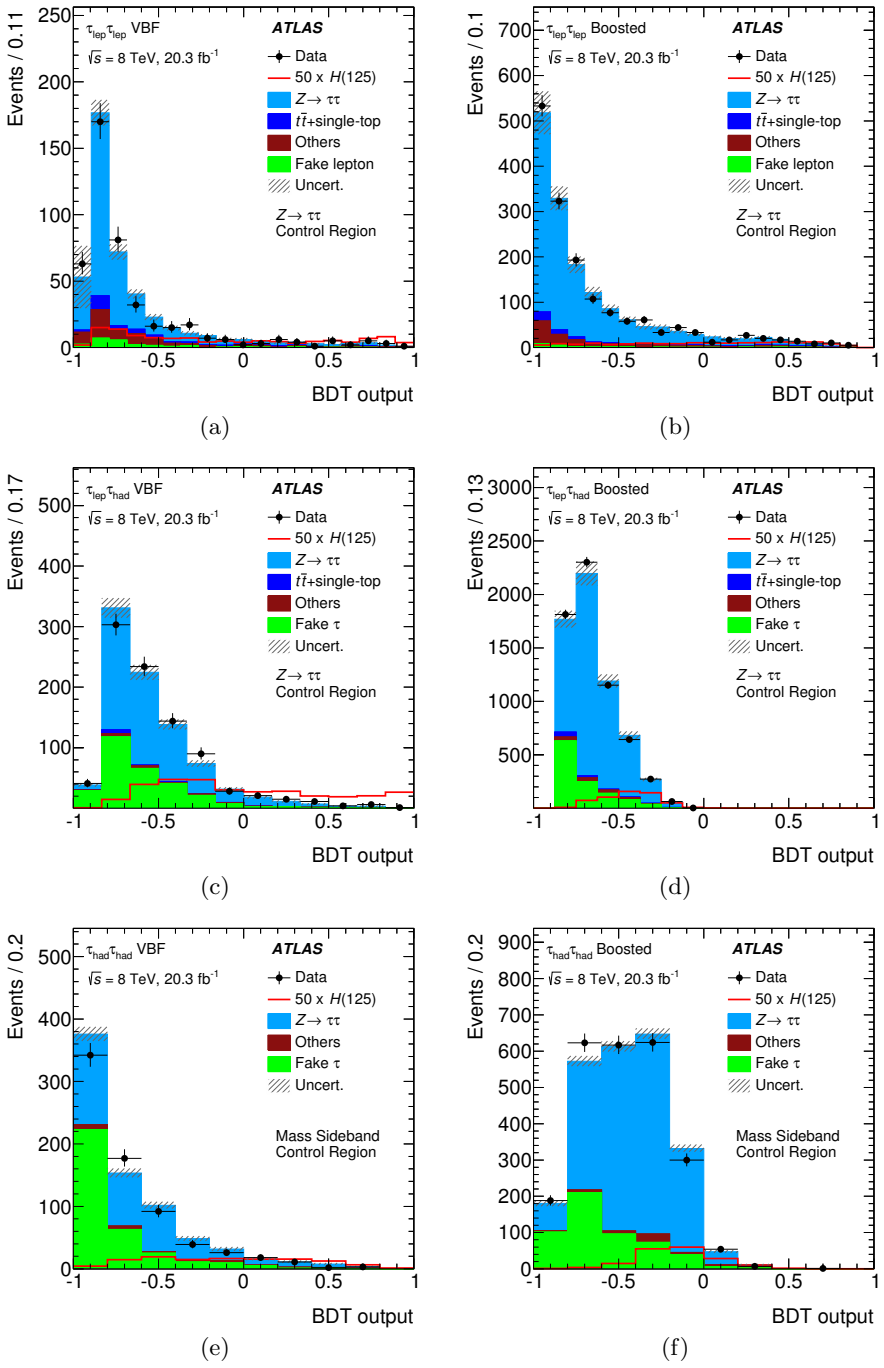


Figure 7. Distributions of the BDT output for data collected at $\sqrt{s} = 8$ TeV, compared to the expected background contributions in important control regions. The distributions are shown for the VBF (left) and boosted (right) categories (a,b) for the $Z \rightarrow \tau\tau$-enriched control region in the $\tau_{\text{lep}}\tau_{\text{lep}}$ channel, (c,d) for the $Z \rightarrow \tau\tau$-enriched control region in the $\tau_{\text{lep}}\tau_{\text{had}}$ channel and (e,f) for the $\tau\tau$ invariant mass sideband control region in the $\tau_{\text{had}}\tau_{\text{had}}$ channel. The contributions from a Standard Model Higgs boson with $m_H = 125$ GeV are superimposed, multiplied by a factor of 50. These figures use background predictions made without the global fit defined in section 8. The error band includes statistical and pre-fit systematic uncertainties.

JHEP04(2015)117

7 Systematic uncertainties

The numbers of expected signal and background events, the input variables to the BDT, and thereby the BDT output and the final discrimination between signal and background are affected by systematic uncertainties. They are discussed below, grouped into three categories: experimental uncertainties, background modelling uncertainties, and theoretical uncertainties. For all uncertainties, the effects on both the total signal and background yields and on the shape of the BDT output distribution are evaluated. Table 8 gives a summary of the systematic uncertainties and their impact on the number of expected events for the signal and the total background for the analysis of the data taken at $\sqrt{s} = 8$ TeV. The dominant sources that affect the shape of the BDT output distribution are marked in the table. All uncertainties are treated either as fully correlated or uncorrelated across channels. The latter are also marked in table 8. The effects of the systematic uncertainties at $\sqrt{s} = 7$ TeV are found to be similar and are not discussed here. The inclusion of the uncertainties in the profile likelihood global fit is described in section 8 and the effect of the most significant systematic uncertainties is presented in table 13.

7.1 Experimental uncertainties

The major experimental systematic uncertainties result from uncertainties on efficiencies for triggering, object reconstruction and identification, as well as from uncertainties on the energy scale and resolution of jets, hadronically decaying taus and leptons. In general, the effects resulting from lepton-related uncertainties are smaller than those from jets and taus. They are not discussed in detail, however, their impact is included in table 8. In addition, uncertainties on the luminosity affect the number of signal and background events from simulation.

- Luminosity: the uncertainty on the integrated luminosity is ±2.8% for the 8 TeV dataset and ±1.8% for the 7 TeV dataset. It is determined from a calibration of the luminosity scale derived from beam-separation scans performed in 2011 and 2012 using the method described in ref. [106].

- Efficiencies: the efficiencies for triggering, reconstructing and identifying electrons, muons, and τ_{had} candidates are measured in data using tag-and-probe techniques. The uncertainties on the τ_{had} identification efficiency are ±(2–3)% for 1-prong and ±(3–5)% for 3-prong tau decays [39]. The b-jet tagging efficiency has been measured from data using $t\bar{t}$ events, where both top quarks decay to leptons, with a total uncertainty of about ±2% for jets with transverse momenta up to 100 GeV [38, 107]. The MC samples used are corrected for differences in these efficiencies between data and simulation and the associated uncertainties are propagated through the analysis.

- Energy scales: the uncertainties on the jet energy scale (JES) arise from several sources. These include, among others, varied response due to the jet flavour composition (quark- versus gluon-initiated jets), pile-up, η intercalibration, and detector

JHEP04(2015)117

response and modelling of in situ jet calibration [35, 36]. The impact of the JES uncertainty in this analysis is reduced because many of the background components are estimated using data. The tau energy scale is obtained by fitting the reconstructed visible mass for $Z \to \tau\tau$ events in data, which can be selected with a satisfactory purity. It is measured with a precision of ±(2–4)% [108]. Since systematic uncertainties on the energy scales of all objects affect the reconstructed missing transverse momentum, it is recalculated after each variation is applied. The scale uncertainty on $E_{\mathrm{T}}^{\mathrm{miss}}$ due to the energy in calorimeter cells not associated with physics objects is also taken into account.

- Energy resolutions: systematic uncertainties on the energy resolution of taus, electrons, muons, jets, and $E_{\mathrm{T}}^{\mathrm{miss}}$ affect the final discriminant. The effects resulting from uncertainties on the tau energy resolution are small. The impact of changes in the amount of material (inactive material in the detector, e.g. support structures), in the hadronic shower model and in the underlying-event tune were studied in the simulation. They result in systematic uncertainties below 1% on the tau energy resolution. The jet energy resolution is determined by in situ measurements, as described in ref. [109], and affects signal modelling and background components modelled by the simulation. The uncertainty of the resolution on $E_{\mathrm{T}}^{\mathrm{miss}}$ is estimated by evaluating the energy resolution of each of the $E_{\mathrm{T}}^{\mathrm{miss}}$ terms. The largest impact results from the soft term (see section 2), arising both from the MC modelling and the effects of pile-up. It is evaluated using simulated $Z(\to \mu\mu)$+jets events.

7.2 Background modelling uncertainties

The most significant systematic uncertainties on the background estimation techniques, as described in section 6, are detailed in the following for the three decay modes considered.

In the $\tau_{\mathrm{lep}}\tau_{\mathrm{lep}}$ channel, systematic uncertainties on the shape and normalisation of fake-lepton background sources are estimated by comparing samples of same-sign lepton events that pass and fail the lepton isolation criteria. These uncertainties amount to ±33% (±20%) at 8 TeV and ±10.5% (±13%) at 7 TeV for the boosted (VBF) category. The extrapolation uncertainty for the $Z \to \ell\ell$ background is obtained by varying the $m_{\ell\ell}$ window that defines the control region for this background, and amounts to about ±6%. The corresponding extrapolation uncertainty for top-quark background sources is ±(3–6)%, obtained from the differences in event yields in the top-quark control regions when using different MC generators. Neither of these extrapolation uncertainties is significant for the final result. The dominant uncertainties on the normalisation of the $t\bar{t}$ background, obtained from the global fit, are the systematic uncertainties on the b-jet tagging efficiency and the jet energy scale.

In the $\tau_{\mathrm{lep}}\tau_{\mathrm{had}}$ channel, an important systematic uncertainty on the background determination comes from the estimated fake background, for which several sources of systematic uncertainty are considered. The statistical uncertainty on the effective fake factor is ±4.3% (±2.3%) in the 8 TeV VBF (boosted) category, and about ±22% (±11%) in the 7 TeV VBF (boosted) category. The dominant systematic uncertainty on the methodology itself arises

JHEP04(2015)117

from the composition of the combined fake background (W+jets, Z+jets, multijet, and $t\bar{t}$ fractions), which is largely estimated based on simulated event samples as explained in section 6.2. The uncertainty is estimated by varying each fractional contribution by ±50%, which affects the effective fake factor by ±3% (±6%) and by ±10% (±15%) in the 8 TeV and 7 TeV boosted (VBF) categories respectively. As a closure test, the method was also applied in a region of data where the lepton and τ_{had} candidate have the same charge, rich in fake τ_{had} candidates. Very good agreement was observed between data and the method's prediction, so that no additional in situ uncertainty was deemed necessary. In addition, the uncertainties on the normalisation of the $t\bar{t}$ background are important. As in the case of the $\tau_{\text{lep}}\tau_{\text{lep}}$ channel, the dominant contribution obtained from the global fit originates from systematic uncertainties on the b-jet tagging efficiency and the jet energy scale, along with statistical uncertainties on the observed data in the respective control regions.

In the $\tau_{\text{had}}\tau_{\text{had}}$ channel, the major background from multijet production is determined using a data-driven template method. The default multijet template, derived from a sample in data where the τ_{had} candidates fail the isolation and opposite-sign charge requirements, is compared with an alternative template derived from a sample where the τ_{had} candidates fail just the opposite-sign charge requirement. The normalisation of the alternative template is fixed to that of the default template at preselection; the alternative multijet template is propagated into the various categories and gives a different set of yields from the default template. This difference, along with the difference in shape between the two templates, constitutes the systematic uncertainty on the background estimate. This leads to an overall multijet yield variation of 10% (3%) in the VBF (boosted) category at $\sqrt{s} = 8\,\text{TeV}$ and of 10% (30%) in the VBF (boosted) category $\sqrt{s} = 7\,\text{TeV}$. However, there is a very strong shape dependence, such that the uncertainties on the BDT output are much larger at higher output values.

For the embedding method used in all channels, the major systematic uncertainties are related to the selection of $Z \to \mu\mu$ events in data and to the subtraction of the muon energy deposits in the calorimeters. The selection uncertainties are estimated by varying the muon isolation criteria in the selection from the nominal value of $I(p_{\text{T}}, 0.2) < 0.2$ (see section 4) to tighter ($I(p_{\text{T}}, 0.4) < 0.06$ and $I(E_{\text{T}}, 0.2) < 0.04$) and looser (no isolation requirements) values. The muon-related cell energies to be subtracted are varied within ±20% (±30%) for the 8 TeV (7 TeV) data. In addition, systematic uncertainties on the corrections for trigger and reconstruction efficiencies are taken into account. Due to the combination of single-lepton and dilepton triggers used, the uncertainties are largest for the $\tau_{\text{lep}}\tau_{\text{lep}}$ channel. All experimental systematic uncertainties relating to the embedded τ decay products (such as tau energy scale or identification uncertainties) are applied normally. The combined effect of all uncertainties on the signal and background yields is included in table 8. Because the $Z \to \tau\tau$ normalisation is determined in the final fit, the impact on the final result is much smaller.

7.3 Theoretical uncertainties

Theoretical uncertainties are estimated for the signal and for all background contributions modelled with the simulation. Since the major background contributions, from $Z \to \tau\tau$

Table 8. Impact of systematic uncertainties on the total signal, S, (sum of all production modes) and on the sum of all background estimates, B, for each of the three channels and the two signal categories for the analysis of the data taken at $\sqrt{s} = 8$ TeV. Each systematic uncertainty is assumed to be correlated across the analysis channels, except those marked with a *. Uncertainties that affect the shape of the BDT-output distribution in a non-negligible way are marked with a †. All values are given before the global fit. The notation UE/PS refers to the underlying event and parton shower modelling.

JHEP04(2015)117

and misidentification of hadronically decaying τ leptons, are estimated using data-driven methods, they are not affected by these uncertainties. Uncertainties on the signal cross sections are assigned from missing higher-order corrections, from uncertainties in the PDFs, and from uncertainties in the modelling of the underlying event.

For VBF and VH Higgs boson production cross sections, the uncertainties due to missing higher-order QCD corrections are estimated by varying the factorisation and renormalisation scales by factors of two around the nominal scale m_W, as prescribed by the LHC Higgs Cross section Working Group [110]. The resulting uncertainties range from $\pm 2\%$ to $\pm 4\%$, depending on the process and the category-specific selection considered. In addition, a 2% uncertainty related to the inclusion of the NLO EWK corrections (see section 3) is assigned.

For Higgs boson production via ggF, the uncertainties on the cross sections due to missing higher order QCD corrections are estimated by varying the renormalisation and factorisation scales around the central values $\mu_{\mathrm{R}} = \mu_{\mathrm{F}} = \sqrt{m_H^2 + p_{\mathrm{T}}^2}$ in the NLO cross section calculations of H + 1-jet and H + 2-jet production. In the calculation of the uncertainties, appropriate cuts on the Higgs p_{T} ($p_{\mathrm{T}}^H > 100$ GeV) and on the jet kinematics ($\Delta\eta, p_{\mathrm{T}}$) are applied at parton level for the boosted and VBF categories respectively. The resulting uncertainties on the ggF contributions are found to be about $\pm 24\%$ in the boosted category and $\pm 23\%$ in the VBF category. The ggF contribution is dominant in the boosted category, whereas it is only about 20% of the signal in the VBF category. Since the two categories are exclusive, their anti-correlation is taken into account following the prescription in ref. [111].

In the present analysis, no explicit veto on jets is applied in the VBF selection, but enough kinematical information is provided as input to the BDT so that the high BDT-output region corresponds to a more exclusive region, where the probability of finding a third jet is reduced. Since the cross section for gluon-fusion events produced with a third jet is only known at LO, this could introduce a large uncertainty on the gluon-fusion contamination in the highest (and most sensitive) BDT-output bins. The uncertainty on the BDT shape of the ggF contribution is evaluated using the MCFM Monte Carlo program [98], which calculates H + 3 jets at LO. Scale variations induce changes of the ggF contribution in the highest BDT bin of about $\pm 30\%$. They are taken into account in the final fit.

Uncertainties related to the simulation of the underlying event and parton shower are estimated by comparing the acceptance from POWHEG+PYTHIA to POWHEG+HERWIG for both VBF and ggF Higgs boson production modes. Differences in the signal yields range from $\pm 1\%$ to $\pm 8\%$ for the VBF and from $\pm 1\%$ to $\pm 9\%$ for ggF production, depending on the channel and category. The BDT-score distribution of the POWHEG+PYTHIA and POWHEG+HERWIG samples are compatible with each other within statistical uncertainties.

The PDF uncertainties are estimated by studying the change in the acceptance when using different PDF sets or varying the CT10 PDF set within its uncertainties. The standard VBF POWHEG sample and a MC@NLO [112] ggF sample, both generated with the CT10 PDFs, are reweighted to the MSTW2008NLO [113], NNPDF [114] and the

JHEP04(2015)117

CT10 eigen-tunes parameterisation. The largest variation in acceptance for each category is used as a constant PDF uncertainty; it varies between approximately ±4.5% and ±6% for ggF production and between about ±0.8% and ±1.0% for VBF production. A shape uncertainty is also included to cover any difference between the BDT score in the default sample and the reweighted ones. The uncertainty on the total cross section for the VBF, VH and ggF production modes due to the PDFs is also considered.

Variations in the acceptance for different Monte Carlo generators are also included, comparing Powheg+Herwig samples to MC@NLO+Herwig samples for ggF, and to aMC@NLO+Herwig [115] samples for VBF. The generator modelling uncertainty is around ±2% for ggF and ±4% for VBF productions modes.

Finally, an uncertainty on the decay branching ratio, BR($H \to \tau\tau$), of ±5.7% [70] affects the signal rates.

The theoretical systematic uncertainties on the background predictions taken from the simulation are evaluated by applying the same procedures as used for the signal samples. Uncertainties resulting from the choice of QCD scales, PDF parameterisation and underlying-event model are estimated. The results are reported in table 8.

8 Signal extraction procedure

The BDT output in the six analysis categories provides the final discrimination between signal and background for both the 7 and 8 TeV datasets. A maximum-likelihood fit is performed on all categories simultaneously to extract the signal strength, μ, defined as the ratio of the measured signal yield to the Standard Model expectation. The value $\mu = 0$ ($\mu = 1$) corresponds to the absence (presence) of a Higgs boson signal with the SM production cross section. The statistical analysis of the data employs a binned likelihood function $\mathcal{L}(\mu, \vec{\theta})$, constructed as the product of Poisson probability terms, to estimate μ.

The impact of systematic uncertainties on the signal and background expectations is described by nuisance parameters, $\vec{\theta}$, which are each parameterised by a Gaussian or log-normal constraint. The expected numbers of signal and background events in each bin are functions of $\vec{\theta}$. The test statistic q_μ is then constructed according to the profile likelihood ratio: $q_\mu = -2\ln[\mathcal{L}(\mu, \hat{\hat{\vec{\theta}}})/\mathcal{L}(\hat{\mu}, \hat{\vec{\theta}})]$, where $\hat{\mu}$ and $\hat{\vec{\theta}}$ are the parameters that maximise the likelihood, and $\hat{\hat{\vec{\theta}}}$ are the nuisance parameter values that maximise the likelihood for a given μ. This test statistic is used to measure the compatibility of the background-only hypothesis with the observed data.

The likelihood is maximised on the BDT distributions in the signal regions, with information from control regions included to constrain background normalisations. The fit includes the event yields from the $Z \to \ell\ell$ and top control regions in the $\tau_{\text{lep}}\tau_{\text{lep}}$ channel, and from the top control region of the $\tau_{\text{lep}}\tau_{\text{had}}$ channel; furthermore the $\Delta\eta(\tau_{\text{had}}, \tau_{\text{had}})$ distribution in the rest control region of the $\tau_{\text{had}}\tau_{\text{had}}$ channel is also included.

The $Z \to \tau\tau$ background is constrained primarily in the signal regions, due to the difference between the BDT distributions for $Z \to \tau\tau$ events and the signal. For the $\tau_{\text{had}}\tau_{\text{had}}$ channel, the $Z \to \tau\tau$ and multijet background rates are constrained by the simultaneous

JHEP04(2015)117

fit of the two signal regions and the $\Delta\eta(\tau_{\text{had}}\tau_{\text{had}})$ distribution in the rest category control region. The top and $Z \to \ell\ell$ background components for the $\tau_{\text{lep}}\tau_{\text{lep}}$ and $\tau_{\text{lep}}\tau_{\text{had}}$ channels are also allowed to float freely, but are primarily constrained by the inclusion of the respective control regions.

As described in section 7, a large number of systematic uncertainties, taken into account via nuisance parameters, affect the final results. It is important to investigate the behaviour of the global fit and in particular to investigate how far the nuisance parameters are pulled away from their nominal values and how well their uncertainties are constrained. Furthermore, it is important to understand which systematic uncertainties have the most impact on the final result. For this purpose a ranking of nuisance parameters is introduced. For each parameter, the fit is performed again with the parameter fixed to its fitted value shifted up or down by its fitted uncertainty, with all the other parameters allowed to vary. The ranking obtained for those nuisance parameters contributing most to the uncertainty on the signal strength is shown in figure 8 for the combined fit of the three channels at the two centre-of-mass energies. The parameters contributing most are those related to the jet energy scale, the normalisation uncertainties for $Z \to \tau\tau$ and top-quark events, and the tau energy scale. The uncertainties on the jet energy scale are decomposed into several uncorrelated components (among others: η intercalibration of different calorimeter regions, jet energy response, and response to jets of different flavour). In addition, theoretical uncertainties on the branching ratio BR ($H \to \tau\tau$) are found to have a significant impact. In general, good agreement is found between the pre-fit and post-fit values for these nuisance parameters and neither large pulls nor large constraints are observed.

The distributions of the BDT discriminants for all channels and categories for the data at 8 TeV are shown in figure 9, with background normalisations, signal normalisation, and nuisance parameters adjusted by the profile likelihood global fit.

The results for the numbers of fitted signal and background events, split into the various contributions, are summarised in tables 9, 10 and 11 for the three channels separately, for the dataset collected at 8 TeV centre-of-mass energy. In addition to the total number of events, the expected number of events in each of the two highest BDT output bins is given. The number of events observed in the data is also included. Within the uncertainties, good agreement is observed between the data and the model predictions for the sum of background components and a Standard Model Higgs boson with $m_H = 125$ GeV.

JHEP04(2015)117

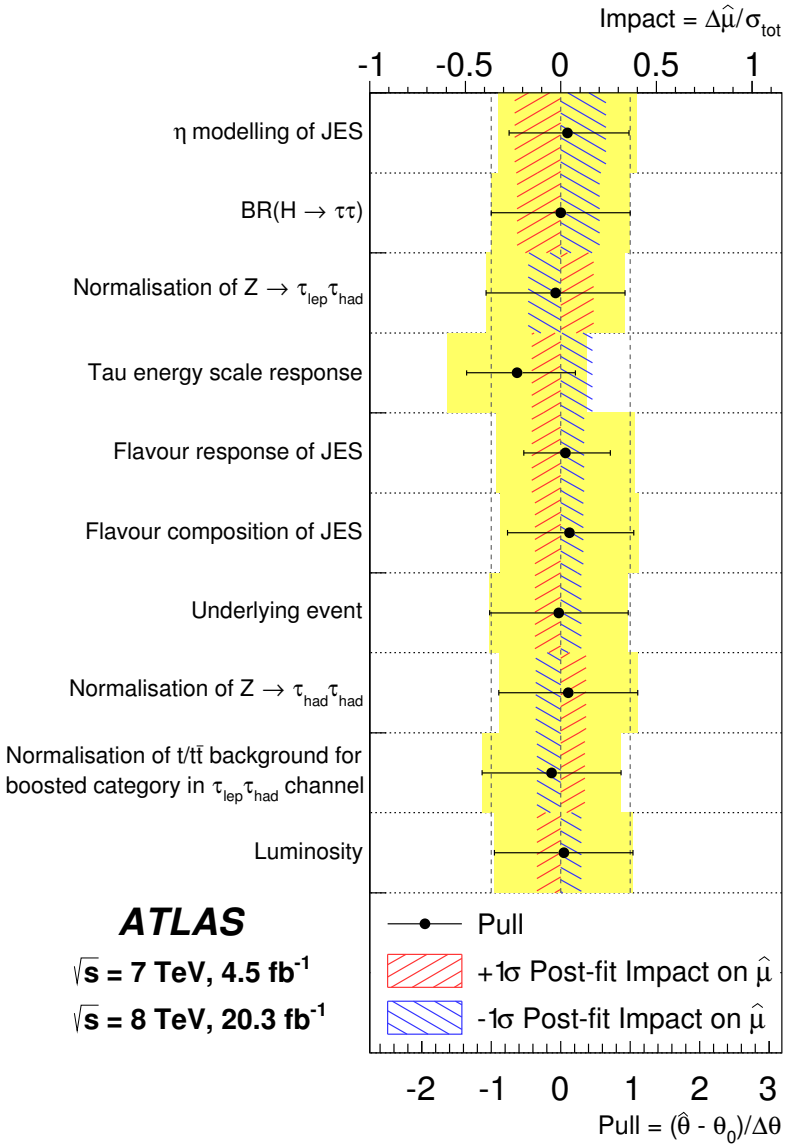

Figure 8. Impact of systematic uncertainties on the fitted signal-strength parameter $\hat{\mu}$ for the combined fit for all channels and both centre-of-mass energies. The systematic uncertainties are listed in decreasing order of their impact on $\hat{\mu}$ on the y-axis. The hatched blue and red boxes show the variations of $\hat{\mu}$ with respect to the total error on μ, σ_{tot}, referring to the top x-axis, when fixing the corresponding individual nuisance parameter θ to its post-fit value $\hat{\theta}$ modified upwards or downwards by its post-fit uncertainty, and repeating the fit. The filled circles, referring to the bottom x-axis, show the pulls of the fitted nuisance parameters, i.e. the deviations of the fitted parameters $\hat{\theta}$ from their nominal values θ_0, normalised to their nominal uncertainties $\Delta\theta$. The black lines show the post-fit uncertainties of the nuisance parameters, relative to their nominal uncertainties, which are indicated by the yellow band. The jet energy scale uncertainties are decomposed into uncorrelated components.

JHEP04(2015)117

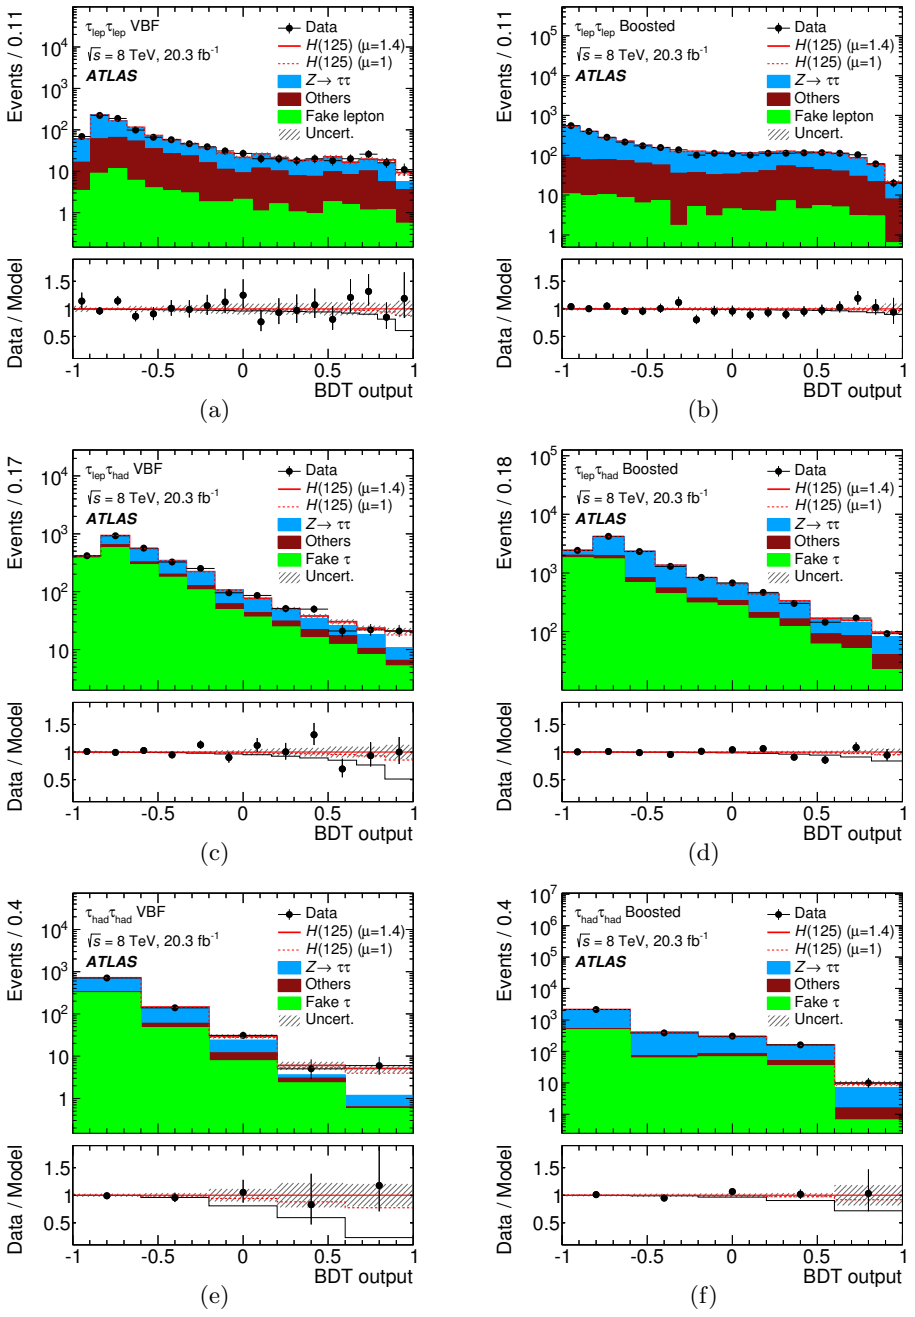

Figure 9. Distributions of the BDT discriminants for the data taken at $\sqrt{s} = 8$ TeV in the signal regions of the VBF (left) and boosted (right) categories for the $\tau_{\text{lep}}\tau_{\text{lep}}$ (top), $\tau_{\text{lep}}\tau_{\text{had}}$ (middle), and $\tau_{\text{had}}\tau_{\text{had}}$ (bottom) channels. The Higgs boson signal ($m_H = 125$ GeV) is shown stacked with a signal strength of $\mu = 1$ (dashed line) and $\mu = 1.4$ (solid line). The background predictions are determined in the global fit (that gives $\mu = 1.4$). The size of the statistical and systematic normalisation uncertainties is indicated by the hashed band. The ratios of the data to the model (background plus Higgs boson contributions with $\mu = 1.4$) are shown in the lower panels. The dashed red and the solid black lines represent the changes in the model when $\mu = 1.0$ or $\mu = 0$ are assumed respectively.

JHEP04(2015)117

9 Results

As explained in the previous section, the observed signal strength is determined from a global maximum likelihood fit to the BDT output distributions in data, with nuisance parameters that are either free or constrained. The results are extracted for each channel and for each category individually as well as for combinations of categories and for the overall combination.

At the value of the Higgs boson mass obtained from the combination of the ATLAS $H \to \gamma\gamma$ and $H \to ZZ^*$ measurements [116], $m_H = 125.36$ GeV, the signal strength obtained from the combined $H \to \tau\tau$ analysis is:

$$\mu = 1.43\ ^{+0.27}_{-0.26}(\text{stat.})\ ^{+0.32}_{-0.25}(\text{syst.})\ \pm 0.09(\text{theory syst.}).$$

The systematic uncertainties are split into two groups: systematic uncertainties (syst.) including all experimental effects as well as theoretical uncertainties on the signal region acceptance, such as those due to the QCD scales, the PDF choice, and the underlying event and parton shower; and, separately, theoretical uncertainties on the inclusive Higgs boson production cross section and $H \to \tau\tau$ branching ratio (theory syst.). The results for each individual channel and for each category as well as for their combination are shown in figure 10. They are based on the full dataset, however, separate combined results are given for the two centre-of-mass energies.

The probability p_0 of obtaining a result at least as signal-like as observed in the data if no signal were present is calculated using the test statistic $q_{\mu=0} = -2\ln(\mathcal{L}(0,\hat{\hat{\vec{\theta}}})/\mathcal{L}(\hat{\mu},\hat{\vec{\theta}}))$ in the asymptotic approximation [117]. For $m_H = 125.36$ GeV, the observed p_0 value is 2.7×10^{-6}, which corresponds to a deviation from the background-only hypothesis of 4.5σ. This can be compared to an expected significance of 3.4σ. This provides evidence at the level of 4.5σ for the decay of the Higgs boson into tau leptons. Table 12 shows the expected and observed significances for the signal strength measured in each channel separately.

Figure 11 shows the expected and observed number of events, in bins of $\log_{10}(S/B)$, for all signal region bins. Here, S/B is the signal-to-background ratio calculated assuming $\mu = 1.4$ for each BDT bin in the signal regions. The expected signal yield for both $\mu = 1$ and the best-fit value $\mu = 1.4$ for $m_H = 125$ GeV is shown on top of the background prediction from the best-fit values. The background expectation where the signal-strength parameter is fixed to $\mu = 0$ is also shown for comparison.

To visualise the compatibility of this excess of events above background predictions with the SM Higgs boson at $m_H = 125$ GeV, a weighted distribution of events as a function of $m_{\tau\tau}^{\text{MMC}}$ is shown in figure 12. The events are weighted by a factor of $\ln(1 + S/B)$, which enhances the events compatible with the signal hypothesis. The excess of events in this mass distribution is consistent with the expectation for a Standard Model Higgs boson with $m_H = 125$ GeV. The distributions for the predicted excess in data over the background are also shown for alternative SM Higgs boson mass hypotheses of $m_H = 110$ GeV and $m_H = 150$ GeV. The data favour a Higgs boson mass of $m_H = 125$ GeV and are less consistent with the other masses considered.

Table 13. Important sources of uncertainty on the measured signal-strength parameter μ. The contributions are given as absolute uncertainties on the best-fit value of $\mu = 1.43$. Various sub-components are combined assuming no correlations.

As discussed in section 8, the dominant uncertainties on the measurement of the signal-strength parameters include statistical uncertainties on the data from the signal regions, uncertainties on the jet and tau energy scales, uncertainties on the normalisation of the $Z \to \tau\tau$ and $t\bar{t}$ background components as well as theoretical uncertainties. The contributions of each of these significant sources to the uncertainty of the measured signal strength are summarised in table 13.

JHEP04(2015)117

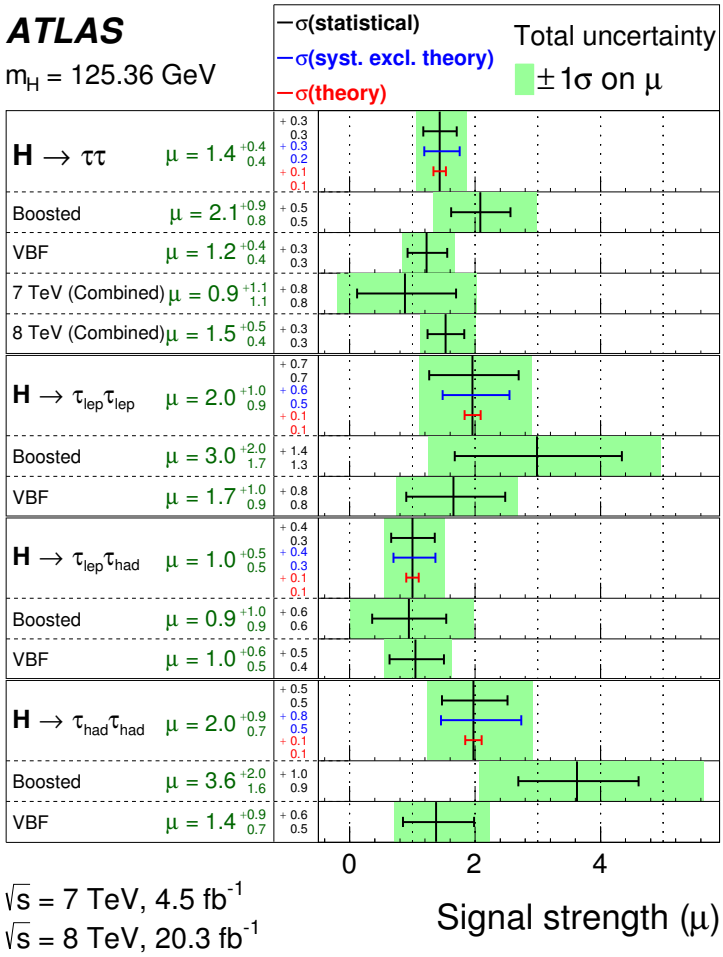

Figure 10. The best-fit value for the signal strength μ in the individual channels and their combination for the full ATLAS datasets at $\sqrt{s} = 7$ TeV and $\sqrt{s} = 8$ TeV. The total $\pm 1\sigma$ uncertainty is indicated by the shaded green band, with the individual contributions from the statistical uncertainty (top, black), the experimental systematic uncertainty (middle, blue), and the theory uncertainty (bottom, red) on the signal cross section (from QCD scale, PDF, and branching ratios) shown by the error bars and printed in the central column.

The normalisation uncertainties on the $Z \to \tau\tau$ embedded sample are correlated across the categories in each respective channel. The global fit also constrains the normalisation for $Z \to \tau\tau$ more strongly than for the $Z \to \ell\ell$ and top-quark background components, as the low BDT-score region is dominated by $Z \to \tau\tau$ events.

The measurement of the overall signal strength discussed above does not give direct information on the relative contributions of the different production mechanisms. Therefore, the signal strengths of different production processes contributing to the $H \to \tau\tau$ decay mode are determined, exploiting the sensitivity offered by the use of the event categories in the analyses of the three channels. The data are fitted separating the vector-boson-mediated VBF and VH processes from gluon-mediated ggF processes. Two signal strength parameters, $\mu^{\tau\tau}_{ggF}$ and $\mu^{\tau\tau}_{\mathrm{VBF}+VH}$, which scale the SM-predicted rates to those ob-

JHEP04(2015)117

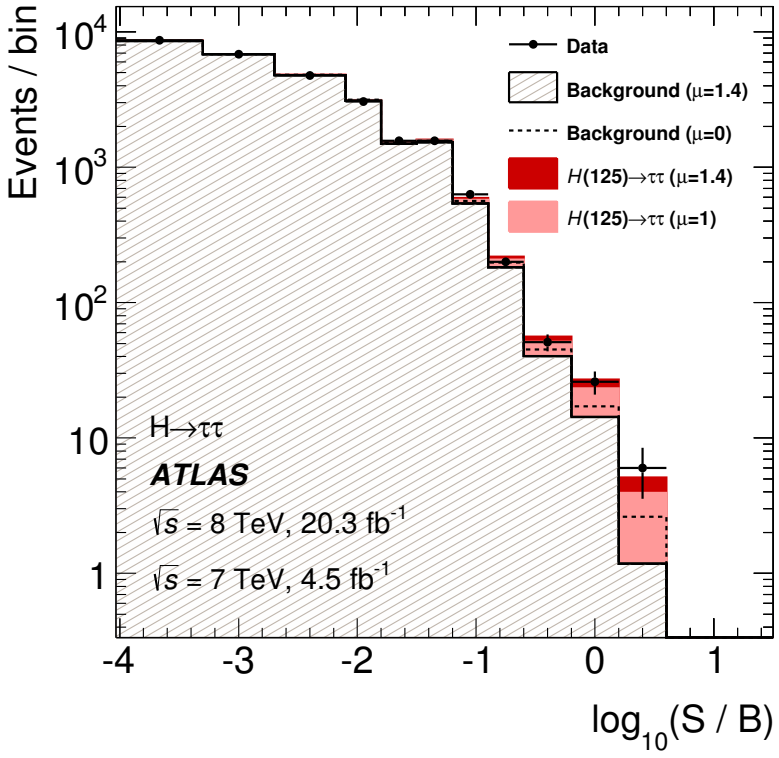

Figure 11. Event yields as a function of $\log_{10}(S/B)$, where S (signal yield) and B (background yield) are taken from the BDT output bin of each event, assuming a signal strength $\mu = 1.4$. Events in all categories are included. The predicted background is obtained from the global fit (with $\mu = 1.4$), and signal yields are shown for $m_H = 125$ GeV at $\mu = 1$ and $\mu = 1.4$ (the best-fit value). The background-only distribution (dashed line) is obtained from the global fit, with μ fixed at zero.

served, are introduced. The two-dimensional 68% and 95% confidence level (CL) contours in the plane of $\mu^{\tau\tau}_{ggF}$ and $\mu^{\tau\tau}_{\mathrm{VBF}+VH}$ [84] are shown in figure 13 for $m_H = 125.36$ GeV. The best-fit values are

$$\mu^{\tau\tau}_{ggF} = 2.0 \ \pm 0.8(\mathrm{stat.}) \ ^{+1.2}_{-0.8}(\mathrm{syst.}) \ \pm 0.3(\mathrm{theory\ syst.})$$

and

$$\mu^{\tau\tau}_{\mathrm{VBF}+VH} = 1.24 \ ^{+0.49}_{-0.45}(\mathrm{stat.}) \ ^{+0.31}_{-0.29}(\mathrm{syst.}) \ \pm 0.08(\mathrm{theory\ syst.}),$$

in agreement with the predictions from the Standard Model. The two results are strongly anti-correlated (correlation coefficient of -48%). The observed (expected) significances of the $\mu^{\tau\tau}_{ggF}$ and $\mu^{\tau\tau}_{\mathrm{VBF}+VH}$ signal strengths are 1.74σ (0.95σ) and 2.25σ (1.72σ) respectively.

A total cross section times branching ratio for $H \to \tau\tau$ with $m_H = 125$ GeV can also be measured. The central value is obtained from the product of the measured μ and the predicted cross section used to define it. The uncertainties are similarly obtained by scaling the uncertainties on μ by the predicted cross section, noting that theoretical uncertainties on the inclusive cross section cancel between μ and the predicted cross section and thus are not included for the production processes under consideration. These include the

JHEP04(2015)117

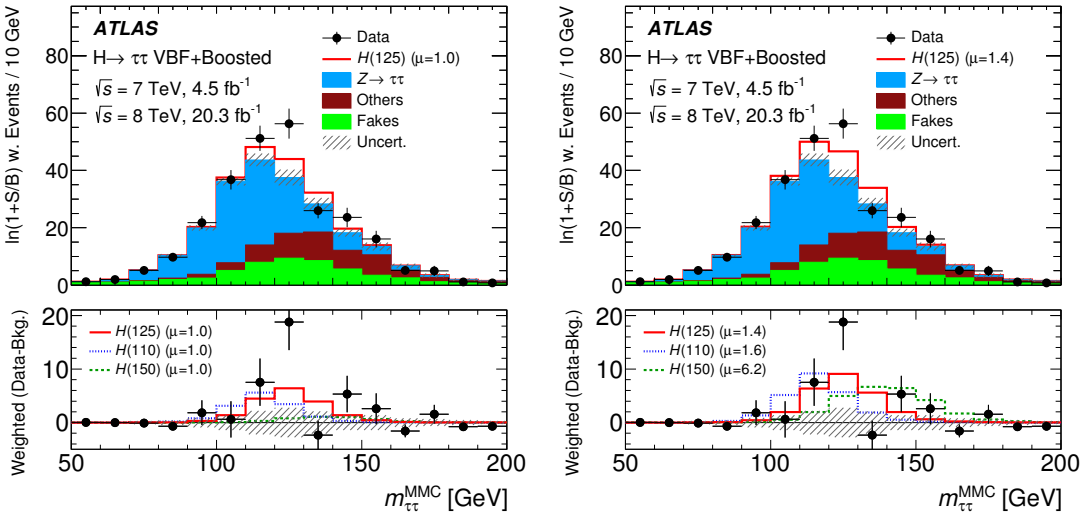

Figure 12. Distributions of the reconstructed invariant $\tau\tau$ mass, $m_{\tau\tau}^{\mathrm{MMC}}$, where events are weighted by $\ln(1 + S/B)$ for all channels. These weights are determined by the signal (S) and background (B) predictions for each BDT bin. The bottom panel in each plot shows the difference between weighted data events and weighted background events (black points), compared to the weighted signal yields. The background predictions are obtained from the global fit with the $m_H = 125$ GeV signal hypothesis (signal strength $\mu = 1.4$). The $m_H = 125$ GeV signal is plotted with a solid red line, and, for comparison, signals for $m_H = 110$ GeV (blue) and $m_H = 150$ GeV (green) are also shown. The signal normalisations are taken from fits to data with the corresponding signal mass hypotheses, and the fitted μ values are given in the figure. The signal strengths are shown for the Standard Model expectations ($\mu = 1$) in (a), while in (b) the best-fit values are used.

uncertainties on the inclusive cross section due to the QCD scale and the PDF choice as well as the uncertainty on the branching ratio $H \to \tau\tau$; however, theoretical uncertainties on the acceptance of the signal regions from the QCD scale and PDF choice are retained, along with the uncertainties due to underlying event and parton shower, and the electroweak correction on VBF production. Table 14 gives the measured values for the total cross section at 7 and at 8 TeV, as well as the measured values at 8 TeV for gluon fusion production and for VBF and VH production separately.

10 Cross-check with cut-based analysis

The search for the SM Higgs boson presented above is cross-checked for the dataset collected at $\sqrt{s} = 8$ TeV in an analysis where cuts on kinematic variables are applied. This search uses improved definitions of event categories and an improved fit model with respect to results previously published for the $\sqrt{s} = 7$ TeV dataset [21]. To allow a straightforward comparison of results, the multivariate and cut-based analyses have common components. The two analyses are performed for the same three channels, $\tau_{\mathrm{lep}}\tau_{\mathrm{lep}}$, $\tau_{\mathrm{lep}}\tau_{\mathrm{had}}$ and $\tau_{\mathrm{had}}\tau_{\mathrm{had}}$, they use the same preselection and share the same strategy for the estimation of background contributions and systematic uncertainties. As in the multivariate analysis, the irreducible

JHEP04(2015)117

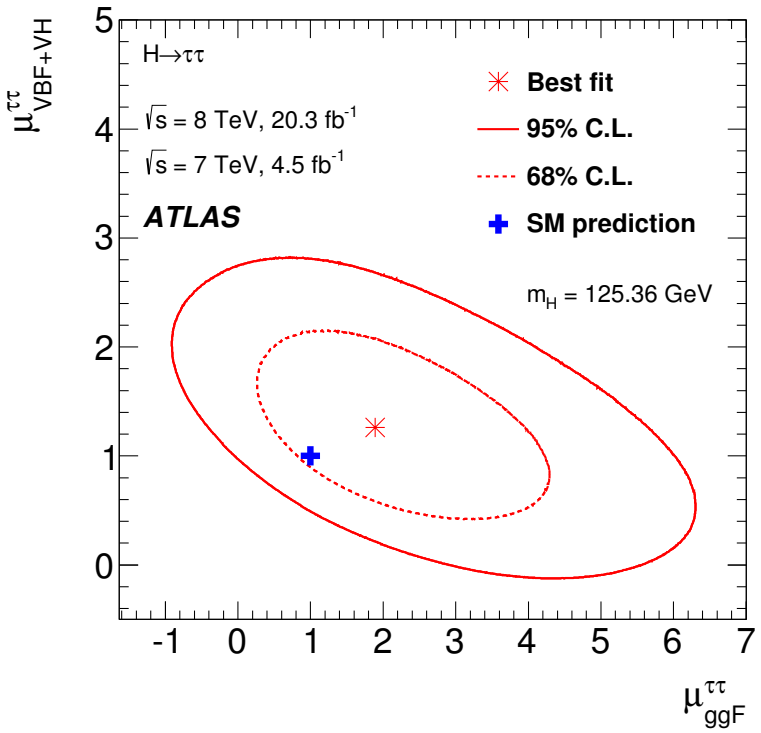

Figure 13. Likelihood contours for the combination of all channels in the ($\mu^{\tau\tau}_{ggF}$, $\mu^{\tau\tau}_{\mathrm{VBF}+VH}$) plane. The signal strength μ is the ratio of the measured signal yield to the Standard Model expectation, for each production mode. The 68% and 95% CL contours are shown as dashed and solid lines respectively, for $m_H = 125.36$ GeV. The SM expectation is shown by a filled plus symbol, and the best fit to the data is shown as a star.

	Measured $\sigma\times$BR [pb]	Predicted $\sigma\times$BR [pb]
7 TeV	$1.0\ ^{+0.9}_{-0.8}(\mathrm{stat.})^{+0.9}_{-0.8}(\mathrm{syst.})$	1.09 ± 0.11
8 TeV	$2.1 \pm 0.4(\mathrm{stat.})^{+0.5}_{-0.4}(\mathrm{syst.})$	1.39 ± 0.14
Gluon fusion, 8 TeV	$1.7 \pm 1.1(\mathrm{stat.})^{+1.5}_{-1.1}(\mathrm{syst.})$	1.22 ± 0.14
VBF+VH, 8 TeV	$0.26 \pm 0.09(\mathrm{stat.})^{+0.06}_{-0.05}(\mathrm{syst.})$	0.17 ± 0.01

Table 14. Measured and predicted total cross section times branching ratio for $H \to \tau\tau$ with $m_H = 125$ GeV, at 7 TeV and at 8 TeV for all production modes, as well as for gluon fusion and for VBF and VH production separately, at 8 TeV only. The theoretical predictions are obtained as described in section 3.

JHEP04(2015)117

$Z \to \tau\tau$ background is estimated using the embedding procedure and the reducible ones are estimated using similar data-driven methods, as described in section 6. Finally, the same statistical methods are used to extract the results, although these are applied to different discriminating variables. While the multivariate analysis performs a fit to the BDT output distribution, the cut-based analysis relies on a fit to the $\tau\tau$ invariant mass distribution. The $\tau\tau$ invariant mass is calculated using the missing mass calculator, as described in section 4.3. The analysis is not designed to be sensitive to a specific value of the Higgs boson mass m_H. The use of the mass as the discriminating variable is motivated not only by its power to separate the irreducible $Z \to \tau\tau$ background from signal, but also by its sensitivity to the mass of the signal itself.

In the cut-based analysis, a categorisation is performed similar to that in the multivariate analysis, i.e. VBF and boosted categories are defined. To increase the separation power, subcategories are introduced for the $\tau_{\text{lep}}\tau_{\text{had}}$ and $\tau_{\text{had}}\tau_{\text{had}}$ channels. These subcategories target events produced via the same production mode, but select different phase-space regions with different signal-to-background ratios. With this strategy the most sensitive subcategories have a small number of events, but a high signal-to-background ratio. Although the combined sensitivity is dominated by the few highly sensitive subcategories, the others are important not just to increase the sensitivity but also to constrain the various background components.

An overview of the defined categories in the three channels is given in table 15. In all channels, the event categorisation is designed by splitting events first according to the production mode, either VBF-like or boosted ggF-like, and second, for the $\tau_{\text{lep}}\tau_{\text{had}}$ and $\tau_{\text{had}}\tau_{\text{had}}$ channels, by signal-to-background ratio. The events accepted in the VBF categories pass a common selection that requires the presence of the two forward jets distinctive of VBF production. In the $\tau_{\text{lep}}\tau_{\text{had}}$ channel, tight and loose *VBF* subcategories are defined, via cuts on the mass of the dijet system, m_{jj}, and p_{T}^{H}, the transverse momentum of the Higgs boson candidate. In the $\tau_{\text{had}}\tau_{\text{had}}$ channel, the variables used to select the most sensitive categories for both production modes are p_{T}^{H} and the separation $\Delta R(\tau_1, \tau_2)$ between the two τ_{had} candidates. In the VBF-like events, correlations between the invariant mass of the selected jets m_{jj} and $\Delta\eta_{jj}$ of the jets characteristic of VBF production are also used. The subcategory with the highest purity is the *VBF high-*p_{T}^{H} subcategory, where tight cuts on p_{T}^{H} and $\Delta R(\tau_1, \tau_2)$ reject almost all non-resonant background sources. The other two VBF-like subcategories are distinguished by a different signal-to-background ratio due to a tighter selection applied to the forward jets. For the $\tau_{\text{had}}\tau_{\text{had}}$ channel, boosted subcategories are also defined. The division is based on the same cuts on p_{T}^{H} and $\Delta R(\tau_1, \tau_2)$ as used in the VBF high-p_{T}^{H} category. Events with low transverse momentum are not used in any category because in such events the signal cannot be effectively distinguished from background channels. The proportion of the signal yield produced via VBF in the VBF-like subcategories is found to be 80% in the $\tau_{\text{lep}}\tau_{\text{lep}}$ channel, between 67% and 85% in the $\tau_{\text{lep}}\tau_{\text{had}}$ channel and between 58% and 78% in the $\tau_{\text{had}}\tau_{\text{had}}$ channel.

The final results are derived from the combined fit of the $m_{\tau\tau}$ distributions observed in the various subcategories. The number of fitted signal and background events in each channel and category is given in table 16. The combined mass distribution for the three

Table 16. The measured signal and background yields of the cut-based analysis at $\sqrt{s} = 8$ TeV in the $\tau_{\text{lep}}\tau_{\text{lep}}$, $\tau_{\text{lep}}\tau_{\text{had}}$ and $\tau_{\text{had}}\tau_{\text{had}}$ channels for $m_H = 125$ GeV. The normalisations and uncertainties are taken from the global fit. The uncertainties on the predicted yields reflect the full statistical and systematic uncertainties.

channels is shown in figure 14, where events are weighted by $\ln(1 + S/B)$, based on the signal and background content of their channel and category. An excess of events above the expected SM background is visible in the mass region around 125 GeV.

The signal strengths extracted in the three analysis channels and their combination are given in table 17. This cut-based analysis also provides evidence for $H \to \tau\tau$ decays, giving a combined signal strength of

$$\mu_{\text{Cut-based}} = 1.43\ ^{+0.36}_{-0.35}(\text{stat.})\ ^{+0.41}_{-0.33}(\text{syst.})\ \pm 0.10(\text{theory syst.})$$

for $m_H = 125.36$ GeV. For comparison, the results obtained in the multivariate analysis for the dataset at $\sqrt{s} = 8$ TeV are also included in table 17. Good agreement between the results of the two analyses is found for the individual channels as well as for their combination. To further quantify the level of agreement, the correlation ρ and the uncertainties on the differences between the μ values obtained, i.e. $\Delta\mu \pm \delta(\Delta\mu)$, were evaluated using the so-called jackknife technique [118, 119]. Using this method, the correlation between the μ values obtained in the two analyses is found to be between 0.55 and 0.75 for each of the three analysis channels. The results of the analyses are found to be fully compatible, with deviations $\Delta\mu/\delta(\Delta\mu)$ below 1 for all analysis channels as well as for the combined result.

The probability p_0 of obtaining a result at least as signal-like as observed if no signal were present is shown as a function of the mass in figure 15 for the cut-based analysis for the combined dataset at $\sqrt{s} = 8$ TeV. The observed p_0 values show a shallow minimum around 125 GeV, corresponding to a significance of 3.2σ. The expected significance for the cut-based analysis is superimposed on the figure and reaches a significance of 2.5σ at $m_H = 125.36$ GeV. The corresponding significance values for the multivariate analysis for

JHEP04(2015)117

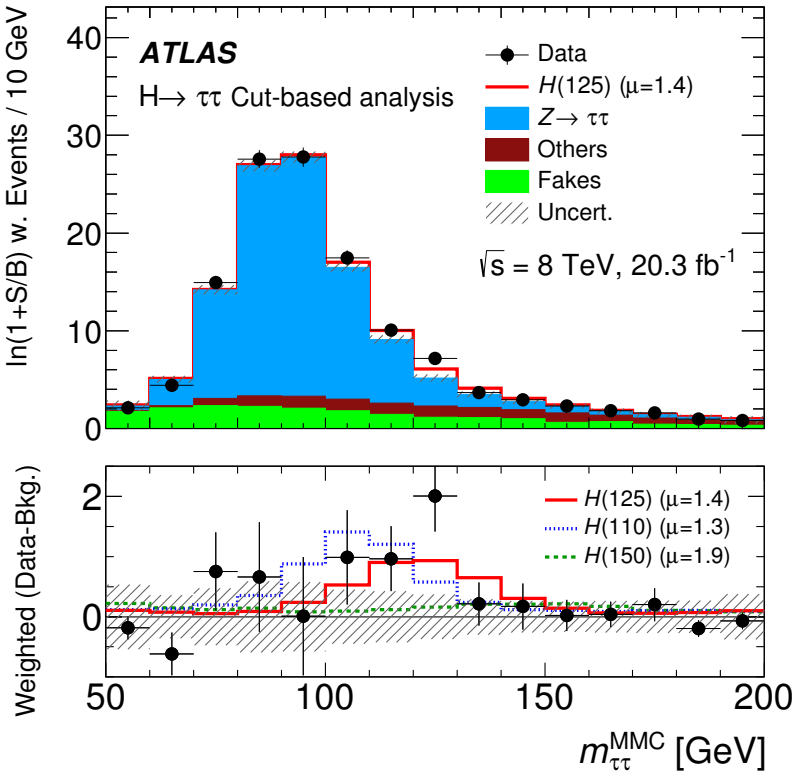

Figure 14. Distribution of the reconstructed invariant $\tau\tau$ mass, $m_{\tau\tau}^{\mathrm{MMC}}$, for the sum of all channels in the cut-based analysis for the data taken at $\sqrt{s} = 8$ TeV. The events are weighted by a factor of $\ln(1 + S/B)$ based on the signal (S) and background (B) yields in each category. The bottom panel shows the difference between weighted data events and weighted background events (black points), compared to the weighted signal yields. The background predictions are obtained from the global fit with the $m_H = 125$ GeV signal hypothesis (signal strength $\mu = 1.4$). The $m_H = 125$ GeV signal is plotted as a solid red line, and, for comparison, signals for $m_H = 110$ GeV (blue) and $m_H = 150$ GeV (green) are also shown. The signal normalisations are taken from fits to data with the corresponding signal mass hypotheses and the fitted μ values are given in the figure.

	Fitted μ values

$\tau_{\mathrm{lep}}\tau_{\mathrm{lep}}$	8 TeV	$1.9^{+1.0}_{-0.9}$	$3.2^{+1.4}_{-1.3}$
$\tau_{\mathrm{lep}}\tau_{\mathrm{had}}$	8 TeV	$1.1^{+0.6}_{-0.5}$	$0.7^{+0.7}_{-0.6}$
$\tau_{\mathrm{had}}\tau_{\mathrm{had}}$	8 TeV	$1.8^{+0.9}_{-0.7}$	$1.6^{+0.9}_{-0.7}$
All channels	8 TeV	$1.53^{+0.47}_{-0.41}$	$1.43^{+0.55}_{-0.49}$

Table 17. Fitted values of the signal strength for the different channels at $\sqrt{s} = 8$ TeV for the multivariate and cut-based analyses, measured at m_H=125.36 GeV. The results for the combinations of all channels are also given. The total uncertainties (statistical and systematic) are quoted.

JHEP04(2015)117

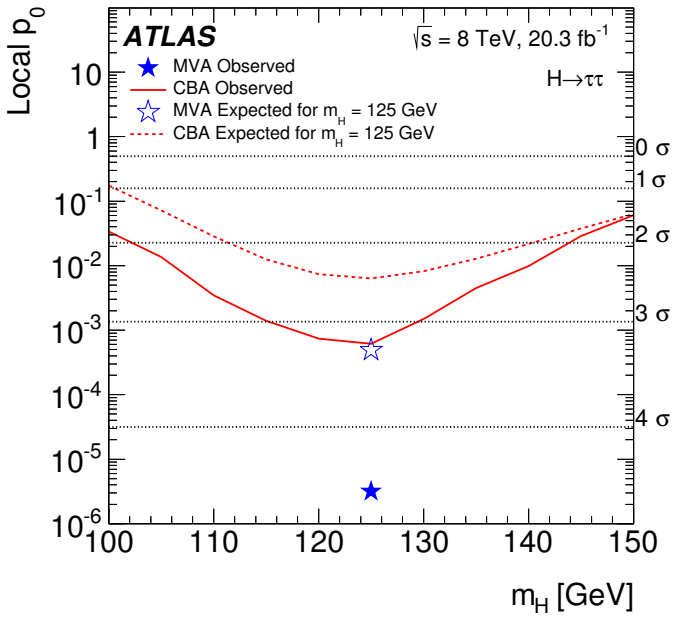

Figure 15. Observed (solid red) and expected (dashed red) p_0 values as a function of m_H for the combination of all channels in the cut-based analysis (CBA) for the data taken at $\sqrt{s} = 8$ TeV. The expected p_0 values are given for the background-only hypothesis. The corresponding observed and expected p_0 values for the multivariate analysis (MVA) are indicated for $m_H = 125$ GeV by a full and open star respectively. The axis labels on the right hand side and the dotted lines display the significance in units of Gaussian standard deviations.

the dataset at $\sqrt{s} = 8$ TeV are found to be 4.5σ (observed) and 3.3σ (expected). They are also indicated in the figure.

Given the mass sensitivity of the cut-based analysis, a two-dimensional likelihood fit for the signal strength μ and the mass m_H is performed. The mass points are tested in steps of 5 GeV in the range between 100 GeV and 150 GeV. The best fit value is found at $\mu = 1.4$ and $m_H = 125$ GeV. The result is shown in the (m_H, μ) plane in figure 16 together with the 68% and 95% CL contours. This result indicates that the observation is compatible with the decay of a Standard Model Higgs boson with a mass of 125 GeV.

11 Conclusions

Evidence for decays of the recently discovered Higgs boson into pairs of tau leptons is presented. The analysis is based on the full set of proton-proton collision data recorded by the ATLAS experiment at the LHC during Run 1. The data correspond to integrated luminosities of 4.5 fb^{-1} and 20.3 fb^{-1} at centre-of-mass energies of $\sqrt{s} = 7$ TeV and $\sqrt{s} = 8$ TeV respectively. All combinations of leptonic and hadronic tau decay channels are included and event categories selecting both the vector boson fusion and highly boosted $\tau\tau$ signatures are considered in a multivariate analysis. An excess of events over the expected background from other Standard Model processes is found with an observed (expected) significance of 4.5 (3.4) standard deviations. This excess is consistent with resulting from

JHEP04(2015)117

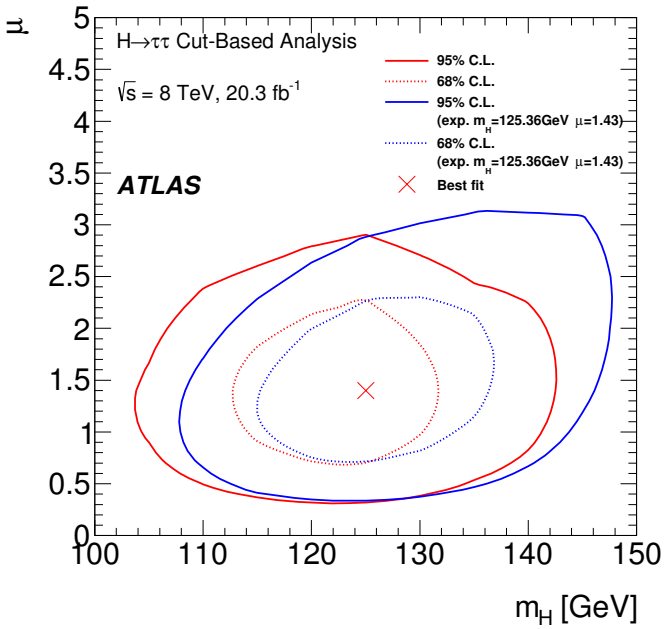

Figure 16. The results of the two-dimensional likelihood fit in the (m_H, μ) plane for the cut-based analysis for the data taken at $\sqrt{s} = 8$ TeV. The signal strength μ is the ratio of the measured signal yield to the Standard Model expectation. The 68% and 95% CL contours are shown as dashed and solid red lines respectively. The best-fit value is indicated as a red cross. The dashed and solid blue lines correspond to the expected 68% and 95% CL contours for $m_H = 125.36$ GeV and $\mu = 1.43$.

$H \to \tau\tau$ decays with $m_H = 125.36$ GeV. The measured signal strength, normalised to the Standard Model expectation, is

$$\mu = 1.43\ ^{+0.27}_{-0.26}(\text{stat.})\ ^{+0.32}_{-0.25}(\text{syst.})\ \pm 0.09(\text{theory syst.}).$$

This value is consistent with the predicted Yukawa coupling strength of the Higgs boson in the Standard Model.

The results of the multivariate analysis are cross-checked for the data collected at $\sqrt{s} = 8$ TeV using a cut-based analysis. The results confirm the findings of the multivariate analysis, and an excess with a compatible signal strength is found. A two-dimensional fit of the signal strength μ and m_H in the cut-based analysis indicates that the observed excess is compatible with the $\tau\tau$ decay of the Higgs boson with a mass of 125 GeV.

計画研究 A02 班

課題名「超対称性の発見と大統一理論の実験的検証」

研究組織

(1)研究代表者
浅井　祥仁（ASAI, Shoji）
東京大学・理学系研究科・教授
研究者番号：60282505

(2)研究分担者
中本　建志（NAKAMOTO, Tatsushi）
高エネルギー加速器研究機構・超伝導低温工学センター・教授
研究者番号：20290851

田中　純一（TANAKA, Junichi）
東京大学・素粒子物理国際研究センター・准教授
研究者番号：80376699

陣内　修（JINNOUCHI, Osamu）
東京工業大学・理学院・准教授
研究者番号：50360566

(3)連携研究者
山本　明（YAMAMOTO, Akira）
高エネルギー加速器研究機構・加速器研究施設 加速器第六研究系・研究員
研究者番号：30113418

佐々木　憲一（SASAKI, Kenichi）
高エネルギー加速器研究機構・超伝導低温工学センター・准教授
研究者番号：70322831

菊池　章弘（KIKUCHI, Akihiro）
物質・材料研究機構・超電導線材ユニット・主席研究員
研究者番号：5034877

横山　広美（YOKOYAMA, Hiromi）
東京大学・理学系研究科・准教授
研究者番号：50401708

交付決定額

計画研究 A02 班に配分された交付額を表 1 に示す。

表 1. 交付決定額（配分額）　（金額単位：円）

年度	直接経費	間接経費	合計
平成 23 年度	43,600,000	13,080,000	56,680,000
平成 24 年度	48,600,000	14,580,000	63,180,000
平成 25 年度	49,900,000	14,970,000	64,870,000
平成 26 年度	47,200,000	14,160,000	61,360,000
平成 27 年度	47,100,000	14,130,000	61,230,000
総計	236,400,000	70,920,000	307,320,000

研究成果

1．研究開始当初の背景

素粒子標準理論はこれまで電弱エネルギースケールにおいて高精度に検証されてきた。しかし、標準理論は暗黒物質を含まないなど観測との矛盾や、階層性問題など幾つかの理論的な課題を抱えており、より本質的な基礎理論が存在すると考えられている。その中で最も有望視されているのが、超対称性理論である。TeV 領域における新しい素粒子現象、特に新粒子群の発見が、LEP などの精密測定、3 つの力の大統一、暗黒物質、階層性問題の解決などから予言されている。超対

称性粒子探索は CERN の LHC 加速器と国際共同実験 ATLAS 検出器を用いて行う。本計画研究開始の前年にはパイロット実験が行われ、研究代表者を中心とした解析チームにより、超対称性粒子の低質量領域を棄却することに成功した。本計画研究は、開始前年度の経験・実績を踏まえ、データ量が大幅に増加する平成 23 年から本格的な探索を開始した。

また本研究で得られる研究成果は次世代実験計画に大きなインパクトを持つ。それらの計画で期待される物理と加速器スペックの策定を行い、次世代の加速器開発を進めることが重要である。これにより、本計画研究で得られた物理成果を発展させることができる。

２．研究の目的

4 つの目的がある。

（1）LHC アトラス実験で、超対称性など、標準理論を超える新しい素粒子現象を直接的に発見することである。探索対象が未知なため、探索は特定の現象論モデルに依存しないよう、観測事象のイベント・トポロジーを基本とした直接探索を系統的に行う。これにより確実な発見を目指す。

（2）背景事象量の評価を、実験データを用いて行う。この研究は(1)の発見に不可欠であると同時に、他の実験系の研究班にとっても、共通に重要な要素となる。

（3）次世代加速器に向けた新しい超伝導素材の開発を行う。また耐放射線性能、高磁場実現を両立させることのできる、次世代超伝導磁石を開発する。プロトタイプ磁石を制作し、性能評価をする。

（4）理論系の計画研究班と共同で得られた成果を元に、新しい素粒子像を創生する。B01 班とは、本研究の新物理と宇宙の暗黒物質との関係、宇宙進化に与えた影響を探る B02, B03 班との共同研究により、超対称性が導く新たな時空像、数学構造を発展させる。

３．研究の方法

平成 23 年、平成 24 年はそれぞれ衝突エネルギー7TeV,8TeV での運転が行われた。それぞれ約 5 fb^{-1}, 20 fb^{-1} の積分ルミノシティに相当する高品質データを収集した。

（1）検出器の理解を進める。特にハドロン・ジェットのエネルギー較正、検出器ノイズや宇宙線事象の除去、消失運動量の算出手法や較正について、精度の向上を目指す。背景事象量を実験データから直接見積り、その不定性を評価する。

（2）超対称性や余剰次元などの信号を、ジェット数、レプトン数、b-jet 数、消失エネルギーの大小などにより、事象トポロジー毎に分類し、系統的な探索を置こなう。

（3）超伝導加速器用の新しい Nb_3Al 超伝導線の開発を行う。超伝導材を機械的に固定する樹脂を選定する。放射線耐性が期待できるシアネートエステル樹脂の性能評価を行う。

更に最終年度の平成 27 年には、衝突エネルギーが倍増され 13TeV での運転を行った。
（4）エネルギー増強により、新物理への感度が上がった。直接探索を組織的に展開し、超対称性粒子や新しい素粒子現象の兆候を確認する。
（5）LHC 高輝度アップグレードを念頭に、強磁場双極超伝導磁石の設計と試作を行い、冷却励磁試験などを通して性能評価を行う。

4．研究成果

LHC 加速器の陽子・陽子衝突を用いて行った。平成 24 年までの 7、8TeV 衝突エネルギー用いた第一実験期(Run1)と、平成 27,28 年の 13TeV を用いた第二実験期(Run2)の結果を合わせて報告する。但し本計画研究では、平成 27 年の段階で、幾つかの探索チャンネルに 3 σ 程度の超過が見られており、物理信号であるかどうか見極めるために、補助事業の期間を延長することとした。従ってここでは平成 28 年前半の結果も含む。

（1）超対称性粒子探索に対する厳しい制限：
観測事象のイベント・トポロジーに探索チャンネルを分類し、組織的な探索を展開した。また背景事象の見積りをシミュレーションによるものに加えて、実験データを用いたものも導入し、評価の不定性を著しく抑えることに成功した。

これらの手法の開発・調整は平成 24 年までに大きな進展が見られた。同様の手法を平成 27 年にも用いて探索を進めた。

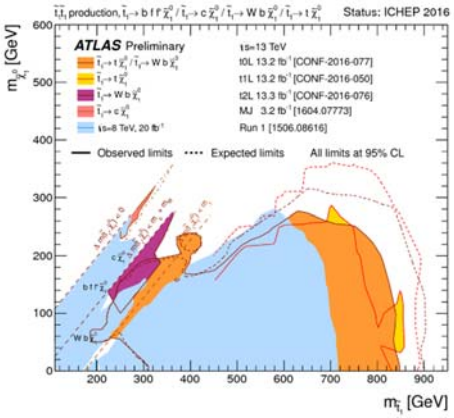

図 1.

(a) Run1 で発見されたヒッグス粒子の質量 125GeV を実現するために、第 3 世代超対称クォーク（スカラートップ等）が 1TeV 以下程度に軽い、というのが自然に期待される。広域な質量領域に渡り、軽いスカラートップの存在を棄却する結果となった。0.85 TeV の制限を設けた(図 1)。

(b) 強い相互作用により生成されるグルイーノ・スクォークを多数ジェット＋消失エネルギー解析により、高統計データを用いて行われた。グルイーノ質量＝スクォーク質量の仮定で 1.85TeV の厳しい制限を設けた(図 2)。

(c) 電弱相互作用によるゲージーノ生成も統計の増加に伴い重要なチャンネルとなった。複数のレプトンを要求する解析では、様々な崩壊過程を考慮して広範囲に渡る質量領域を棄却した。

（2）超対称性粒子以外の新粒子・現象も含む事象に対する厳しい制限

(a) 飛跡検出器の理解が進み、検出器内で崩壊するような長寿命の新粒子探索が可能になった。飛跡が検出器内で消失する事象や、崩壊バーテックスが検出器中央からずれるような特異な事象の探索を進めた(図 3)。

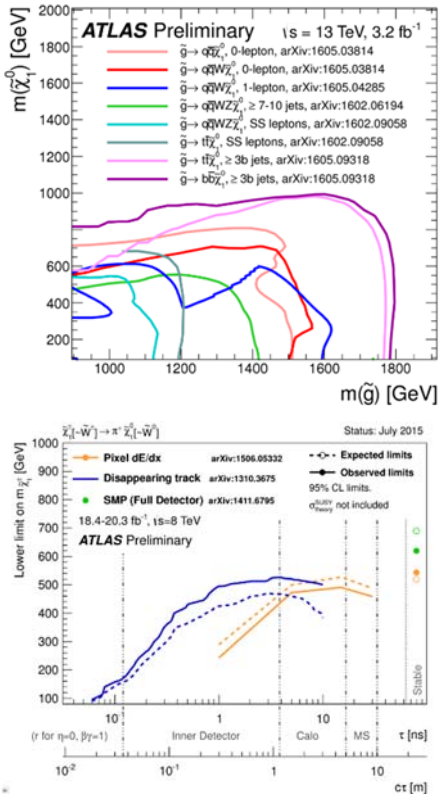

図 3.

(b) レプトン対生成や 2 本ジェット等の不変質量分布を用いた、余剰次元模型や、その他幾つかの新しい理論体系が予言する新粒子に対して、直接探索を行った。余剰次元模型の一つである RS 模型が予言する重力子に対しては、3.2TeV の下限を設けた。

(c) マイクロ・ブラックホール生成、ベクターライク・クォーク等、特異な終状態をもつ新物理の探索も行った。これまでのところ、背景事象からの超過は見られていない。

（3）加速器開発：LHC 高輝度アップグレードに向けたビーム分離用大口径双極超伝導磁石の開発を行い、電磁設計・機械構造設計などの基礎開発を進めた。2m 長モデル機を試作し、1.9K における冷却励磁試験を行った。また、耐放射線性に優れた有機絶縁構造材料の開発を進めた。放射線照射による試験、並びに 2m 長モデル機に搭載して性能評価を行った。

次世代高エネルギー加速器（FCC）計画に向けた、高磁場超電導磁石及び、線材の開発も行った。10T（テスラ）を超える高磁場下でも臨界電流密度が安定する機械特性に優れた Nb_3Al 線材に着目し研究開発を進めた。こちらはラザフォードケーブル（撚線）の試作に成功し、その性能評価を行った。

（4）総括班が主催して開催した「テラスケール研究会」は 11 回に及び、2 回/年のペースで行われた。領域全域に渡る議論が、長日に渡り行われるが、特に超対称性探索、新粒子探索、暗黒物質、時空構造に関する議論を実験・理論間で展開することができた。理論・実験合同研究から発展した論文も出版された。

Summary of the searches for squarks and gluinos using $\sqrt{s} = 8$ TeV pp collisions with the ATLAS experiment at the LHC

The ATLAS collaboration

E-mail: atlas.publications@cern.ch

Abstract: A summary is presented of ATLAS searches for gluinos and first- and second-generation squarks in final states containing jets and missing transverse momentum, with or without leptons or b-jets, in the $\sqrt{s} = 8$ TeV data set collected at the Large Hadron Collider in 2012. This paper reports the results of new interpretations and statistical combinations of previously published analyses, as well as a new analysis. Since no significant excess of events over the Standard Model expectation is observed, the data are used to set limits in a variety of models. In all the considered simplified models that assume R-parity conservation, the limit on the gluino mass exceeds 1150 GeV at 95% confidence level, for an LSP mass smaller than 100 GeV. Furthermore, exclusion limits are set for left-handed squarks in a phenomenological MSSM model, a minimal Supergravity/Constrained MSSM model, R-parity-violation scenarios, a minimal gauge-mediated supersymmetry breaking model, a natural gauge mediation model, a non-universal Higgs mass model with gaugino mediation and a minimal model of universal extra dimensions.

1 Introduction

Supersymmetry (SUSY) [1–9] is a generalization of space-time symmetries that predicts new bosonic partners for the fermions and new fermionic partners for the bosons of the Standard Model (SM). If R-parity is conserved [10–13], SUSY particles (called sparticles) are produced in pairs and the lightest supersymmetric particle (LSP) is stable. The scalar partners of the left- and right-handed quarks, the squarks ($\tilde{q}_\mathrm{L}$ and $\tilde{q}_\mathrm{R}$ which mix to form two mass eigenstates $\tilde{q}_1$ and $\tilde{q}_2$, ordered by increasing mass), and the fermionic partners of the gluons, gluinos ($\tilde{g}$), could be produced in strong interaction processes at the Large Hadron Collider (LHC) [14] and decay via cascades ending with a stable LSP. The rest of the cascade would yield final states with multiple jets and possibly leptons arising from the decay of sleptons ($\tilde{\ell}$), the superpartners of leptons, or W, Z and Higgs (h) bosons originating from the decays of charginos ($\tilde{\chi}^\pm$) or neutralinos ($\tilde{\chi}^0$), where the charginos and neutralinos

JHEP10(2015)054

are the mass eigenstates formed from the linear superpositions of the superpartners of the charged and neutral electroweak and Higgs bosons. In the Minimal Supersymmetric extension of the Standard Model (MSSM) [10–13, 15], there are four charginos, $\tilde{\chi}_1^{\pm}$ and $\tilde{\chi}_2^{\pm}$, and four neutralinos, $\tilde{\chi}_i^0$ ($i = 1$ to 4, ordered by increasing mass); unless stated otherwise, this is assumed in the following. In a large variety of models, the LSP is the lightest neutralino ($\tilde{\chi}_1^0$), which interacts weakly and is a possible candidate for dark matter [16]. Undetected $\tilde{\chi}_1^0$ LSPs would result in substantial missing transverse momentum ($\boldsymbol{E}_{\mathrm{T}}^{\mathrm{miss}}$, with magnitude $E_{\mathrm{T}}^{\mathrm{miss}}$). Significant $E_{\mathrm{T}}^{\mathrm{miss}}$ can also arise in R-parity-violating (RPV) scenarios in which the LSP decays to final states containing neutrinos or in scenarios where neutrinos are present in the cascade decay chains of the produced SUSY particles. Significant mass splitting between the top squark (stop) mass eigenstates $\tilde{t}_1$ and $\tilde{t}_2$ is possible due to the large top Yukawa coupling.[1] Because of the SM weak isospin symmetry the mass of the left-handed bottom squark (sbottom, $\tilde{b}_{\mathrm{L}}$) is tied to the mass of the left-handed stop ($\tilde{t}_{\mathrm{L}}$), and as a consequence the lightest sbottom ($\tilde{b}_1$) and stop ($\tilde{t}_1$) could be produced via the strong interaction with relatively large cross-sections at the LHC, either through direct pair production or in the decay of pair-produced gluinos.

The ATLAS experiment [17] performed several searches for supersymmetric particles in Run 1. No statistically significant excesses of events compared to the predictions of the Standard Model were observed. Therefore the results were expressed as model-independent limits on the production cross-sections of new particles and limits in the parameter space of supersymmetric or simplified models.

The large cross-sections of squark and gluino production in strong interaction processes offer sensitivity to a broad range of SUSY models. This paper provides a summary of the results from inclusive searches for gluinos and first- and second-generation squarks performed by ATLAS, using data from proton-proton (pp) collisions at a centre-of-mass energy of 8 TeV collected during Run 1 of the LHC. The results for direct production of third-generation squarks are reported elsewhere [18]. In addition to summarizing already published searches for squarks and gluinos, this paper presents new signal regions, new interpretations and statistical combinations of those searches, as well as an additional search using the Razor variable set [19], thus improving the sensitivity to supersymmetric models. In order to differentiate strongly produced SUSY events from the SM background, the searches typically require high $E_{\mathrm{T}}^{\mathrm{miss}}$ due to the presence of the LSP and possibly neutrinos, several high-p_{T} jets and large deposited transverse energy. They are further classified according to the presence of leptons and b-jets. A first class of searches applies a veto on leptons [20–22], a second considers final states containing electrons and muons [23–25], and a third requires tau leptons in the final state [26]. A fourth class of searches concentrates on final states containing multiple b-jets [27].

The paper is organized as follows. Section 2 summarizes the SUSY signals in the strong production of gluinos and light-flavour squarks. Section 3 describes the ATLAS experiment and the data sample used, and section 4 the Monte Carlo (MC) simulation samples used for

[1] The masses of the $\tilde{t}_1$ and $\tilde{t}_2$ are the eigenvalues of the stop mass matrix. The stop mass matrix involves the top quark Yukawa coupling in the off-diagonal elements, which typically induces a large mass splitting.

JHEP10(2015)054

background and signal modelling. The physics object reconstruction and identification are presented in section 5. A description of the analysis strategy is given in section 6, and the experimental signatures are presented in section 7. A summary of systematic uncertainties is presented in section 8. Results obtained using the new signal regions with selections similar to those used in previous publications as well as the new analysis using the Razor variable set are reported in section 9. The strategy used for the combination of the results from different analyses is discussed in section 10. Limits in phenomenological and simplified models are presented in section 11. Section 12 is devoted to a summary and conclusions.

2 SUSY models

Since no superpartners of any of the SM particles have been observed, SUSY, if realized in nature, must be a broken symmetry with a mechanism for breaking the symmetry taking place at a higher energy scale. It is difficult to construct a realistic model of spontaneously broken low-energy supersymmetry where the SUSY breaking arises solely as a consequence of the interactions of the particles of the MSSM [28–30]. Therefore, it is often assumed that the SUSY breaking originates in a "hidden" sector, and its effects are transmitted to the MSSM by some unknown mechanism. Various such mechanisms have been proposed, such as gravity-mediated SUSY breaking (SUGRA) [31–36], gauge-mediated SUSY breaking (GMSB) [37–42] and anomaly-mediated SUSY breaking (AMSB) [43, 44]. As a result, these models consider only a small part of the parameter space of the more general MSSM. In such SUSY models, the particle spectrum is typically specified by fixing parameters at the high scale. In order to translate this set of parameters into physically meaningful quantities that describe physics near the electroweak scale, it is necessary to evolve them using their renormalization group equations.

Another approach to constraining SUSY at the electroweak scale is to use simplified models [45, 46] which are based on an effective Lagrangian that only describes a small set of kinematically accessible particles, interactions, production cross-sections and branching ratios. The simplest case corresponds to considering one specific SUSY production process with a fixed decay chain.

Several classes of phenomenological and simplified models, as well as a minimal Universal Extra Dimensions (mUED) scenario [47, 48], covering different combinations of physics objects in the final state, are considered in this paper. Unless otherwise specified, R-parity is assumed to be conserved and the lightest neutralino, $\tilde{\chi}_1^0$, is taken to be the LSP. The phenomenological models include a scenario for the phenomenological MSSM (pMSSM) [49–51], minimal Supergravity/Constrained MSSM (mSUGRA/CMSSM) [31–36], bilinear R-parity violation (bRPV) [52], a minimal gauge-mediated supersymmetry breaking model (mGMSB) [37–42], natural gauge mediation (nGM) [53], and a non-universal Higgs mass model with gaugino mediation (NUHMG) [54]. The simplified models presented here include the pair production of gluinos or first- and second-generation squarks with various hypotheses for their decay chains (direct, one-step or two-step decay), as well as gluino decays via real or virtual third-generation squarks. Direct decays are those where the considered SUSY particles decay directly into SM particles and the LSP, e.g., $\tilde{q} \to q\tilde{\chi}_1^0$.

JHEP10(2015)054

One-step (two-step) decays refer to the cases where the decays occur via one (two) intermediate on-shell SUSY particle(s), e.g., $\tilde{q} \to q\tilde{\chi}_1^{\pm} \to qW\tilde{\chi}_1^0$ ($\tilde{q} \to q\tilde{\chi}_1^{\pm} \to qW\tilde{\chi}_2^0 \to qWZ\tilde{\chi}_1^0$). In gluino decays via third-generation squarks, gluinos undergo a one-step decay to a stop or sbottom such as $\tilde{g} \to t\tilde{t} \to tt\tilde{\chi}_1^0$, or decay directly to final states containing top or bottom quarks, for example $\tilde{g} \to tt\tilde{\chi}_1^0$ if the stop is off-shell. In these simplified models, all supersymmetric particles which do not directly enter the production and decay chain are effectively decoupled, i.e. with masses set above a few TeV. The list of models considered is not comprehensive, and the searches presented here are sensitive to a larger class of decay patterns, mass combinations and hierarchies.

2.1 Phenomenological models

2.1.1 A phenomenological MSSM model

In the pMSSM scenario, no specific theoretical assumption is introduced at the scale of Grand Unification Theories (GUT), or associated with a SUSY breaking mechanism. A short list of experimentally motivated considerations is used to reduce the 120 parameters of the MSSM to 19 real, weak-scale parameters:

- R-parity is exactly conserved,
- there are no new sources of CP violation beyond that already present in the quark mixing matrix,
- Minimal Flavour Violation [55] is imposed at the electroweak scale,
- the first two generations of squarks and sleptons with the same quantum numbers are mass-degenerate, and their Yukawa couplings are too small to affect sparticle production or precision observables.

The remaining 19 independent parameters are: 10 squark and slepton masses, the gaugino masses (M_1, M_2, M_3, associated with the $\mathrm{U(1)_Y}$, $\mathrm{SU(2)_L}$, $\mathrm{SU(3)_C}$ gauge groups, respectively), the higgsino mass parameter (μ), the ratio ($\tan\beta$) of the vacuum expectation values of the two Higgs fields, the mass of the pseudoscalar Higgs boson (m_A), and the trilinear couplings for the third generation (A_b, A_t and A_τ) [49].

In the pMSSM model considered here only the left-handed squarks of the first two generations, the two lightest neutralinos $\tilde{\chi}_2^0$ and $\tilde{\chi}_1^0$, and the lightest chargino $\tilde{\chi}_1^{\pm}$ are assumed to be within kinematic reach. Three gluino masses are considered, $m_{\tilde{g}} = 1.6$, 2.2 and 3.0 TeV, while the masses of all other SUSY particles are kinematically decoupled with masses set to 5 TeV. The parameter $\tan\beta$ is set to 4. The model is further specified by four parameters: $m_{\tilde{q}_\mathrm{L}}$, μ, and M_1 and M_2, from which $m_{\tilde{\chi}_1^0}$, $m_{\tilde{\chi}_2^0}$ and $m_{\tilde{\chi}_1^{\pm}}$ can be calculated. Either M_1 is fixed to 60 GeV and M_2 is varied independently, or M_1 is varied and M_2 is set to $(M_1 + m_{\tilde{q}_\mathrm{L}})/2$.

Left-handed squarks can be pair produced only via t-channel gluino exchange. They can undergo a direct $\tilde{q}_\mathrm{L} \to q\tilde{\chi}_1^0$ decay, or one-step decays: $\tilde{q}_\mathrm{L} \to q + \tilde{\chi}_2^0 \to q + Z/h + \tilde{\chi}_1^0$ or $\tilde{q}_\mathrm{L} \to q + \tilde{\chi}_1^{\pm} \to q + W^{\pm} + \tilde{\chi}_1^0$. Here the lightest Higgs boson h is assumed to have the SM

JHEP10(2015)054

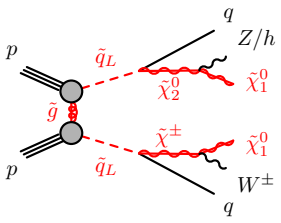

Figure 1. Example of a one-step decay topology of the left-handed squark in the phenomenological MSSM.

decay branching fractions, and its mass is set to 125 GeV. The $\tilde{\chi}_1^\pm$ always decays to $W^\pm$ and $\tilde{\chi}_1^0$ (figure 1). The branching fraction to a left-handed squark via the one-step decay with $\tilde{\chi}_2^0$ ($\tilde{\chi}_1^\pm$) is $\sim 30\%$ (65%). The branching fraction of the $\tilde{\chi}_2^0 \to h\tilde{\chi}_1^0$ decay is between 70% and 90% depending on $m_{\tilde{q}_L}$.

2.1.2 Minimal Supergravity/Constrained MSSM and bilinear R-parity-violation models

The mSUGRA/CMSSM model is specified by five parameters: a universal scalar mass (m_0), a universal gaugino mass ($m_{1/2}$) , a universal trilinear scalar coupling (A_0), all defined at the grand unification scale, $\tan\beta$, and the sign of the higgsino mass parameter (μ). The dependence of the SUSY particle mass spectrum on these five parameters is such that all masses increase with increasing $m_{1/2}$, while squark and slepton masses also depend on m_0. In the mSUGRA/CMSSM model studied here the values $\tan\beta = 30$, $A_0 = -2m_0$ and $\mu > 0$ are chosen, such that the lightest scalar Higgs boson mass is approximately 125 GeV in a large fraction of the (m_0, $m_{1/2}$) parameter space studied.

The bRPV scenario uses the same parameters as the mSUGRA/CMSSM model, but R-parity violation is allowed through the bilinear terms[2] $\epsilon_i L_i H_2$, whose coupling parameters are determined by a fit to neutrino oscillation data [56] under the tree-level dominance scenario [57]. In this scenario, the $\tilde{\chi}_1^0$ LSP decays promptly to $W\mu$, $W\tau$, $Z\nu_\tau$ or $h\nu_\tau$ (where the $W/Z/h$ boson can either be on- or off-shell) with branching fractions which are weakly dependent on m_0 and $m_{1/2}$ and are typically on the order of 20–40%, 20–40%, 20–30% and 0–20%, respectively.

2.1.3 Minimal gauge-mediated supersymmetry breaking model

In gauge-mediated SUSY breaking models, the LSP is a very light gravitino ($\tilde{G}$). The mGMSB model is described by six parameters: the SUSY-breaking mass scale felt by the low-energy sector (Λ), the mass of the SUSY breaking messengers (M_{mess}), the number of SU(5) messenger fields (N_5), $\tan\beta$, μ and the gravitino coupling scale factor (C_{grav}) which determines the lifetime of the next-to-lightest SUSY particle (NLSP). Four parameters are fixed to the values previously used in refs. [58–60]: $M_{\text{mess}} = 250$ TeV, $N_5 = 3$, $\mu > 0$ and $C_{\text{grav}} = 1$. With this choice of parameters the production of squark and/or gluino pairs is

[2]In this notation, L_i indicates a lepton SU(2)-doublet superfield, the Higgs SU(2)-doublet superfield H_2 contains the Higgs field that couples to up-type quarks, and the ϵ_i parameters have dimension of mass.

JHEP10(2015)054

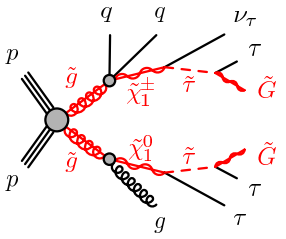

Figure 2. Example of a gluino-pair production followed by the two possible decay chains within the nGM scenario.

expected to dominate over other SUSY processes at the LHC. These SUSY particles decay into the NLSP, which subsequently decays to the LSP. The experimental signatures are largely determined by the nature of the NLSP: this can be either the lightest stau ($\tilde{\tau}$), a selectron or a smuon ($\tilde{\ell}$), the lightest neutralino ($\tilde{\chi}_1^0$), or a sneutrino ($\tilde{\nu}$), leading to final states usually containing tau leptons, light leptons ($\ell = e, \mu$), photons, or neutrinos, respectively.

2.1.4 Natural gauge mediation model

In the nGM scenario, which assumes general gauge mediation [61, 62], the phenomenology depends on the nature of the NLSP [63, 64]. Various models assume that the mass hierarchies of squarks and sleptons are generated by the same physics responsible for breaking SUSY (for example refs. [65, 66]). Typically in these models the third generation of squarks and sleptons is lighter than the other two, and together with the fact that sleptons only acquire small masses through hypercharge interactions in gauge mediation, this leads to a stau NLSP. In the model considered here, it is also assumed that the gluino is the only light coloured sparticle. All squark and slepton mass parameters are set to 2.5 TeV except the lightest stau mass, $m_{\tilde{\tau}}$, which is assumed to be smaller. The parameters M_1 and M_2 are also set to 2.5 TeV, while all trilinear coupling terms are set to zero. The value of μ is set to 400 GeV to ensure that strong production dominates in the parameter space studied. This leaves the gluino mass M_3 and the stau mass $m_{\tilde{\tau}}$ as the only free parameters. The chosen value of the μ parameter sets the masses of the $\tilde{\chi}_1^\pm$, $\tilde{\chi}_1^0$ and $\tilde{\chi}_2^0$, which are almost mass-degenerate. The only light sparticles in the model are the stau, a light gluino, higgsino-dominated charginos and neutralinos, and a very light gravitino LSP. Therefore, the strong production process allowed in this model is gluino-pair production followed by the three possible decay chains: $\tilde{g} \to g\tilde{\chi}_{1,2}^0 \to g\tilde{\tau}\tau \to g\tau\tau\tilde{G}$, $\tilde{g} \to q\bar{q}\tilde{\chi}_{1,2}^0 \to q\bar{q}\tilde{\tau}\tau \to q\bar{q}\tau\tau\tilde{G}$ and $\tilde{g} \to qq\tilde{\chi}_1^\pm \to qq\nu_\tau\tilde{\tau} \to qq\nu_\tau\tau\tilde{G}$ (figure 2), where the final-state quarks are almost exclusively top or bottom quarks. A range of signals with varying gluino and stau masses is studied. The lightest Higgs boson mass is specifically set to 125 GeV.

2.1.5 Non-universal Higgs mass models with gaugino mediation

The NUHMG model is specified with parameters $m_0 = 0$, $\tan\beta = 10$, $\mu > 0$, $m_{H_2}^2 = 0$, and A_0 chosen to maximize the mass of the lightest Higgs boson. The ranges of the two remaining free parameters of the model, $m_{1/2}$ and $m_{H_1}^2$, are chosen such that the NSLP is a tau sneutrino with properties satisfying Big Bang nucleosynthesis constraints [54]. The

squared mass terms of the two Higgs doublets, $m_{H_1}^2$ and $m_{H_2}^2$, are defined at the unification scale. This model is characterized by significant cross-sections for $\tilde{q}$ and $\tilde{g}$ production. The gluino decays mainly to a light quark/squark pair $q\tilde{q}$ ($\approx 50\%$), but also to $t\tilde{t}$ ($\approx 30\%$) or $b\tilde{b}$ ($\approx 20\%$), while the squark multi-step decays typically involve charginos, neutralinos and/or sleptons.

2.1.6 Minimal Universal Extra Dimensions model

The mUED model is the minimal extension of the SM with one additional universal spatial dimension. In this non-SUSY model, the Kaluza-Klein (KK) quark excitation's decay chain to the lightest KK particle, the KK photon, gives a signature very similar to the supersymmetric decay chain of a squark to the lightest neutralino. The properties of the model depend on two parameters: the compactification radius R_c and the cut-off scale Λ. This cut-off is interpreted as the scale at which some new physics underlying the effective non-renormalizable UED framework becomes relevant. The Higgs boson mass is fixed to 125 GeV.

2.2 Simplified models

The details of the simplified models considered are given below and summarized in tables 1–3.

2.2.1 Direct decays of squarks and gluinos

Simplified models with direct decay of the pair-produced strongly interacting supersymmetric particles assume the production of gluino pairs with decoupled squarks, light-flavour

squark pairs with decoupled gluinos, or light-flavour squarks and gluinos; all other superpartners except the lightest neutralino are decoupled. This assumption forces squarks or gluinos to decay directly to quarks or gluons and the lightest neutralino, as shown in figure 3. In the case of squark-gluino production, the masses of the light-flavour squarks are set to 0.96 times the mass of the gluino as suggested in refs. [67, 68], and gluinos can decay via on-shell squarks as $\tilde{g} \to \tilde{q}q \to qq\tilde{\chi}_1^0$. For models with decoupled gluinos two scenarios have been considered: a scenario with eight mass-degenerate light-flavour squarks ($\tilde{q}_\text{L}$ and $\tilde{q}_\text{R}$, with $\tilde{q} = \tilde{u}, \tilde{d}, \tilde{s}, \tilde{c}$), or a scenario with only one accessible light-flavour squark [69]. Changing the number of light-flavoured squarks affects only the cross-section but not the kinematics of the events. The free parameters in these models are $m_{\tilde{q}}$ or $m_{\tilde{g}}$, and $m_{\tilde{\chi}_1^0}$.

An additional set of simplified models with direct decay of pair-produced gluinos assumes that all squarks and sleptons are much heavier than the gluino, which remains relatively light and decays promptly into a gluon and a neutralino [70], as shown in figure 3(d). The free parameters in these models are $m_{\tilde{g}}$ and $m_{\tilde{\chi}_1^0}$.

Table 3. Simplified models of gluino pair production with decays via third-generation squarks. For each model the diagram of the decay topology, the model parameters and assumptions about mass relations and branching ratios are listed. The last column refers to the experimental results presented in section 11.2. Horizontal dashed lines separate different mass or branching ratio assumptions within a model.

2.2.2 One-step decays of squarks and gluinos

Simplified models with one-step decays of the pair-produced squarks or gluinos assume that these particles decay via the $\tilde{\chi}_1^\pm$ into a W boson and the $\tilde{\chi}_1^0$, as shown in figure 4. The free parameters in these models are $m_{\tilde{q}}$ or $m_{\tilde{g}}$, and either $m_{\tilde{\chi}_1^\pm}$ with a fixed $m_{\tilde{\chi}_1^0} = 60\,\text{GeV}$ or $m_{\tilde{\chi}_1^0}$ with $m_{\tilde{\chi}_1^\pm} = (m_{\tilde{g}/\tilde{q}} + m_{\tilde{\chi}_1^0})/2$.

2.2.3 Two-step decays of squarks and gluinos

Two categories of simplified models with two-step decays of squarks and gluinos are considered: models with and without sleptons.

In the two-step models with sleptons the pair-produced squarks or gluinos decay with equal probability to either the lightest chargino or the next-to-lightest neutralino ($\tilde{\chi}_2^0$). These subsequently decay via left-handed sleptons (or sneutrinos) which then further decay into a lepton (or neutrino) and the lightest neutralino. In these models, the free parameters are the mass of the initially produced particle and the mass of the lightest neutralino. The

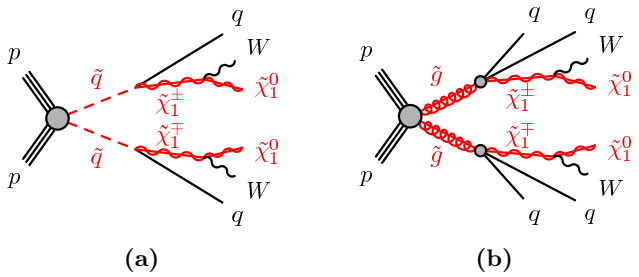

Figure 4. The decay topologies of (a) squark- or (b) gluino-pair production, in the simplified models with one-step decays.

masses of the intermediate charginos or neutralinos are equal and set to be $m_{\tilde{\chi}_1^\pm,\tilde{\chi}_2^0} = (m_{\tilde{g}/\tilde{q}} + m_{\tilde{\chi}_1^0})/2$, while the slepton and sneutrino masses are set to be $m_{\tilde{\ell}_\mathrm{L},\tilde{\nu}} = (m_{\tilde{\chi}_1^\pm/\tilde{\chi}_2^0} + m_{\tilde{\chi}_1^0})/2$. All three slepton flavours are mass-degenerate in this model. A separate model in which the slepton is exclusively a $\tilde{\tau}$ is also considered.

In the second category, two-step models without sleptons, the initial supersymmetric particle decays via the lightest chargino, which itself decays into a W boson and the next-to-lightest neutralino. The latter finally decays into a Z boson and the lightest neutralino. The lightest chargino mass is fixed at $m_{\tilde{\chi}_1^\pm} = (m_{\tilde{g}/\tilde{q}} + m_{\tilde{\chi}_1^0})/2$ and the next-to-lightest neutralino mass is set to be $m_{\tilde{\chi}_2^0} = (m_{\tilde{\chi}_1^\pm} + m_{\tilde{\chi}_1^0})/2$.

These two categories of simplified models with two-step decays of squarks and gluinos are illustrated in figure 5.

2.2.4 Gluino decays via third-generation squarks

Two classes of simplified models with gluino decays via third-generation squarks are considered. In the first, the lightest stop or sbottom is lighter than the gluino, such that $\tilde{t}_1$ or $\tilde{b}_1$ are produced via gluino-pair production followed by $\tilde{g} \to \tilde{t}_1 t$ or $\tilde{g} \to \tilde{b}_1 b$ decays. Gluino-stop models within this class assume that the $\tilde{t}_1$ is the lightest squark while all other squarks are heavier than the gluino, and $m_{\tilde{g}} > m_{\tilde{t}_1} + m_t$ such that the branching ratio for $\tilde{g} \to \tilde{t}_1 t$ decays is 100%. Top squarks are assumed to decay via either $\tilde{t}_1 \to t\tilde{\chi}_1^0$, $\tilde{t}_1 \to b\tilde{\chi}_1^\pm$, $\tilde{t}_1 \to c\tilde{\chi}_1^0$, or via $\tilde{t}_1 \to sb$ with R-parity and baryon number violation, as illustrated in figure 6. For the model with the $\tilde{t}_1 \to b\tilde{\chi}_1^\pm$ decay, the chargino mass is assumed to be twice the mass of the neutralino, and the chargino decays into a neutralino and a W boson. In the model with the $\tilde{t}_1 \to c\tilde{\chi}_1^0$ decay, which proceeds via a loop and is most relevant when the $\tilde{t}_1 \to bW\tilde{\chi}_1^0$ decay is kinematically forbidden, the mass gap between the $\tilde{t}_1$ and the lightest neutralino is fixed to 20 GeV. Using gluino-pair production to probe this decay is particularly interesting because it is complementary to the direct pair production of $\tilde{t}_1$, which is more difficult to extract from the background for this specific decay mode [21]. Gluino-sbottom models within this class assume that the $\tilde{b}_1$ is the lightest squark, all other squarks are heavier than the gluino, and $m_{\tilde{g}} > m_{\tilde{b}_1} + m_b$ such that the branching ratio for $\tilde{g} \to \tilde{b}_1 b$ decays is 100%. The bottom squarks are assumed to decay exclusively via $\tilde{b}_1 \to b\tilde{\chi}_1^0$ (figure 7).

In the second class of simplified models with gluino decays via top or bottom squarks, all sparticles apart from the gluino and the neutralino have masses well above the TeV scale such that the $\tilde{t}_1$ or the $\tilde{b}_1$ are only produced off-shell via prompt decay of the gluinos and have little impact on the kinematics of the final state. For the gluino-off-shell-stop model illustrated in figure 8(a), the $\tilde{t}_1$ is assumed to be the lightest squark, but $m_{\tilde{g}} < m_{\tilde{t}_1}$. A three-

Decay topologies in the gluino-stop simplified models with the top squark decays: (a) $\tilde{t}_1 \to t\tilde{\chi}_1^0$, (b) $\tilde{t}_1 \to b\tilde{\chi}_1^\pm$, (c) $\tilde{t}_1 \to c\tilde{\chi}_1^0$ and (d) $\tilde{t}_1 \to sb$ with R-parity and baryon number violation, with a strength determined by the parameter λ''_{323}.

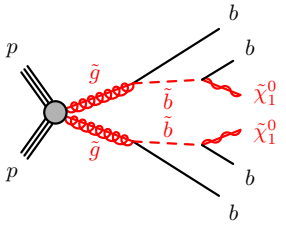

Figure 7. The decay topology in the gluino-sbottom simplified models, with the bottom squark decay $\tilde{b}_1 \to b\tilde{\chi}_1^0$.

body decay $\tilde{g} \to t\bar{t}\tilde{\chi}_1^0$ via an off-shell stop is assumed for the gluino with a branching ratio of 100%. For the configuration $m_{\tilde{g}} < 2m_t + m_{\tilde{\chi}_1^0}$, decays of the gluino involve an off-shell top quark, e.g. the four-body decay $\tilde{g} \to tWb\tilde{\chi}_1^0$. Only four- and five-body decays of this type are considered, because for higher multiplicities the gluinos do not decay promptly. For the gluino-off-shell-sbottom model shown in figure 8(b), the $\tilde{b}_1$ is assumed to be the lightest squark but with $m_{\tilde{g}} < m_{\tilde{b}_1}$. A three-body decay $\tilde{g} \to b\bar{b}\tilde{\chi}_1^0$ via an off-shell sbottom is assumed for the gluino with a branching ratio of 100%. In the gluino-off-shell-stop/sbottom model illustrated in figure 8(c), the $\tilde{b}_1$ and $\tilde{t}_1$ are the lightest squarks, with $m_{\tilde{g}} < m_{\tilde{b}_1,\tilde{t}_1}$. Pair production of gluinos is the only process taken into account, with gluinos decaying via off-shell stops or sbottoms, and a branching ratio of 100% assumed for $\tilde{t}_1 \to b + \tilde{\chi}_1^\pm$ and $\tilde{b}_1 \to t + \tilde{\chi}_1^\pm$ decays. The mass difference between charginos and neutralinos is set to 2 GeV, such that the fermions produced in $\tilde{\chi}_1^\pm \to \tilde{\chi}_1^0 + ff'$ decays do not contribute to the event selection, and gluino decays result in effective three-body decays $bt\tilde{\chi}_1^0$.

3 The ATLAS detector and data sample

The ATLAS detector [17] is a multi-purpose particle physics detector with a forward-backward symmetric cylindrical geometry and nearly 4π coverage in solid angle.[3] The inner tracking detector (ID) consists of pixel and silicon microstrip detectors covering the pseudorapidity region $|\eta| < 2.5$, surrounded by a transition radiation tracker (TRT) which enhances electron identification in the region $|\eta| < 2.0$. The ID is surrounded by a thin superconducting solenoid providing an axial 2 T magnetic field and by a fine-granularity lead/liquid-argon (LAr) electromagnetic calorimeter covering $|\eta| < 3.2$. A steel/scintillator-tile calorimeter provides hadronic coverage in the central pseudorapidity range ($|\eta| < 1.7$). The endcap and forward regions ($1.5 < |\eta| < 4.9$) of the hadronic calorimeter are made of LAr active layers with either copper or tungsten as the absorber material. An extensive muon spectrometer with an air-core toroid magnet system surrounds the calorimeters. Three layers of high-precision tracking chambers provide coverage in the range $|\eta| < 2.7$, while dedicated fast chambers allow triggering in the region $|\eta| < 2.4$. The ATLAS trigger system [71] consists of three levels; the first level (L1) is a hardware-based system, while the second and third levels are software-based systems and are together called the High Level Trigger (HLT).

The data used in these searches were collected from March to December 2012 with the LHC operating at a centre-of-mass energy of 8 TeV. After the application of beam, detector and data quality requirements, the total integrated luminosity ranges from 20.1 to 20.3 fb^{-1}, depending on the triggers used for the event selection, with a relative uncertainty of $\pm 2.8\%$. The uncertainty is derived following the methodology detailed in ref. [72]. During the data-taking period, the peak instantaneous luminosity per LHC fill was typically $7 \times 10^{33}\,\text{cm}^{-2}\text{s}^{-1}$, while the average number of pp interactions per LHC bunch crossing ranged from approximately 6 to 40, with a mean value of 21. In order to maximize the efficiency of selecting the various final states used by the analyses included in this paper, different

[3] ATLAS uses a right-handed coordinate system with its origin at the nominal interaction point in the centre of the detector. The positive x-axis is defined by the direction from the interaction point to the centre of the LHC ring, with the positive y-axis pointing upwards, while the beam direction defines the z-axis. Cylindrical coordinates (r, ϕ) are used in the transverse plane, ϕ being the azimuthal angle around the z-axis. The pseudorapidity η is defined in terms of the polar angle θ by $\eta = -\ln\tan(\theta/2)$.

JHEP10(2015)054

triggers or combinations of triggers were used: $E_{\mathrm{T}}^{\mathrm{miss}}$ triggers, multi-jet triggers, combined $E_{\mathrm{T}}^{\mathrm{miss}}$ +jet, lepton+$E_{\mathrm{T}}^{\mathrm{miss}}$ or lepton+jet+$E_{\mathrm{T}}^{\mathrm{miss}}$ triggers, single-lepton or dilepton triggers. Details of the trigger selections used in the published ATLAS searches included in this paper are not discussed here and can be found in the corresponding publications [20–27].

4 Monte Carlo simulated samples

The simulated event samples for the SM backgrounds are summarized in table 4, together with the choices of Monte Carlo generator, cross-section calculation, set of tunable parameters (tune) used for the underlying event and parton distribution functions (PDFs). The Powheg-Box+Pythia $t\bar{t}$ sample is used for all analyses except for the analysis that requires high jet multiplicities (at least seven to at least ten jets) and large missing transverse momentum [22], which uses the Sherpa $t\bar{t}$ sample. The Sherpa Drell-Yan samples have a lepton filter requiring $p_{\mathrm{T}}^{\ell_1(\ell_2)} > 9\ (5)$ GeV and $|\eta^{\ell_1(\ell_2)}| < 2.8$. This filter prevents its use in analyses requiring the presence of soft leptons in the final state. Such analyses instead use Alpgen samples with a lepton p_{T} threshold at 5 GeV. When using the baseline Powheg-Box+Pythia top quark pair production sample, in some of the analyses events are reweighted in bins of $p_{\mathrm{T}}(t\bar{t})$ to match the top quark pair differential cross-section measured in ATLAS data [73, 74]. The exact usage of MC simulated samples together with the additional samples used to assess modelling uncertainties are detailed in the corresponding publication of each analysis.

Signal samples for the pMSSM, mSUGRA, mGMSB, nGM and mUED models, as well as the samples for the simplified models of gluino-mediated top squark production (for $m_{\tilde{g}} - m_{\tilde{\chi}_1^0} > 2m_t$) are generated with Herwig++ 2.5.2 [106]. Samples for all the other simplified models are generated with up to one extra parton in the matrix element using Madgraph 5 1.3.33 interfaced to Pythia 6.426. The MLM matching scheme [107] is applied with a scale parameter that is set to a quarter of the mass of the lightest sparticle in the hard-scattering matrix element, with a maximum value of 500 GeV. The signal samples used for the bRPV and NUHMG models are generated with Pythia 6.426.

For the gluino-off-shell-stop model in the region $m_{\tilde{g}} - m_{\tilde{\chi}_1^0} < 2m_t$, the production of gluino pairs is generated with Madgraph 5 1.3.33. The events are subsequently combined with separately generated gluino decays $\tilde{g} \to f\bar{f}'f''\bar{f}'''b\bar{b}\tilde{\chi}_1^0$ based on the full matrix element amplitude (also using Madgraph), preserving spin-dependent distributions. A summary of the studies related to event generation in this model can be found in appendix A. Potential effects of the gluino lifetime (displaced decays, hadronization), which are strongly model dependent, have been neglected.

The ATLAS underlying-event tune AUET2B [80] is used for Madgraph 5 and Pythia 6 samples while the UE-EE-3C tune [108] is used for Herwig++ samples. The parton distribution functions from CTEQ6L1 [81] are used for all signal samples.

For all except the mUED sample, the signal cross-sections are calculated to next-to-leading order in the strong coupling constant, including the resummation of soft gluon emission at next-to-leading-logarithmic accuracy (NLO+NLL) [109–113]. In each case the nominal cross-section and its uncertainty are taken from an ensemble of cross-section

Table 4. The Standard Model background Monte Carlo simulation samples used in this paper. The generators, the order in α_s of cross-section calculations used for yield normalization (leading order (LO), next-to-leading order (NLO), next-to-next-to-leading order (NNLO), next-to-next-to-leading logarithm (NNLL)), tunes used for the underlying event and PDF sets are shown. For the γ+jets process the LO cross-section is taken directly from the MC generator.

predictions using different PDF sets and factorization and renormalization scales, as described in ref. [114]. For the mUED model, the cross-section is taken at leading order from Herwig++. For the mSUGRA/CMSSM and NUHMG samples, Susy-Hit [115] and Sdecay 1.3b [116], interfaced to the Softsusy 3.1.6 spectrum generator [117], are used to calculate the sparticle mass spectra and decay tables, and to ensure consistent electroweak symmetry breaking.

The decays of tau leptons are simulated directly in the generators in the case of event samples produced with Sherpa, Herwig++ 2.5.2 and Pythia 8.165, while in all other cases Tauola 2.4 [118, 119] is used.

Standard Model background samples are passed through either the full ATLAS detector simulation [120] based on Geant4 [121], or through a fast simulation using a parameterization of the performance of the ATLAS electromagnetic and hadronic calorimeters [122] and Geant4 elsewhere; the latter applies to $W/Z/\gamma$+jets samples with boson $p_{\mathrm{T}} < 280$ GeV and Powheg-Box+Pythia $t\bar{t}$ samples. All SUSY signal samples are passed through the fast simulation, with the exception of the mSUGRA/CMSSM model samples which are produced with the Geant4 simulation. The fast simulation of SUSY signal

JHEP10(2015)054

events was validated against full GEANT4 simulation for several signal models. Differing pile-up (multiple pp interactions in the same or neighbouring bunch-crossings) conditions as a function of the instantaneous luminosity are taken into account by overlaying simulated minimum-bias events (simulated using PYTHIA 8 with the MSTW2008LO PDF set [123] and the A2 tune [95]) onto the hard-scattering process and reweighting events according to the distribution of the mean number of interactions observed in data.

5 Object reconstruction and identification

This paper summarizes different analyses which are combined to improve the sensitivity to a variety of possible topologies originating from the production and decay of squarks and gluinos. Although different event selections are used among these analyses, they share common definitions of the reconstructed objects. Analysis-specific exceptions to these definitions are detailed in the corresponding publication of each analysis.

The reconstructed primary vertex of the event is required to be consistent with the beamspot envelope and to have at least five associated tracks with $p_{\mathrm{T}} > 400\,\mathrm{MeV}$. When more than one such vertex is found, the vertex with the largest $\sum p_{\mathrm{T}}^2$ of the associated tracks is chosen.

Jet candidates are reconstructed using the anti-k_t jet clustering algorithm [124, 125] with a radius parameter of 0.4. The inputs to this algorithm are topological clusters [126, 127] of calorimeter cells seeded by those with energy significantly above the measured noise (topoclusters). The local cluster weighting (LCW) calibration method [127, 128] is used to classify topoclusters as being either of electromagnetic or hadronic origin, and based on this classification it applies energy corrections derived from MC simulations and measurements in data. The jets are corrected for energy from pile-up using the method suggested in ref. [129]: a contribution equal to the product of the jet area and the median energy density of the event is subtracted from the jet energy [130]. Further corrections, referred to as the jet energy scale (JES) corrections, are derived from MC simulation and data and used to calibrate on average the energies of jets to the scale of their constituent particles [127, 131]. Only jet candidates with $p_{\mathrm{T}} > 20\,\mathrm{GeV}$ and $|\eta| < 4.5$ after all corrections are retained. To remove events with jets from detector noise and non-collision backgrounds, events are rejected if they include jets failing to satisfy the "loose" quality criteria described in ref. [127].

A neural-network-based algorithm [132] is used to identify jets containing a b-hadron (b-jets). It uses as inputs the output weights of several algorithms exploiting the impact parameter of the inner detector tracks, secondary vertex reconstruction and the topology of b- and c-hadron decays inside the jet. The algorithm used has an efficiency of 70% for tagging b-jets, determined with simulated $t\bar{t}$ events [133]. For this efficiency, the algorithm provides a rejection factor of approximately 140 for light-quark and gluon jets, and of approximately 5 for charm jets [134]. Candidate b-jets are required to have $p_{\mathrm{T}} > 40\,\mathrm{GeV}$ and $|\eta| < 2.5$.

Electrons are reconstructed from energy clusters in the electromagnetic calorimeter matched to tracks in the inner detector [135] and are required to have $p_{\mathrm{T}} > 10\,\mathrm{GeV}$ and $|\eta| < 2.47$. The preselected electron candidates are required to pass a variant of the "medium" selection [135], which was modified in 2012 to reduce the impact of pile-up.

JHEP10(2015)054

Photon candidates, which in the analyses presented are used only for the measurement of the missing transverse momentum, are required to have $p_{\mathrm{T}} > 10\,\mathrm{GeV}$ and $|\eta| < 1.37$ or $1.52 < |\eta| < 2.47$, to satisfy photon shower shape and electron rejection criteria [136], and to be isolated.

Muon candidates are formed by combining information from the muon spectrometer and inner tracking detectors [137]. The preselected muon candidates are required to have $p_{\mathrm{T}} > 10\,\mathrm{GeV}$ and $|\eta| < 2.4$ or 2.5, depending on the analysis.

Reconstruction of hadronically decaying tau leptons starts from jets with $p_{\mathrm{T}} > 10\,\mathrm{GeV}$ [138], and an η- and p_{T}-dependent energy calibration to the tau energy scale for hadronic decays is applied [139]. Tau lepton candidates must have one or three associated track(s) with a charge sum of ± 1, and satisfy $p_{\mathrm{T}} > 20\,\mathrm{GeV}$ and $|\eta| < 2.5$. The "loose" and "medium" working points [138] are used and correspond to efficiencies of approximately 70% and 60%, independent of p_{T}, with rejection factors of 10 and 20 against jets misidentified as tau candidates, respectively.

After these selections, ambiguities between candidate jets with $|\eta| < 2.8$ and leptons (electrons and muons) are resolved as follows. First, any such jet candidate lying within a distance $\Delta R = \sqrt{(\Delta\eta)^2 + (\Delta\phi)^2} = 0.2$ of a preselected electron is discarded; then any lepton candidate within a distance $\Delta R = 0.4$ of any surviving jet candidate is discarded. In analyses requiring the presence of one lepton (electron or muon) in the final state, electrons are also required to be well separated from muon candidates with $\Delta R(e, \mu) > 0.01$. If two preselected electrons are found within an angular distance $\Delta R(e, e) = 0.05$ of each other, only the electron with the higher p_{T} is kept. Finally, in the analyses that require the presence of at least one or two opposite-sign leptons in the final state, any event containing a preselected electron in the transition region between the barrel and endcap electromagnetic calorimeters, $1.37 < |\eta| < 1.52$, is rejected.

The measurement of the missing transverse momentum vector is based on the transverse momenta of all electron, photon, jet and muon candidates, and all calorimeter energy clusters not associated with such objects [140]. Fully calibrated electrons and photons with $p_{\mathrm{T}} > 10\,\mathrm{GeV}$ and jets with $p_{\mathrm{T}} > 20\,\mathrm{GeV}$ are used. Energy deposits not associated with these objects are also taken into account in the $\boldsymbol{E}_{\mathrm{T}}^{\mathrm{miss}}$ calculation using an energy-flow algorithm that considers calorimeter energy deposits as well as ID tracks [141]. In the $E_{\mathrm{T}}^{\mathrm{miss}}$ measurement tau leptons are not distinguished from jets and it has been checked that this does not introduce a bias in any kinematic variables used in the analyses.

Corrections derived from data control samples are applied to account for differences between data and simulation for the lepton trigger and reconstruction efficiencies, momentum/energy scale and resolution, and for the efficiency and mis-tag rate for tagging jets originating from b-quarks.

6 Analysis strategy

A search for squarks and gluinos under various decay mode assumptions necessitates many different event selections targeting the wide range of experimental signatures. This section summarizes the common analysis strategy and statistical techniques that are employed in

JHEP10(2015)054

all searches included in this paper. Signal regions (SRs) are defined using the Monte Carlo simulation of the signal processes and the SM backgrounds, and are optimized to maximize the expected significance for each model considered. To estimate the SM backgrounds in a consistent and robust fashion, corresponding control regions (CRs) are defined for each of the signal regions. They are chosen to be non-overlapping with the SR selections in order to provide independent data samples enriched in particular background sources. The CR selections are optimized to have negligible SUSY signal contamination for the models under investigation, while minimizing as much as possible the systematic uncertainties arising from the extrapolation of the CR event yields to the expectations in the SR. Cross-checks of the background estimates are performed using several validation regions (VRs) selected with requirements such that these regions do not overlap with the CR and SR selections, again with a low probability of signal contamination.

Several classes of profile likelihood fits that utilize the observed numbers of events in the various regions are employed in the analyses [142]. In some analyses, the shape of a final discriminating variable in the SRs is also used. A background-only fit is used to determine the compatibility of the observed event yield in each SR with the corresponding SM background expectation. This fit uses as constraints only the observed event yields or the shape of the discriminating variable distributions from the CRs associated with the SR, but not the SR itself. It is assumed that signal events from physics beyond the Standard Model (BSM) do not contribute to these yields. The numbers of observed and predicted events in each of these CRs are described using Poisson probability density functions. The systematic uncertainties and the MC statistical uncertainties on the expected values are included in the fit as nuisance parameters which are constrained by Gaussian distributions with widths corresponding to the sizes of the uncertainties considered and Poisson distributions, respectively. Correlations of a given nuisance parameter across the various regions, between the various backgrounds, and possibly the signal, are taken into account. The product of the various probability density functions forms the likelihood, which the fit maximizes by adjusting the inputs to the fit and the nuisance parameters. The inputs to the fit for each of the SRs are the number of events observed in each of the CRs, and the corresponding number of events expected from simulation, the extrapolation factors obtained from the simulation which relate the number of predicted SM background events in their associated CR to that predicted in the SR, and the number of events predicted by the simulation in each region for the other background processes. The background fit results are cross-checked in validation regions. The data in the validation regions are not used to constrain the fits; they are only used to compare the results of the fits to statistically independent observations.

A model-independent fit is used to set upper limits on the number of BSM signal events in each SR. This fit proceeds in the same way as the background-only fit, except that the number of events observed in the SR is added as an input to the fit, and the BSM signal strength, constrained to be non-negative, is added as a free parameter. The observed and expected upper limits at 95% confidence level (CL) on the number of events from BSM phenomena for each signal region ($S^{95}_{\rm obs}$ and $S^{95}_{\rm exp}$) are derived using the $CL_{\rm S}$ prescription [143], neglecting any possible signal contamination in the control regions; an uncertainty on $S^{95}_{\rm exp}$ is also computed from the $\pm 1\sigma$ uncertainty on the expectation. These

JHEP10(2015)054

limits, when normalized by the integrated luminosity of the data sample, may be interpreted as upper limits on the visible cross-section of BSM physics ($\langle\epsilon\sigma\rangle^{95}_{\rm obs}$), where the visible cross-section is defined as the product of production cross-section, acceptance and efficiency. The model-independent fit is also used to compute the one-sided p-value (p_0) of the background-only hypothesis which quantifies the statistical significance of an excess.

Model-dependent fits are used to set exclusion limits on the signal cross-sections for specific SUSY models. Such a fit proceeds in the same way as the model-independent fit, except that signal contamination in the CRs is taken into account as well as the yield in the signal region and, in some analyses, the model shape information. Correlations between signal and background systematic uncertainties are taken into account where appropriate. The systematic uncertainties on the signal expectations originating from detector effects and the theoretical uncertainties on the signal acceptance are included in the fit. The impact of the theoretical uncertainties on the signal cross-section is shown on the limit plots obtained (section 11). Numbers quoted in the text are evaluated from the observed exclusion limit based on the nominal signal cross-section minus its 1σ theoretical uncertainty.

Background-only and model-independent fit results are presented in this paper only for new analyses or signal regions which are not available in earlier ATLAS publications. In the context of this publication, model-dependent exclusion fits for various simplified and phenomenological models are combined to include results from different searches for each model individually, in order to maximize the expected exclusion reach for each model. Where possible a full statistical combination of non-overlapping searches is applied, as explained in section 10.

7 Experimental signatures

This paper summarizes and combines the results of several individual inclusive squark and gluino analyses previously published by the ATLAS experiment. Each of these searches uses one or more sets of signal regions targeting specific experimental signatures which originate from different squark or gluino decay modes and mass hierarchies. Several extensions to the previously published searches in the form of additional signal regions are also included, along with one new analysis channel. The full list of searches and their signal regions used in this paper is presented in table 5, together with the corresponding references. The details of the signal region selections for all searches listed in table 5 can be found in appendix B. The details of the control and validation region selections, together with the strategies used for the estimation of the background processes, can be found in the corresponding publications. The new analysis and extended signal regions, which are also presented in table 5, are discussed in more detail in the subsequent subsections. Each signal region is referred to with an acronym, listed in table 5, indicating the analysis origin, so for example the '2jl' region from the 0-lepton + 2–6 jets + $E_{\rm T}^{\rm miss}$ analysis is referred to as '0L_2jl'. The correspondence between the searches and the various models probed is provided in table 6 and a summary of the limits in simplified models presented in the respective papers is given in table 7. The 0-lepton + 2–6 jets + $E_{\rm T}^{\rm miss}$ and 1-lepton (soft+hard) + jets +

Table 5. List of analysis names referring to the experimental signatures addressed, with references to the appropriate publications; their acronyms; and all signal region names. The new analysis is denoted with ($\bullet$), while the extended signal regions are denoted with ($\star$). The details of the signal region selections for all searches listed in the table can be found in appendix B.

$E_{\mathrm{T}}^{\mathrm{miss}}$ statistical combination, referred to as (0+1)-lepton combination, is used to probe the models for which both analyses have comparable sensitivity.

7.1 Final states with high-p_{T} jets, missing transverse momentum and no electrons or muons

Several searches to address final states without electrons or muons, containing high-p_{T} jets and missing transverse momentum, have been performed in ATLAS. These searches are split according to the jet multiplicity into three categories: searches with at least one, two to six and seven to ten jets. They are presented in table 5 as Monojet, 0-lepton + 2–6 jets + $E_{\mathrm{T}}^{\mathrm{miss}}$ (extended with two additional signal regions) and 0-lepton + 7–10 jets + $E_{\mathrm{T}}^{\mathrm{miss}}$, respectively. Events with reconstructed electrons or muons are vetoed in these searches. A new search using kinematic variables, known as Razor variables [19], which provide longitudinal and transverse information about each event (listed as 0-lepton Razor in table 5), has also been performed and is included in the results presented in this paper.

Table 7. The 95% CL exclusion limits obtained in published ATLAS searches listed in table 5 for the indicated processes and related assumptions. A dedicated search for $\tilde{c}\tilde{c}$ pair production [144] excludes charm squark masses up to 490 GeV for $m_{\tilde{\chi}_1^0} < 200\,\text{GeV}$ (95% CL).

The monojet (MONOJ) analysis, originally designed to search for direct production of top squarks ($\tilde{t}$), each decaying into a charm quark and a neutralino ($\tilde{\chi}_1^0$) [21], targets final states characterized by at least one high-p_T jet (with $p_\text{T} > 150\,\text{GeV}$ and $|\eta| < 2.8$) and large missing transverse momentum. Signal regions have been specifically optimized for models with a very small mass difference ($\leq 20\,\text{GeV}$) between the top squark and the neutralino. The event selection makes use of the presence of initial-state radiation (ISR) jets to identify signal events, and the squark-pair system is boosted, leading to large E_T^miss. Three signal regions which are based only on different selection criteria related to the jet p_T and E_T^miss have been used to bring additional sensitivity to models with very small mass differences between SUSY particles. These signal regions do not impose any criteria to specifically select events originating from the top squarks and as such they can be used to select events in which squarks are produced in pairs and decay directly via $\tilde{q} \to q\tilde{\chi}_1^0$ with a small $\tilde{q}$–$\tilde{\chi}_1^0$ mass difference.

$m_{\mathrm{eff}}^{\mathrm{incl}}$ [GeV] $\geq$	2200	1900

Table 8. Additional 0L signal regions optimized to increase the sensitivity of the search for left-handed squarks within the pMSSM.

The 0-lepton + 2–6 jets + $E_{\mathrm{T}}^{\mathrm{miss}}$ (0L) search [20] targets final states where each initial squark yields one jet and $E_{\mathrm{T}}^{\mathrm{miss}}$ and each initial gluino yields two jets and $E_{\mathrm{T}}^{\mathrm{miss}}$. Additional decay modes can include the production of charginos via $\tilde{q} \to q\tilde{\chi}_1^{\pm}$ and $\tilde{g} \to q\bar{q}\tilde{\chi}_1^{\pm}$, where the subsequent decay of these charginos to a W boson and $\tilde{\chi}_1^0$ can lead to final states with larger jet multiplicity. The search strategy is optimized for various squark and gluino masses, for a range of models. Fifteen inclusive signal regions are characterized by increasing the minimum jet-multiplicity from two to six (for jets with $p_{\mathrm{T}} > 40\,\mathrm{GeV}$ and $|\eta| < 2.8$), and are based on different selection criteria on the effective mass $m_{\mathrm{eff}}^{\mathrm{incl}}$, defined as the scalar sum of $E_{\mathrm{T}}^{\mathrm{miss}}$ and the p_{T} of the jets; the ratio of $E_{\mathrm{T}}^{\mathrm{miss}}/m_{\mathrm{eff}}^{N_{\mathrm{j}}}$, where $m_{\mathrm{eff}}^{N_{\mathrm{j}}}$ is m_{eff} constructed from only the leading N_{j} jets; and the minimum azimuthal angle between jets and $E_{\mathrm{T}}^{\mathrm{miss}}$. Two of the signal regions are designed to improve sensitivity to models with the cascade $\tilde{q}$ or $\tilde{g}$ decay via $\tilde{\chi}_1^{\pm}$ to W and $\tilde{\chi}_1^0$, in cases where the $\tilde{\chi}_1^{\pm}$ is nearly degenerate in mass with the $\tilde{q}$ or $\tilde{g}$. These signal regions place additional requirements on the invariant masses $m(W_{\mathrm{cand}})$ of the candidate W bosons reconstructed from a single high-mass jet, or from a pair of jets.

Following the same analysis strategy, two additional signal regions are included in this paper, which are optimized to increase the sensitivity of the 0L search for left-handed squarks within the pMSSM model described in section 2. These two signal regions target the two one-step decays of $\tilde{q}_{\mathrm{L}}$, $\tilde{q}_{\mathrm{L}} \to q\tilde{\chi}^{\pm} \to qW^{\pm}\tilde{\chi}_1^0$ and $\tilde{q}_{\mathrm{L}} \to q\tilde{\chi}_2^0 \to q(Z/h)\tilde{\chi}_1^0$ and are obtained by optimizing on two variables, $E_{\mathrm{T}}^{\mathrm{miss}}/m_{\mathrm{eff}}^{N_{\mathrm{j}}}$ and $m_{\mathrm{eff}}^{\mathrm{incl}}$, in the channels with at least four or at least five jets. All other selection criteria are exactly the same as for the corresponding channels described in the original publication. The two new signal regions, named 4jt+ and 5jt following the naming convention from ref. [20], are summarized in table 8.

A high jet multiplicity is expected from the decays of gluino pairs via a top squark, or via squarks involving the production of $\tilde{\chi}^{\pm}$ and $\tilde{\chi}_2^0$ in their decay chain, and is the main topology targeted by the 0-lepton + 7–10 jets + $E_{\mathrm{T}}^{\mathrm{miss}}$ (MULTJ) analysis [22]. The sensitivity of the search is enhanced by the subdivision into two categories. First, in the multi-jet+flavour stream, an event classification based on the number of jets ($p_{\mathrm{T}} > 50\,\mathrm{GeV}$ and $|\eta| < 2$) and number of b-jets ($p_{\mathrm{T}} > 40\,\mathrm{GeV}$ and $|\eta| < 2.5$) gives enhanced sensitivity to models which predict either more or fewer b-jets than the SM background. In the second category (multi-jet+M_J^{Σ} stream), which targets models with large numbers of objects in the final state, the jets reconstructed with the jet radius parameter $R = 0.4$ are reclustered into large composite jets using the anti-k_t algorithm with $R = 1.0$. The event variable M_J^{Σ} is computed as the sum of the masses of the composite jets: $M_J^{\Sigma} \equiv \sum_j m_j^{R=1.0}$, where the composite jets satisfy $p_{\mathrm{T}}^{R=1.0} > 100\,\mathrm{GeV}$ and $|\eta^{R=1.0}| < 1.5$. In total, nineteen signal regions

JHEP10(2015)054

	0LRaz_SR$_{\text{loose}}$	**0LRaz_SR$_{\text{tight}}$**

$\Delta\phi(\text{jet}_{1,2}, E_{\text{T}}^{\text{miss}})$ >	0.4	1.4
R >	0.5	0.6
M_R' [GeV] >	700	900

Table 9. Overview of the selection criteria for the two signal regions used by the 0LRaz analysis. The 0LRaz_SR$_{\text{tight}}$ targets high masses of the heavy produced sparticle, and the 0LRaz_SR$_{\text{loose}}$ targets small mass splittings between the heavy produced sparticle and the LSP. Details of the construction of Razor variables $M_R^{'}$ and R can be found in appendix C.1.

are defined, based on different selection criteria on the total number of jets, number of b-jets, $E_{\text{T}}^{\text{miss}}/\sqrt{H_{\text{T}}}$ (where H_{T} is the scalar sum of the p_{T} of all jets) and on the event variable M_J^{Σ}.

The Razor variable set is designed to group together visible final-state particles associated with heavy produced sparticles, and in doing so contains information about the mass scale of those sparticles. The events are selected using a combination of $E_{\text{T}}^{\text{miss}}$ triggers which are fully efficient for the event selections considered in this search. The new 0-lepton Razor (0LRaz) analysis presented here selects events with at least two high-p_{T} jets and $E_{\text{T}}^{\text{miss}}$. The baseline object selection and event cleaning, as well as the choice of MC generators for SM background processes and the approach for calculating systematic uncertainties exactly follow those of the 0L search [20]. Two signal regions are identified by optimizing criteria on the Razor variables to give the best expected sensitivity in the model with squark pair production followed by the direct decay of the squarks. One signal region, SR$_{\text{loose}}$, targets models with small mass splittings which typically have softer visible objects, while the other signal region, SR$_{\text{tight}}$, is designed to target models with high squark masses which typically contain harder visible objects. Appendix C describes in detail the construction of the event variables, optimization strategy for these signal regions and corresponding control and validation regions, explicitly showing the distributions of the variables used for the selection, and the impact of the selection on the expected SM background and signal yields. An overview of the selection criteria for the two signal regions used in this search is given in table 9.

7.2 Final states with high-p_{T} jets, missing transverse momentum and at least one electron or muon

Three types of searches addressing decays of squarks and gluinos in events containing electrons or muons, jets and missing transverse momentum are summarized here: searches with at least one isolated lepton, which have been extended with an additional signal region with high jet multiplicity, a search with two same-flavour opposite-sign leptons inconsistent with Z boson decay (off-Z search), and searches in final states with a same-sign lepton pair or at least three leptons.

JHEP10(2015)054

The 1-lepton (soft+hard)/2-leptons + jets + $E_{\mathrm{T}}^{\mathrm{miss}}$ (1L(S,H), 2L(S), 2LRaz) searches [23] require the presence of at least one isolated lepton (electron or muon) in the decay chains of strongly produced squarks or gluinos. Different categories of events are defined in order to cover a broad parameter space: first the events are separated by different requirements on the transverse momentum of the leptons, either using an electron or muon with p_{T} >25 GeV in the hard lepton selection, or an electron (muon) with $p_{\mathrm{T}} > 7$ (6) GeV in the soft lepton selection. Each of these selections is further subdivided into a single-lepton and a dilepton search channel. The soft and hard lepton channels are designed to be complementary, and are more sensitive to supersymmetric spectra with small or large mass splittings, respectively, while the different lepton multiplicities cover different production and decay modes. To enhance the sensitivity to gluino or squark production, high and low jet multiplicity signal regions, respectively, are defined. The single-lepton channels (1L(S,H)) use a statistically independent set of events, compared to the 0L search, allowing the statistical combination of the two searches in the models for which it is relevant. The hard dilepton channel (2LRaz) targets gluino and first- and second-generation squark production, as well as mUED searches. This channel uses a Razor variable set and is not designed to search for signal events in which a real Z boson is present. In all search channels except the soft dimuon channel (2L(S)), two separate selections are performed for each jet multiplicity: one single-bin signal region optimized for discovery reach, which is also used to place limits on the visible cross-section, and one signal region which is binned in an appropriate variable in order to exploit the expected shape of the distribution of signal events when placing model-dependent limits.

An additional signal region with one hard lepton (electron or muon), high jet multiplicity and $E_{\mathrm{T}}^{\mathrm{miss}}$, referred to as 1L(H)_7-jet in table 5, is considered in this paper. The selection is based on looser missing transverse momentum selection criteria compared to the value used in ref. [23] together with the requirement for high jet multiplicity, which is suggested in refs. [145, 146] in the search for natural SUSY. The 1L(H)_7-jet signal region selection follows the concepts of the 1L(H) analysis [23], only modifying the criteria for the signal, validation and control regions to take into account a selection of events with at least seven jets in the final state. Due to these changes, a re-evaluation of the systematic uncertainties, in particular of the theoretical uncertainties on the background, is also performed. The selection criteria are summarized in table 10.

The 2-leptons off-Z (2L-offZ) search [24] targets events where the final state same-flavour opposite-sign leptons originate from the decay $\tilde{\chi}_2^0 \to \ell^+\ell^-\tilde{\chi}_1^0$, where $\tilde{\chi}_2^0$ is produced in the decays of squarks and gluinos, e.g. $\tilde{q} \to q\tilde{\chi}_2^0$ and $\tilde{g} \to qq\tilde{\chi}_2^0$. Compared to the decay $Z \to \ell^+\ell^-$, which leads to a peak in the $m_{\ell\ell}$ distribution around the Z boson mass, the decay $\tilde{\chi}_2^0 \to \ell^+\ell^-\tilde{\chi}_1^0$ leads to a rising distribution in $m_{\ell\ell}$ that terminates at an endpoint ("edge") [147] because events with larger $m_{\ell\ell}$ values are kinematically forbidden. Four signal regions are defined by requirements on jet multiplicity, b-tagged jet multiplicity and $E_{\mathrm{T}}^{\mathrm{miss}}$. The selection criteria are optimized for the simplified models of pair-produced squarks or gluinos followed by their two-step decays with sleptons, described in section 2.2.2. The signal regions with a b-jet veto provide the best sensitivity in the two-step simplified models considered here, since the signal b-jet content is lower than that of the dominant $t\bar{t}$ background. Signal regions with a requirement of at least one b-tagged jet

Table 10. Overview of the selection criteria for the 1L(H) + 7 jets + $E_{\mathrm{T}}^{\mathrm{miss}}$ analysis, for the signal region (1L(H)_7-jet), W+jets and semileptonic $t\bar{t}$ control regions (1L(H)_WR_7-jet and 1L(H)_TR_7-jet respectively) and two validation regions used to cross-check the background estimates (1L(H)_VR_7-jet $E_{\mathrm{T}}^{\mathrm{miss}}$ and 1L(H)_VR_7-jet m_{T}). The p_{T} selections for leptons are given for electrons (muons).

JHEP10(2015)054

target other signal models not explicitly considered here, such as those with bottom squarks that are lighter than the other squark flavours. One signal region with similar requirements to those used by the CMS experiment in a comparable search [148] which reported an excess of events above the SM background with a significance of 2.6 standard deviations, is also used for comparison purposes. No evidence for an excess is observed in this region.

Another leptonic search channel [25] is used for an analysis of final states with multiple jets, and either two leptons of the same electric charge or at least three leptons (SS/3L). The motivation for searches using these final states is that pair-produced gluinos have the same probability to decay to pairs of leptons with the same charge as with opposite charge. Squark production (directly in pairs or through $\tilde{g}\tilde{g}$ or $\tilde{g}\tilde{q}$ production with subsequent $\tilde{g} \to q\tilde{q}$ decay) can also lead to same-sign lepton or three-lepton signatures when the squarks decay in cascades involving top quarks, charginos, neutralinos or sleptons. Requiring a pair of leptons with the same electric charge largely suppresses the background coming from the SM processes, giving a very clean and powerful signature to search for new physics processes. It also allows the use of relatively loose kinematic requirements on $E_{\mathrm{T}}^{\mathrm{miss}}$, increasing the sensitivity to scenarios with small mass differences between SUSY particles or with R-parity violation. Five statistically independent signal regions are defined: two signal regions requiring same-sign leptons and b-jets (optimized for gluino decays via top squarks), a complementary signal region requiring a b-jet veto (optimized for the gluino decays via first- and second-generation squarks), and two signal regions requiring three leptons (designed for scenarios characterized by multi-step decays).

7.3 Final states with high-p_{T} jets, missing transverse momentum and at least one hadronically decaying tau lepton

A search for squarks and gluinos in events with large missing transverse momentum, jets and at least one hadronically decaying tau lepton [26] is motivated by naturalness arguments [149, 150], and by the assumption that light sleptons could play a role in the co-annihilation with neutralinos in the early universe [151]. In particular, models with light tau sleptons are consistent with dark-matter searches [152]. Four distinct topologies are studied in order to optimize the tau + jets + $E_{\mathrm{T}}^{\mathrm{miss}}$ (TAU) search for various models: one hadronically decaying tau (1τ) or two or more hadronically decaying taus (2τ) in the final state with no additional light leptons (e/μ) and one or more tau leptons with exactly one lepton (one electron ($\tau+e$) or muon ($\tau+\mu$)). The different topologies (1τ, 2τ and $\tau+\ell$, where ℓ is electron or muon) have been optimized separately, and, where relevant, are statistically combined to increase the analysis sensitivity. The same signal regions are used for additional model interpretations, not presented in ref. [26]. These are simplified models of squark- or gluino-pair production where the squark or gluino undergoes a two-step cascade decay via sleptons, as shown in figures 5(a) and 5(c), where the sleptons are assumed to be exclusively staus, since the first two generations of sleptons and sneutrinos are kinematically decoupled.

7.4 Final states with many b-jets and missing transverse momentum

A search requiring at least three b-jets [27] is one of the most sensitive searches to various SUSY models favoured by naturalness arguments, where top or bottom quarks are produced

JHEP10(2015)054

in the gluino decay chains. The search is carried out in statistically independent zero- and one-lepton channels (0/1L3B) which are combined to maximize the sensitivity. Three sets of signal regions, two for the zero-lepton channel and one for the one-lepton channel, are defined to enhance the sensitivity to the various models considered. They are characterized by having relatively hard $E_{\mathrm{T}}^{\mathrm{miss}}$ requirements and at least four, six or seven jets, amongst which at least three are required to be b-jets. Signal regions with zero leptons and at least four jets target SUSY models with sbottoms in the decay chain, while the one-lepton and the zero-lepton signal regions with at least six or seven jets aim to probe SUSY models where top-quark-enriched final states are expected.

8 Systematic uncertainties

Systematic uncertainties on background estimates in all searches included in this paper arise from the use of transfer factors which relate observations in the control regions to background expectations in the signal regions, and from the MC modelling of minor backgrounds. Since CRs are designed to be kinematically as close as possible to the SRs, many sources of systematic uncertainty largely cancel. In searches which include leptons in the final state, systematic uncertainties also impact the estimation of jets misidentified as leptons or of non-prompt leptons. The full details of all sources of systematic uncertainty and their impact on background predictions for each search included in this paper can be found in the corresponding original publication. Only the dominant uncertainties on the background estimations, common to all searches, are mentioned here.

Since at least one high-p_{T} jet and significant missing transverse momentum are present in all searches summarized in this paper, the primary common sources of systematic uncertainty for the SM backgrounds estimated with transfer factors derived from MC simulation are the JES and the jet energy resolution (JER). The theoretical modelling of background processes and the limited number of data events in the CRs and in the MC simulation are also typically important.

The JES uncertainty is estimated from a combination of simulation, test beam data and in-situ measurements [127, 153], and depends on the p_{T} and η of the jet. Additional contributions accounting for the jet-flavour composition, the calorimeter response to different jet flavours, pile-up and b-jet calibration uncertainties are also taken into account. Uncertainties on the JER are obtained with an in-situ measurement [154] of the jet transverse momentum balance in dijet events. Uncertainties in jet measurements are propagated to the $E_{\mathrm{T}}^{\mathrm{miss}}$, and additional subdominant uncertainties on $E_{\mathrm{T}}^{\mathrm{miss}}$ arising from the contribution from energy deposits not associated with reconstructed objects are also included. In signal regions designed for searches based on large jet multiplicities these uncertainties can be as large as 30% of the estimated background yield in the SRs.

Searches requiring the presence of tau leptons in the final state are subject to additional systematic uncertainties from the tau energy scale [139] and the tau lepton identification [138]. The uncertainties from the jet and tau energy scales are the largest experimental uncertainties in these searches, being as large as 13% and 8% of the estimated background yield respectively, and are treated as uncorrelated, since the calibration methods differ.

JHEP10(2015)054

In searches that require the presence of b-jets in the final state, the uncertainty associated with flavour-tagging efficiencies is evaluated by varying the p_{T}- and flavour-dependent correction factors applied to each jet in the simulation within a range that reflects the systematic uncertainty on the measured tagging efficiencies and mistag rates. This uncertainty varies between 10% and 16% in the different SRs requiring at least three b-jets in the final state.

Uncertainties arising from the theoretical modelling of background processes are typically evaluated by comparing the estimates to those obtained with different MC generators. The uncertainty due to the factorization and renormalization scales is computed by varying these scales up and down by a factor of two with respect to the nominal setting. Uncertainties from PDFs are computed following the PDF4LHC recommendations [155]. These uncertainties vary across the different searches and in some signal regions are the dominant source of systematic uncertainties.

The same sources of experimental uncertainty apply to the signal acceptance. Several theoretical uncertainties on the acceptance for the various signal models are taken into account. These uncertainties are estimated using the MADGRAPH5+PYTHIA6 samples by varying the following parameters up and down by a factor of two: the MADGRAPH scale used to determine the event-by-event renormalization and factorization scale, the parameters used to determine the scales for initial- and final-state QCD radiation and the parameters used for jet matching. The uncertainty on the modelling of initial-state radiation plays an important role in simplified models with small mass differences in the decay cascade, and is as large as 20–30% in such regions. For all models, except the mUED model, the NLO+NLL cross-section uncertainty is taken from an envelope of cross-section predictions using different PDF sets and factorization and renormalization scales, as described in ref. [114]. The mUED model cross-sections are based on a calculation at LO in QCD, and the events are generated with a leading-order MC event generator. No theoretical uncertainties on the acceptance are considered for this case.

The overall background uncertainties for the two new signal regions defined in the 0LRaz search are estimated to be 6% in the 0LRaz_SR$_{\mathrm{loose}}$ signal region and 9% in the 0LRaz_SR$_{\mathrm{tight}}$ signal region. These uncertainties are dominated by the modelling of the Z+jets process and by the uncertainties on diboson production due to renormalization and factorization scales and PDF uncertainties for which a conservative uniform 50% uncertainty is applied. In the additional signal region for the 1-lepton (hard) + jets + $E_{\mathrm{T}}^{\mathrm{miss}}$ analysis, 1L(H)_7-jet, the overall background uncertainty is estimated to be 35%, and it is dominated by the modelling of the $t\bar{t}$ process in the events with high jet multiplicity. The estimated background uncertainties in the two additional signal regions for the 0-lepton + 2–6 jets + $E_{\mathrm{T}}^{\mathrm{miss}}$ analysis, 0L_4jt+ and 0L_5jt, are consistent with the uncertainties obtained for the two closest signal regions (4jt and 5j) from the original publication [20].

9 Results for the new signal regions

The number of events observed in the data and expected from SM processes are shown for all new signal regions in tables 11, 12 and 13. Table 11 summarizes the results for the two

JHEP10(2015)054

additional signal regions for the 0L analysis. Table 12 displays the equivalent results for the two signal regions of the new 0LRaz analysis, and those for the additional region of the 1L(H) analysis are shown in table 13. All results are determined using the background-only fit. The pre-fit background expectations are also shown in the tables, for comparison purposes. The prediction of the W/Z+jets background processes by the simulation prior to the fit is found to be overestimated in the phase space of interest and is consequently decreased by the fit. This is consistent with the behaviour observed in previous publications probing a similar phase space [20]. In all new signal regions presented in this paper the number of events observed is consistent with the post-fit SM expectations. The observed and expected upper limits at 95% CL on the number of BSM events ($S^{95}_{\rm obs}$ and $S^{95}_{\rm exp}$), together with the upper limits on the visible cross-section of BSM physics ($\langle\epsilon\sigma\rangle^{95}_{\rm obs}$) and the p-value for the background-only hypothesis, are also presented in the tables 11–13. The confidence levels are calculated with the $CL_{\rm S}$ prescription [143]. For an observed number of events lower than expected, the p-value is truncated at 0.5.

10 Combination strategy

Statistical combinations of the analyses, as listed in table 6, are performed in order to increase the exclusion reach in several SUSY models in which at least two analyses designed to be statistically independent in their signal and control region definitions provide comparable sensitivities. The conditions are satisfied for a combination of the 1L(S,H) and 0L searches. These analyses search for squarks and gluinos in final states containing jets and missing transverse momentum, either with at least one isolated electron or muon (1L(S,H)), or applying an explicit veto on events containing electrons or muons (0L). They are statistically independent due to a veto on any electron or muon with $p_{\rm T} > 10\,{\rm GeV}$ in the case of the 0L search, and requiring an electron or muon with $p_{\rm T}(e/\mu) > 25\,{\rm GeV}$ (hard single-lepton) or $p_{\rm T}(e/\mu) > 7/6\,{\rm GeV}$ (soft single-lepton) in the case of the 1L(S,H) search. It has been checked explicitly that the difference in lepton-$p_{\rm T}$ thresholds in the 0L and soft single-lepton analyses does not result in events selected by both analyses. The control regions used to estimate contributions from W+jets and top backgrounds used by the 0L search have been slightly modified with respect to the original regions [20] such that events which are selected by the respective control regions in the 1L(S,H) analyses are vetoed. This modification ensures complete statistical independence of the three analyses, which can therefore be combined where relevant.

The statistical combination is obtained from the individual likelihoods of the analyses involved. In the case of the 0L analysis the likelihood for the signal region that provides the best expected $CL_{\rm S}$ value for the signal model considered, and its corresponding control regions, is chosen. The choice of this signal region can vary as a function of sparticle masses. For the 1L(S,H) analyses, all the available signal regions are statistically independent and hence a single likelihood that describes all of them serves as input for the combination procedure. Some of the systematic uncertainties can be correlated when building the combined likelihood. The correlated uncertainties in the combination procedure are the luminosity uncertainty, the uncertainty on the SUSY cross-sections,

Also shown are the 95% CL upper limits on the visible cross-section ($\langle\epsilon\sigma\rangle^{95}_{\rm obs}$) and on the number of signal events ($S^{95}_{\rm obs}$). The expected upper limit on the number of signal events ($S^{95}_{\rm exp}$) is calculated from the expected number of background events after fit, with uncertainties indicating the $\pm 1\sigma$ deviations from the expectation. The p-value ($p(s=0)$) is also presented in the table.

b-tagging uncertainties, and the jet energy resolution and $E_{\rm T}^{\rm miss}$-related uncertainties. Other systematic uncertainties, such as theoretical uncertainties, are not correlated, e.g. the uncertainties due to different Monte Carlo generators used in the analyses considered. The jet energy scale uncertainty, which is subdominant, is not correlated due to the use of different prescriptions in the analyses involved. The combination of the analyses was carefully validated by ensuring that the combined likelihood did not lead to artificial correlations between fit parameters or major changes in post-fit values of nuisance parameters with respect to the individual analysis fits discussed in refs. [20, 23].

Figures 9 and 10 show the result of the combination of the 1L(S,H) and 0L analyses for both squark-pair and gluino-pair production for the one-step decays of squarks and gluinos described in section 2.2.2. The limits obtained improve the results of the separate analyses, reaching higher $\tilde{\chi}^0_1$ mass and approximately 50 GeV higher squark or gluino mass

JHEP10(2015)054

regions are referred to by their acronyms defined in table 5. An overview of all searches used to probe the phenomenological models described in section 2.1 and the simplified models described in section 2.2 is given in table 6. A limit obtained from the statistical combination of 1L(S,H) and 0L analyses is presented for models for which both analyses have comparable sensitivity and is used as a single contribution to the final combined limit. The final combined observed and expected 95% CL exclusion limits are obtained from the signal regions belonging to the contributing analyses that provide the best expected CL_S value. Expected limits from the individual analyses which contribute to the final combined limits are also presented for comparison. The $\pm 1\sigma^{\text{SUSY}}_{\text{theory}}$ lines around the observed limits in the figures are obtained by changing the signal cross-section by one standard deviation ($\pm 1\sigma$), as described in section 8. All mass limits on supersymmetric particles quoted later in this section are derived from the $-1\sigma^{\text{SUSY}}_{\text{theory}}$ line.

11.1 Limits in phenomenological models

This section summarizes the exclusion limits placed on the phenomenological models described in section 2.1.

11.1.1 A phenomenological MSSM model

The measurements are interpreted in a phenomenological MSSM model, which possesses three parameters: $m_{\tilde{q}_L}$, M_1 and M_2, where M_1 and M_2 are the masses associated with the bino and wino fields. For the exclusion limits in figure 11 either M_1 is fixed to 60 GeV and M_2 is varied independently, or M_1 is varied and M_2 is set to $M_2 = (M_1 + m_{\tilde{q}_L})/2$. The figures show limits in the $(m_{\tilde{q}}, m_{\tilde{\chi}_1^\pm, \tilde{\chi}_2^0})$ and $(m_{\tilde{q}}, m_{\tilde{\chi}_1^0})$ planes, for various gluino masses, as obtained from the 0L analysis with the additional 0L_4jt+ and 0L_5jt signal regions optimized specifically for this model. As expected, for the relatively light gluino mass of 1600 GeV, a large range of squark masses (up to 1500 GeV) and $\tilde{\chi}_1^\pm/\tilde{\chi}_2^0$ masses (up to 1150 GeV) can be excluded. The exclusion reach decreases with increasing gluino mass.

11.1.2 Minimal Supergravity/Constrained MSSM and bilinear R-parity-violation models

The exclusion limits in the (m_0, $m_{1/2}$) mSUGRA/CMSSM plane with $\tan\beta = 30$, $A_0 = -2m_0$ and $\mu > 0$ are shown in figure 12. In the parameter space region with m_0 values smaller than about 1800 GeV the best sensitivity is obtained with the (0+1)-lepton combination, which slightly improves the individual limit obtained by the 0L_3jt signal region from the 0L search. For high m_0 values, final states with four top quarks dominate, and consequently the best sensitivity is provided by the 0/1L3B search. This search excludes gluino masses smaller than 1280 GeV.

The exclusion limits for the RPV model, which uses the same parameters as the mSUGRA/CMSSM but allows for bilinear R-parity-violating terms in the superpotential resulting in an unstable LSP, are shown in the (m_0, $m_{1/2}$) plane in figure 13. The best sensitivity is provided by the TAU and the SS/3L searches. For m_0 values smaller than approximately 750 GeV the sensitivity is dominated by the TAU search which excludes $m_{1/2}$ values up to 680 GeV using the combination of all final states considered in the search. At

JHEP10(2015)054

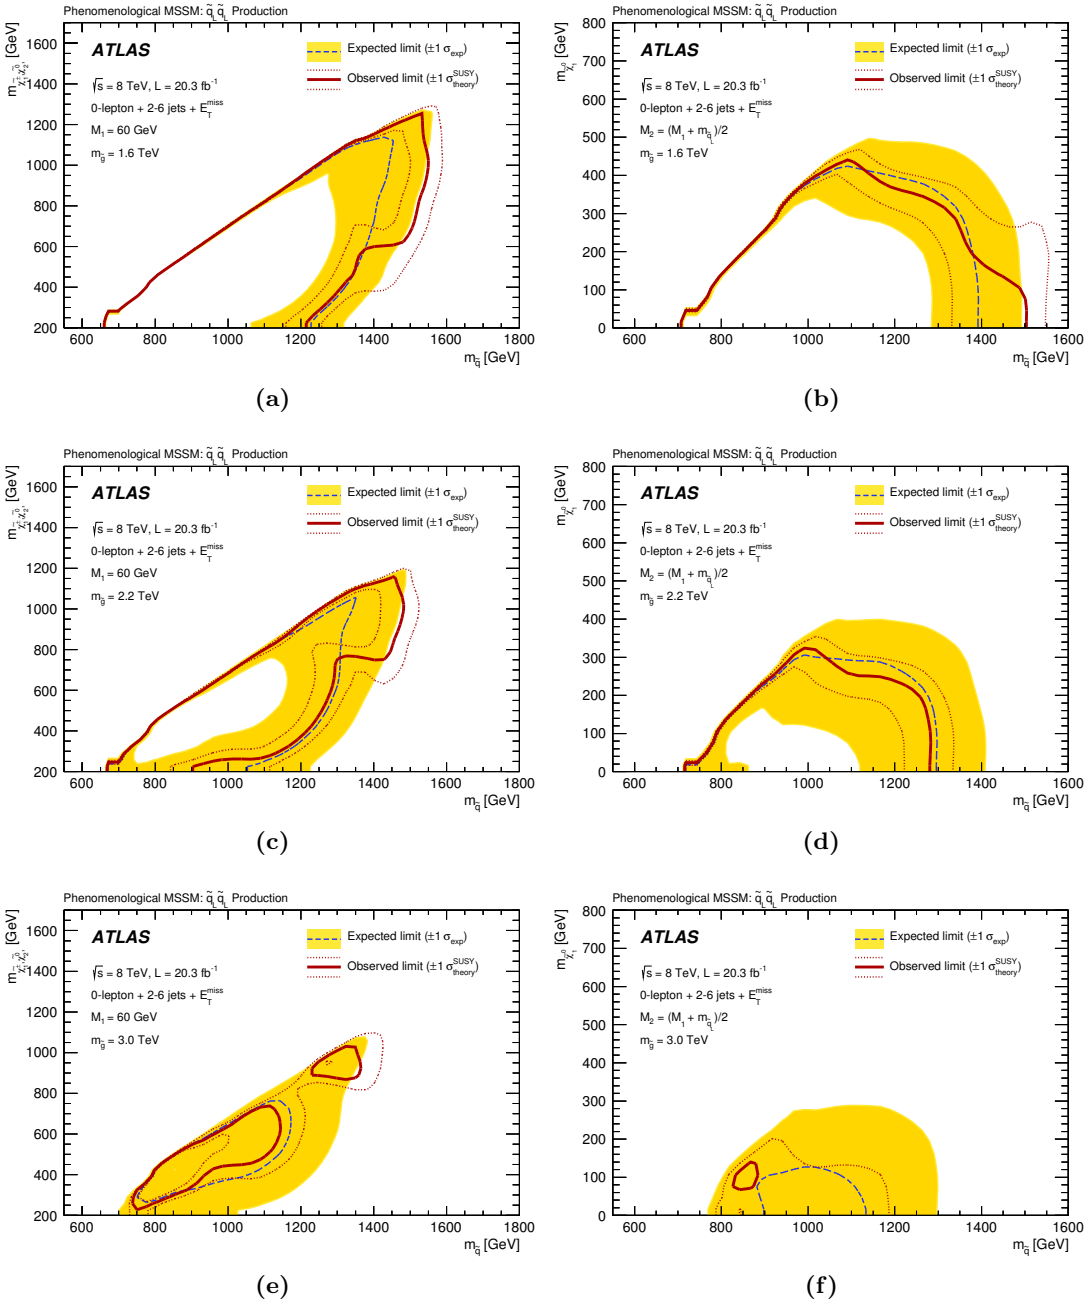

Figure 11. 95% CL exclusion limits in the pMSSM considered in the search for left-handed squarks, with mass parameters M_1 and M_2, which are associated with the bino and wino masses, respectively. The limits are obtained from the 0L analysis with the additional 0L_4jt+ and 0L_5jt signal regions optimized specifically for this model. The parameter set considered here has either (a, c, e) $M_1 = 60\,\text{GeV}$ and M_2 varying or (b, d, f) $M_2 = (M_1 + m_{\tilde{q}_L})/2$ and M_1 varying. For each M_1, M_2 combination three gluino masses are considered, $m_{\tilde{g}} = 1600, 2200, 3000\,\text{GeV}$. Gluino pair production is not included. The solid red line and the dashed blue line show respectively the combined observed and expected 95% CL exclusion limits.

JHEP10(2015)054

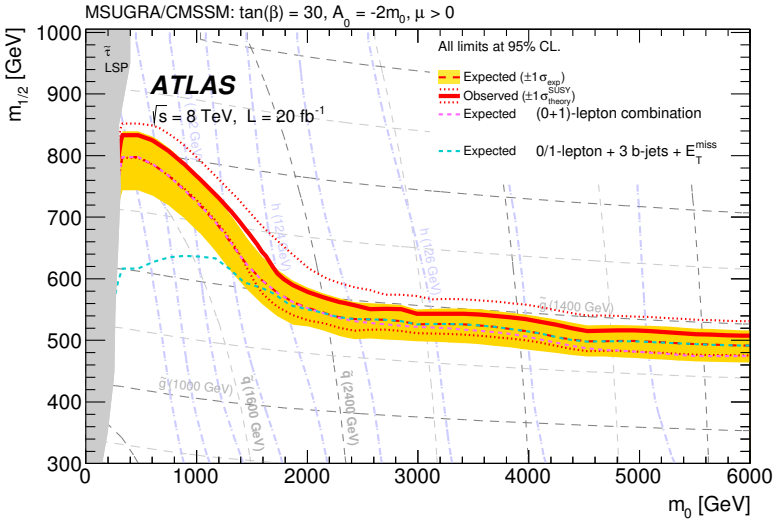

Figure 12. Exclusion limits in the $(m_0,\ m_{1/2})$ plane for the mSUGRA/CMSSM model. The solid red line and the dashed red line show respectively the combined observed and expected 95% CL exclusion limits. Expected limits from the individual analyses which contribute to the final combined limits are also shown for comparison.

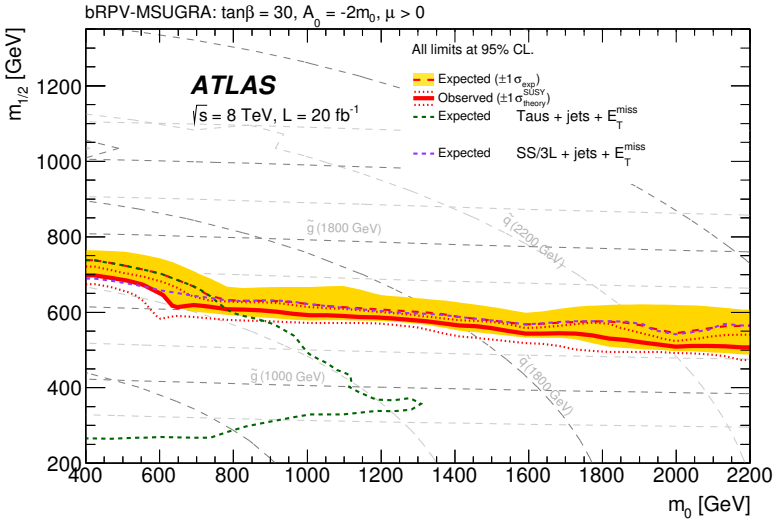

Figure 13. Exclusion limits in the $(m_0,\ m_{1/2})$ plane for the bRPV model. The solid red line and the dashed red line show respectively the combined observed and expected 95% CL exclusion limits. Expected limits from the individual analyses which contribute to the final combined limits are also shown for comparison.

high m_0 values the best sensitivity is provided by the SS/3L_SR3b signal region from the SS/3L search, which excludes values of $m_{1/2}$ between 200 GeV and 490 GeV. For m_0 values below 2200 GeV, signal models with $m_{1/2} < 200$ GeV are not considered because the lepton acceptance is significantly reduced due to the increased LSP lifetime in that region.

JHEP10(2015)054

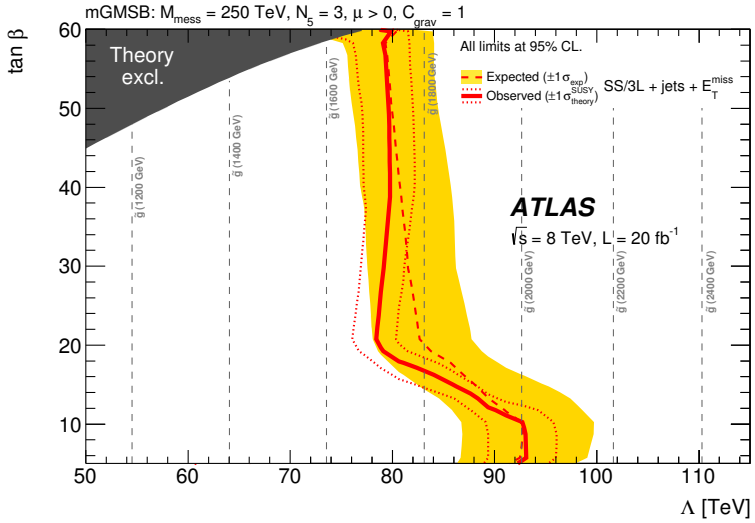

Figure 14. Exclusion limits in the (Λ, $\tan\beta$) plane for the mGMSB model. The solid red line and the dashed red line show respectively the combined observed and expected 95% CL exclusion limits. The region of small Λ and large $\tan\beta$ just above the exclusion limit is excluded theoretically since it leads to tachyonic states.

11.1.3 Minimal gauge-mediated supersymmetry breaking model

The observed and expected limits for the mGMSB scenario are shown in figure 14, in the plane defined by the SUSY breaking scale Λ and the $\tan\beta$ value. The region of small Λ and large $\tan\beta$ just above the exclusion limit is excluded theoretically since it leads to tachyonic states. The SS/3L search provides the best sensitivity for this model and excludes values of Λ up to about 75 TeV.

11.1.4 Natural gauge mediation model

The limits obtained for the nGM scenario are shown in figure 15 in the ($m_{\tilde{\tau}}$, $m_{\tilde{g}}$) plane. The best limits are obtained by the 1L(S,H) and TAU searches, resulting in an exclusion of gluino masses below approximately 1100 GeV independent of the $\tilde{\tau}$ mass.

11.1.5 Non-universal Higgs mass model with gaugino mediation

The exclusion limits in the context of a NUHMG model with parameters $m_0 = 0$, $\tan\beta = 10$, $\mu > 0$ and $m^2_{H_2} = 0$ are shown in the ($m^2_{H_1}$, $m_{1/2}$) plane in figure 16. They are provided by the (0+1)-lepton combination. A band in the ($m^2_{H_1}$, $m_{1/2}$) plane can be excluded, extending up to the ranges $2000 \times 10^3\,\text{GeV}^2 < m^2_{H_1} < 5400 \times 10^3\,\text{GeV}^2$ and $450\,\text{GeV} < m_{1/2} < 620\,\text{GeV}$.

11.1.6 Minimal Universal Extra Dimension model

Finally, the limits obtained for the mUED scenario are shown in figure 17 in the ($1/R_c$, ΛR_c) plane. The 2L(S), 2LRaz and SS/3L searches provide competitive sensitivities for this model in which the mass spectrum is naturally degenerate and the decay chain of the

Kaluza-Klein (KK) quark excitation to the lightest KK particle, the KK photon, gives a signature very similar to the supersymmetric decay chain of a squark via cascades involving top quarks, charginos, neutralinos or sleptons, which can subsequently produce many leptons. In the region where the cut-off scale times radius (ΛR_c) is smaller than 13, the combined exclusion is dominated by the 2L(S) and 2LRaz searches which are combined based on the best expected CL_S value, while in the remaining regions of the parameter space the final exclusion is dominated by the SS/3L_SR3Lhigh and SS/3L_SR0b signal regions from the SS/3L search. Values of $1/R_c$ below 850 GeV are excluded.

11.2 Limits in simplified models

11.2.1 Direct decays of squarks and gluinos

This section summarizes the exclusion limits in simplified models with direct decays of gluinos and squarks of the first and second generation described in section 2.2.1. Here and in sections 11.2.2 and 11.2.3, unless otherwise stated, the eight light-flavoured squarks are always assumed to be mass-degenerate.

Figure 18 shows the exclusion limits in simplified models with squark-pair production and subsequent direct squark decays to a quark and the lightest neutralino. The expected limits from the three most sensitive searches (0L, MONOJ and 0LRaz) are presented individually along with the combined expected and observed exclusion limits. The 0L and 0LRaz analyses yield in general higher expected mass limits, but the MONOJ search provides the best sensitivity close to the diagonal line, in the region of parameter space where the mass difference between the squark and the lightest neutralino is small. From the observed limits, neutralino masses below about 280 GeV can be excluded for squark masses

JHEP10(2015)054

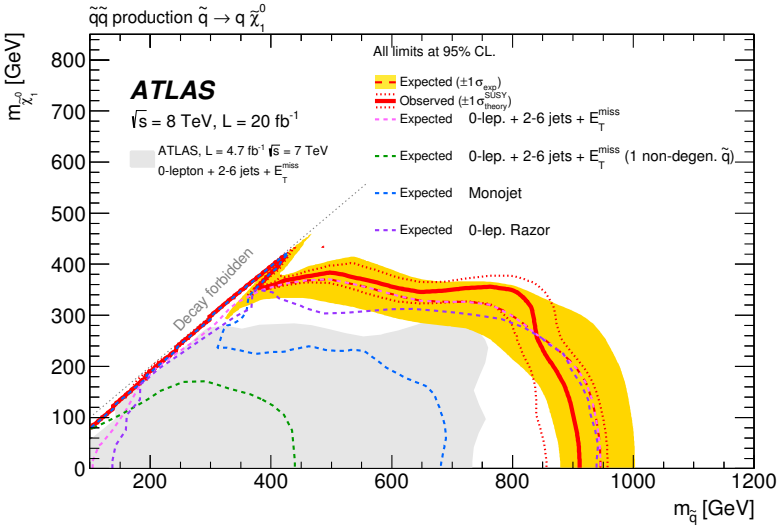

Figure 18. Exclusion limits in the mass plane of the lightest neutralino and first- and second-generation squarks assuming squark-pair production and direct decays $\tilde{q} \to q\tilde{\chi}_1^0$. The solid red line and the dashed red line show respectively the combined observed and expected 95% CL exclusion limits. Expected limits from the individual analyses which contribute to the final combined limits are also shown for comparison. A previous result from ATLAS [156] using 7 TeV proton-proton collisions is represented by the shaded (grey) area. A limit obtained with the 0L search [20] in a scenario with only one light-flavour squark produced is also presented for completeness.

up to 800 GeV, and for a neutralino mass of 100 GeV squark masses are excluded below 850 GeV. In a scenario with only one light-flavour squark produced, which affects only the cross-section but not the kinematics of the events, a lower limit on the squark mass of 440 GeV is obtained with the 0L search [20].

Another example of a direct decay is shown in figure 19, taken from ref. [20], where gluino-pair production with the subsequent decay $\tilde{g} \to qq\tilde{\chi}_1^0$ is considered. Due to the higher production cross-sections compared to the squark-pair production, higher mass limits can be obtained. For gluino masses up to about 1000 GeV, neutralino masses can be excluded below about 500 GeV or close to the kinematic limit near the diagonal. For small neutralino masses the observed limit is as large as 1330 GeV.

A simplified model of $\tilde{q}\tilde{g}$ strong production with the direct decays of squarks $\tilde{q} \to q\tilde{\chi}_1^0$ and gluinos $\tilde{g} \to qq\tilde{\chi}_1^0$ is considered in figure 20, taken from ref. [20], for the 0L analysis. The squark mass is fixed at $0.96m_{\tilde{g}}$ in figure 20(a), and gluinos can decay via on-shell squarks as $\tilde{g} \to \tilde{q}q \to qq\tilde{\chi}_1^0$. The exclusion limit for the neutralino mass is very close to the kinematic limit near the diagonal line and reaches 700 GeV for gluino masses up to 1200 GeV. For a massless neutralino, gluino masses below 1500 GeV are excluded.

Figure 20(b) expresses the mass limits in the $(m_{\tilde{g}}, m_{\tilde{q}})$ plane in the model with combined production of squark pairs, gluino pairs, and of squark-gluino pairs, for different assumptions on the neutralino mass: $m_{\tilde{\chi}_1^0} = 0$ GeV, 395 GeV or 695 GeV. Depending on the mass hierarchy, the $\tilde{g} \to \tilde{q}q$ and $\tilde{q} \to \tilde{g}q$ one-step decays are taken into account. The masses of all other supersymmetric particles are set outside the kinematic reach. A lower limit of 1650 GeV for equal squark and gluino mass is found for the scenario with a massless $\tilde{\chi}_1^0$.

JHEP10(2015)054

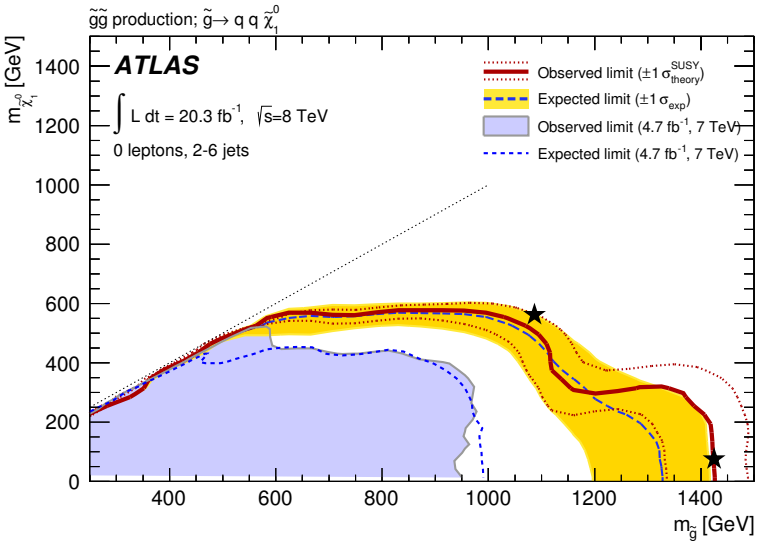

Figure 19. Exclusion limits in the mass plane of the lightest neutralino and the gluino for gluino-pair production with direct decay $\tilde{g} \rightarrow qq\tilde{\chi}_1^0$ taken from the 0L search [20]. The solid red line and the dashed blue line show respectively the observed and expected 95% CL exclusion limits. The star symbols indicates two benchmark models which are investigated in more detail in the publication. A previous result from ATLAS [156] using 7 TeV proton-proton collisions is represented by the shaded (light blue) area.

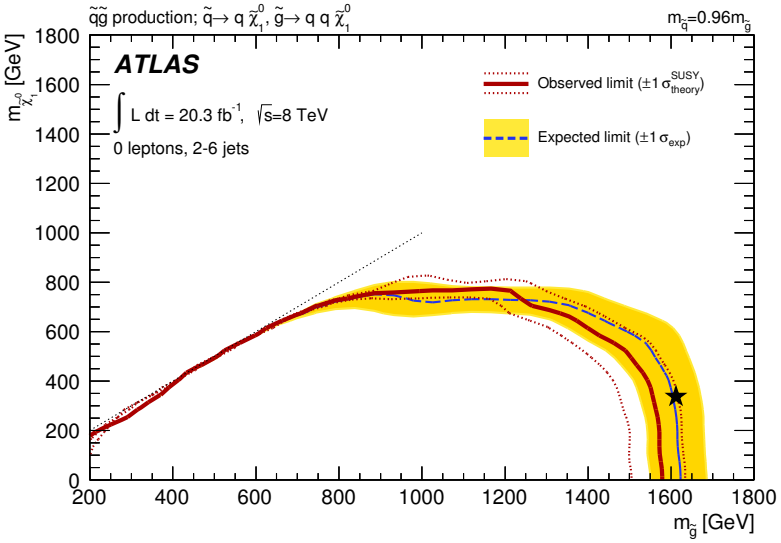

Figure 21 shows the cross-section times branching ratio limits for gluino-pair production with direct gluino decays to a gluon and the lightest neutralino based on the 0L search. For a massless neutralino (figure 21(a)), gluino masses below 1250 GeV can be excluded. The result can also be used to obtain lower mass limits on $\tilde{\chi}_1^0$, e.g. 550 GeV for a gluino mass of 850 GeV (figure 21(b)). The cross-section exclusion for the $\tilde{g} \rightarrow g\tilde{\chi}_1^0$ model is very similar to that for the $\tilde{q} \rightarrow q\tilde{\chi}_1^0$ as would be expected if there is not much difference between quark- and gluon-initiated jets.

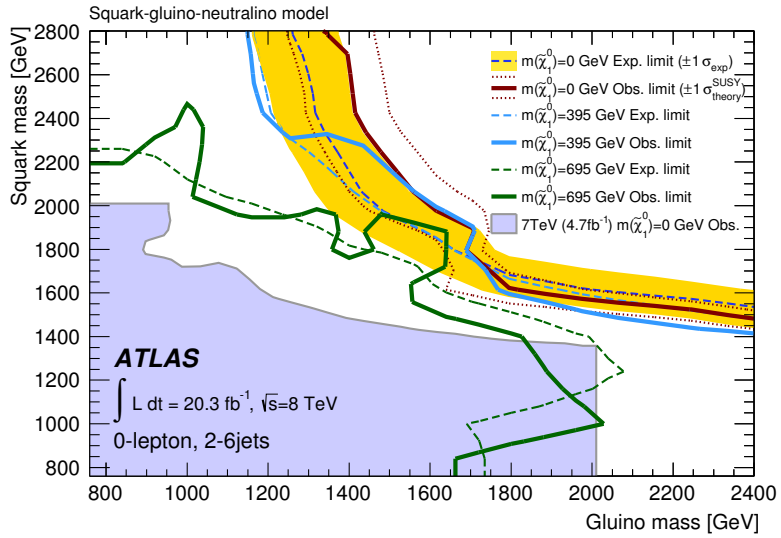
11.2.2 One-step decays of squarks and gluinos



This section presents the limits in simplified models with one-step decays of squarks and gluinos described in section 2.2.2.

Figure 22 shows the exclusion limits for squark-pair production where the squark decays via an intermediate chargino (one step) to a quark, W boson and neutralino. For the model presented in figure 22(a) the chargino mass is fixed at $m_{\tilde{\chi}_1^\pm} = (m_{\tilde{q}} + m_{\tilde{\chi}_1^0})/2$ and the result is shown in the $(m_{\tilde{q}}, m_{\tilde{\chi}_1^0})$ plane. The best sensitivity is obtained by the (0+1)-lepton combination. Neutralino masses up to 370 GeV are excluded. For a neutralino mass of 100 GeV, squark masses are excluded below 790 GeV. Figure 22(b) shows the exclusion limits in the $(m_{\tilde{q}}, x)$ plane, where x is defined as $x = \Delta m(\tilde{\chi}_1^\pm, \tilde{\chi}_1^0)/\Delta m(\tilde{q}, \tilde{\chi}_1^0)$, in models in which the neutralino mass is fixed at 60 GeV. Squark masses are excluded up to 830 GeV for the most favourable x values. The 1L(S,H) search yields stronger limits than the 0L analysis for most of the parameter space of both types of models.

JHEP10(2015)054

(b)

Figure 20. Exclusion limits on the production of a first- or second-generation squark and a gluino with direct decays of both particles, taken from the 0L search [20]. The solid red line and the dashed blue line show respectively the observed and expected 95% CL exclusion limits. The squark mass is fixed at 0.96 $m_{\tilde{g}}$ in (a) and allowed to vary freely in (b) with three assumptions on the neutralino mass of 0, 395 GeV or 695 GeV. The black star indicates a benchmark model as discussed in ref. [20]. Previous results for a massless neutralino from ATLAS at 7 TeV [156] are represented by the shaded (light blue) area. The 7 TeV results are valid for squark or gluino masses below 2000 GeV, the mass range studied for that analysis.

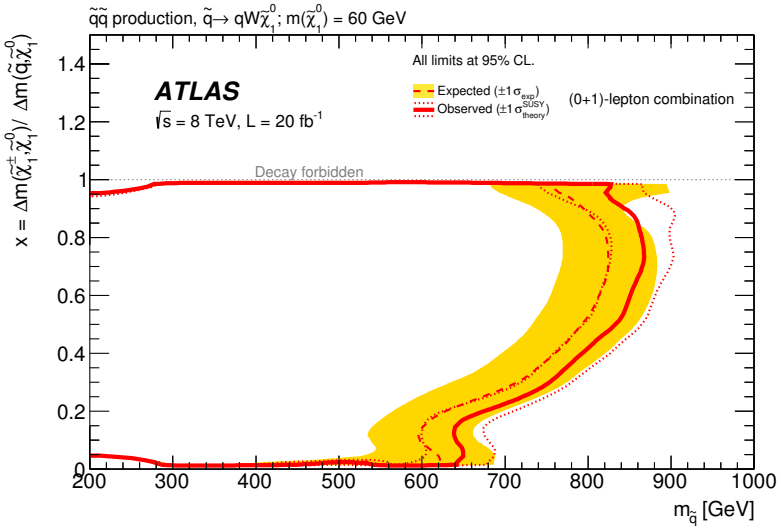
(a)



(b)

Figure 22. Exclusion limits for squark-pair production with a one-step decay via an intermediate chargino into $qW\tilde{\chi}_1^0$. Figure (a) shows the limits in the $(m_{\tilde{q}}, m_{\tilde{\chi}_1^0})$ plane for a chargino mass fixed at $m_{\tilde{\chi}_1^\pm} = (m_{\tilde{q}} + m_{\tilde{\chi}_1^0})/2$. Alternatively (b), the neutralino mass is fixed at 60 GeV and exclusion limits are given for $x = \Delta m(\tilde{\chi}_1^\pm, \tilde{\chi}_1^0)/\Delta m(\tilde{q}, \tilde{\chi}_1^0)$ as function of the squark mass. The solid red line and the dashed red line show respectively the combined observed and expected 95% CL exclusion limits.

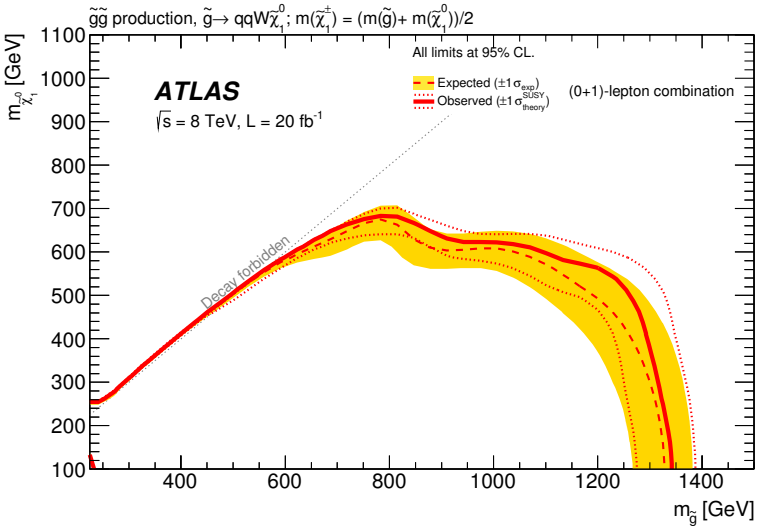
JHEP10(2015)054

The results of the searches for gluino-pair production with a one-step decay via an intermediate chargino into $qqW\tilde{\chi}_1^0$ are shown in figure 23. Figure 23(a) shows the limit for a chargino mass fixed at $m_{\tilde{\chi}_1^\pm} = (m_{\tilde{g}} + m_{\tilde{\chi}_1^0})/2$, where the (0+1)-lepton combination provides the best sensitivity. For a neutralino mass of 100 GeV, gluino masses below 1270 GeV are excluded. Neutralino masses are excluded below 480 GeV for gluino masses up to 1200 GeV. Fixing the neutralino mass at 60 GeV (figure 23(b)), one obtains limits on the variable $x = \Delta m(\tilde{\chi}_1^\pm, \tilde{\chi}_1^0)/\Delta m(\tilde{g}, \tilde{\chi}_1^0)$. Nearly the whole range $0 < x < 1$ is excluded for gluino masses below 1100 GeV.

11.2.3 Two-step decays of squarks and gluinos

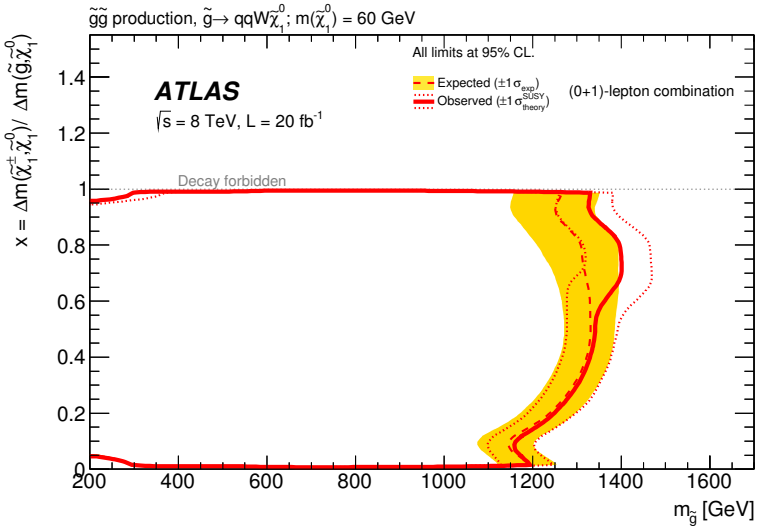
This section presents the limits in simplified models with two-step decays of squarks and gluinos described in section 2.2.3.

Exclusion limits for squark-pair production with a subsequent two-step squark decay via a chargino and neutralino to $qWZ\tilde{\chi}_1^0$ are shown in figure 24. Results are obtained with two searches, the 0L and the SS/3L searches. The 0L search is mainly sensitive in the low-mass region of 240 GeV $< m_{\tilde{q}} <$ 300 GeV, whereas the SS/3L search is most sensitive for squark masses between 450 and 650 GeV, where $\tilde{\chi}_1^0$ masses below 250 GeV are excluded.



Exclusion limits in a simplified model of gluino-pair production with a subsequent two-step gluino decay via a chargino and neutralino to $qqWZ\tilde{\chi}_1^0$ are shown in figure 25. The results are obtained with the (0+1)-lepton combination, MULTJ, and the SS/3L searches. The (0+1)-lepton combination provides the highest $\tilde{\chi}_1^0$ mass limits at low gluino masses. For the intermediate range around $m_{\tilde{g}} \approx 900$ GeV the SS/3L search is most sensitive, while for high gluino masses the best limits are obtained by the MULTJ analysis. For gluino masses below 500 GeV, $\tilde{\chi}_1^0$ masses are excluded up to the kinematic limit indicated by the diagonal line, and in the range 500 GeV $< m_{\tilde{g}} <$ 1000 GeV lower limits on $\tilde{\chi}_1^0$ masses are set around 400 GeV. For $m_{\tilde{\chi}_1^0} = 100$ GeV, gluino masses are excluded below 1150 GeV.

Another example of a simplified model with squark-pair production is considered in figure 26, where squarks decay through a two-step process via a chargino or neutralino and a slepton into final states with jets, leptons and missing transverse momentum. Figure 26 shows the exclusion limits in the $(m_{\tilde{q}}, m_{\tilde{\chi}_1^0})$ plane, for which the best results are obtained by the 2LRaz and the SS/3L searches. Masses for the lightest neutralino can be excluded nearly up to the kinematic limit (diagonal line) for squark masses below 630 GeV. For $\tilde{\chi}_1^0$ masses below 100 GeV, squark masses can be excluded below 820 GeV.



Similarly, a simplified model with gluino-pair production is considered in figure 27, where gluinos decay through a two-step process via a chargino or neutralino and sleptons into final states with jets, leptons and missing transverse momentum. Figure 27 shows the exclusion limits in the $(m_{\tilde{g}}, m_{\tilde{\chi}_1^0})$ plane. The combined 1L(S,H)+2LRaz searches based on the best expected CL_S value and the SS/3L search provide the best sensitivities for this model. Masses for the lightest neutralino can be excluded nearly up to the kinematic limit (diagonal line) for gluino masses below 600 GeV. For $\tilde{\chi}_1^0$ masses below 100 GeV, gluino masses can be excluded below 1320 GeV.

A further example of a simplified model of squark-pair production and decay through a two-step process is shown in figure 28, where squarks decay via charginos or neutralinos

JHEP10(2015)054

The solid red line and the dashed red line show respectively the combined observed and expected 95% CL exclusion limits. Expected limits from the individual analyses which contribute to the final combined limits are also shown for comparison.

JHEP10(2015)054

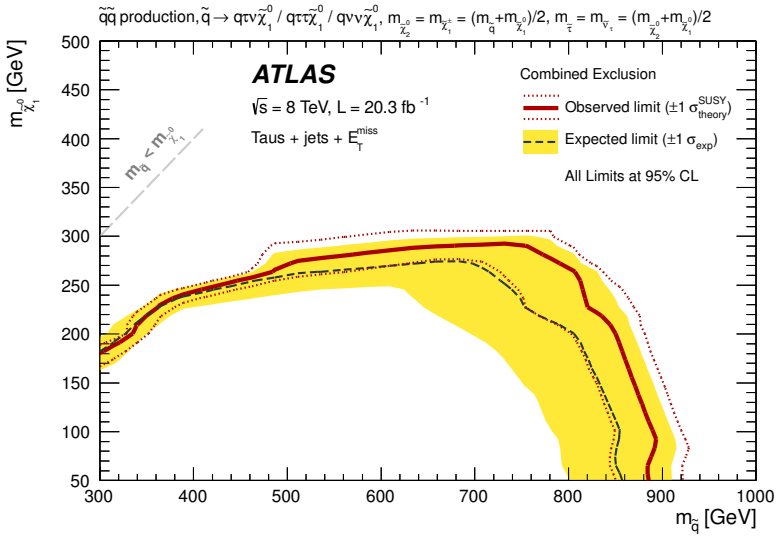

Figure 28. 95% CL exclusion limits in the $(m_{\tilde{q}}, m_{\tilde{\chi}_1^0})$ plane for a simplified model of squark-pair production with two-step decay via staus. The solid red line and the dashed black line show respectively the observed and expected 95% CL exclusion limits.

and staus. The exclusion limits obtained by the TAU search are indicated in the $(m_{\tilde{q}}, m_{\tilde{\chi}_1^0})$ plane. For light $\tilde{\chi}_1^0$ masses around 50 GeV, squark masses below 850 GeV are excluded; and for light squark masses of 300 GeV, neutralino masses below 170 GeV are excluded.

A simplified model of gluino-pair production and decay through a two-step process is shown in figure 29, where gluinos decay via charginos or neutralinos and staus. The exclusion limits obtained by the TAU search are indicated in the $(m_{\tilde{g}}, m_{\tilde{\chi}_1^0})$ plane. For light $\tilde{\chi}_1^0$ masses around 100 GeV, gluino masses below 1220 GeV are excluded; and for light gluino masses of 400 GeV, neutralino masses below 280 GeV are excluded.

11.2.4 Gluino decays via third-generation squarks

This section summarizes the exclusion limits placed in the various simplified models with gluino decays via third-generation squarks described in section 2.2.4.

The combined expected and observed exclusion limits for the gluino-off-shell-stop models are given in the $(m_{\tilde{g}}, m_{\tilde{\chi}_1^0})$ plane in figure 30, where a 100% branching ratio for the decay $\tilde{g} \to t\bar{t}^{(*)}\tilde{\chi}_1^0$ via an off-shell stop is assumed. In the regions where $m_{\tilde{g}} < 2m_t + m_{\tilde{\chi}_1^0}$, the three-body decays $(\tilde{g} \to t\bar{t}\tilde{\chi}_1^0)$ are replaced by the more complex multi-body decays proceeding via off-shell top quarks and W bosons, as discussed in appendix A. The best sensitivity for this model is provided by the 0/1L3B and the SS/3L searches. In the regions of parameter space where the mass difference between the gluino and the lightest neutralino is small, the most sensitive search is the SS/3L, and the sensitivity is dominated by the SS/3L_SR3b signal region. In the regions with a large mass splitting between the gluino and the neutralino, where hard jets and large $E_{\mathrm{T}}^{\mathrm{miss}}$ are expected, the sensitivity is dominated by the 0/1L3B_SR-0l-7j signal regions from the 0/1L3B search. For these models, gluino masses below about 1310 GeV are excluded for $m_{\tilde{\chi}_1^0} < 400$ GeV.

JHEP10(2015)054

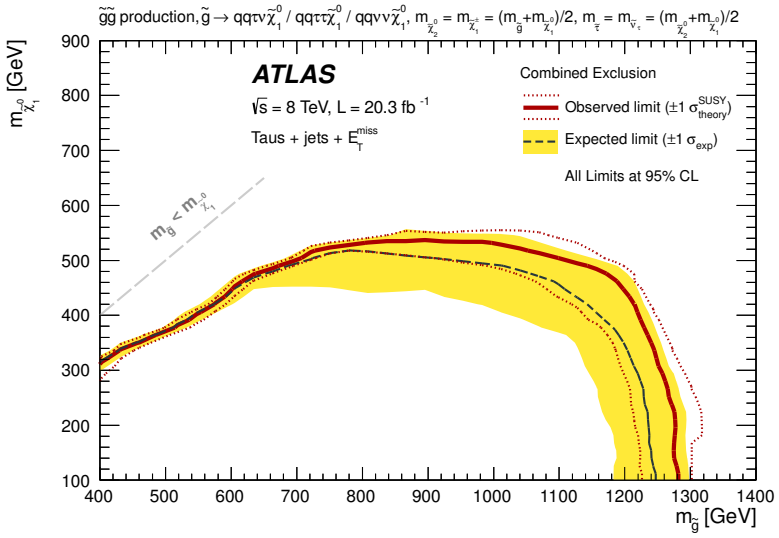

Figure 29. 95% CL exclusion limits in the $(m_{\tilde{g}}, m_{\tilde{\chi}_1^0})$ plane for a simplified model of gluino-pair production with two-step decay via staus. The solid red line and the dashed black line show respectively the observed and expected 95% CL exclusion limits.

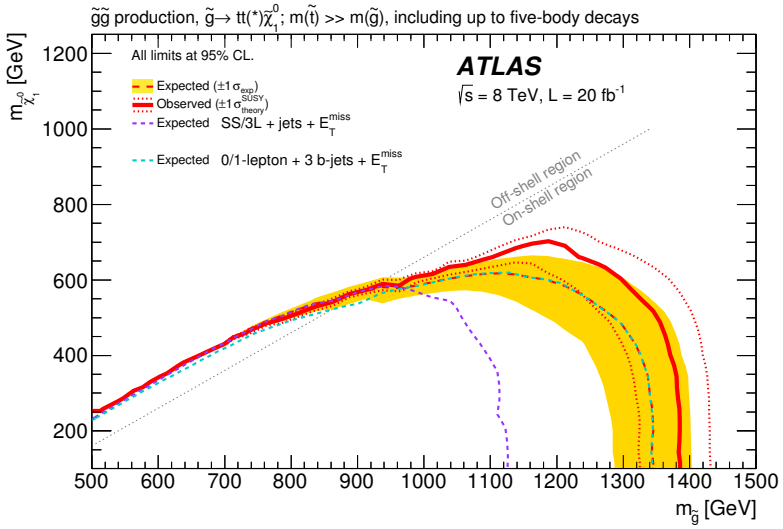

Figure 30. Exclusion limits in the $(m_{\tilde{g}}, m_{\tilde{\chi}_1^0})$ plane for the gluino-off-shell-stop simplified models in which the pair-produced gluinos decay via an off-shell stop, as $\tilde{g} \to t\bar{t}\tilde{\chi}_1^0$. In the region below the grey dashed line labelled "On-shell region", $m_{\tilde{g}} > 2m_t + m_{\tilde{\chi}_1^0}$ and thus gluinos decay to two real top quarks. In the "Off-shell region", $m_{\tilde{g}} < 2m_t + m_{\tilde{\chi}_1^0}$ and the decays of the gluino involve an off-shell top quark. Only four-body ($\tilde{g} \to tWb\tilde{\chi}_1^0$) and five-body ($\tilde{g} \to WbWb\tilde{\chi}_1^0$) decays are considered because for higher multiplicities the gluinos do not decay promptly. The solid red line and the dashed red line show respectively the combined observed and expected 95% CL exclusion limits. Expected limits from the individual analyses which contribute to the final combined limits are also shown for comparison.

JHEP10(2015)054

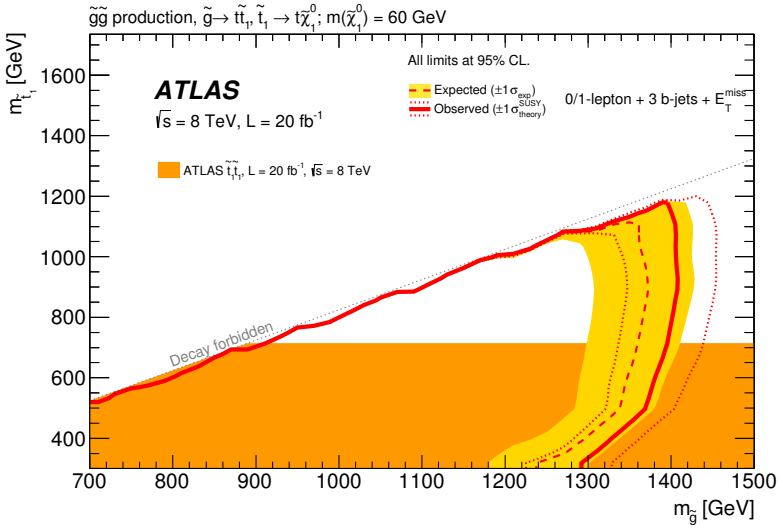

Figure 31. Exclusion limits in the $(m_{\tilde{g}}, m_{\tilde{t}_1})$ plane for the gluino-stop simplified models in which the top squarks are produced in the decay of pair-produced gluinos and decay via $\tilde{t}_1 \to t\tilde{\chi}_1^0$. The neutralino mass is set to 60 GeV. The solid red line and the dashed red line show respectively the combined observed and expected 95% CL exclusion limits. Also shown for reference is the limit from the ATLAS search for direct stop-pair production [18].

The exclusion limits for the gluino-stop simplified models are given in the $(m_{\tilde{g}}, m_{\tilde{t}_1})$ plane in figure 31. The $\tilde{t}_1$ is assumed to be the lightest squark while all other squarks are heavier than the gluino, and $m_{\tilde{g}} > m_{\tilde{t}_1} + m_t$ such that the branching ratio is 100% for $\tilde{g} \to \tilde{t}_1 t$ decays, and the top squark decays as $\tilde{t}_1 \to t\tilde{\chi}_1^0$. The 0/1L3B search provides the best sensitivity in these models, excluding gluino masses below 1220 GeV for stop masses up to 1000 GeV. Limits for the same class of simplified models, but assuming the $\tilde{t}_1 \to b\tilde{\chi}_1^{\pm}$ decay of the top squark, are also given in the $(m_{\tilde{g}}, m_{\tilde{t}_1})$ plane, and summarized in figure 32. The mass of the lightest neutralino in these models is set to 60 GeV, and the mass of the chargino is assumed to be twice the mass of the neutralino. The chargino decays into a neutralino and a virtual W boson. The strongest limits are provided by the 0/1L3B search. Compared to the models where the top squark decays via $\tilde{t}_1 \to t\tilde{\chi}_1^0$, presented in figure 31, the sensitivity in these models is lower for most of the parameter space where soft $E_{\mathrm{T}}^{\mathrm{miss}}$ and jets are expected from the chargino decay $\tilde{\chi}_1^{\pm} \to W^*\tilde{\chi}_1^0$. Gluino masses below 1180 GeV are excluded for stop masses up to 1000 GeV in these models.

Another possible decay of the top squark, $\tilde{t}_1 \to c\tilde{\chi}_1^0$, is considered within the same class of simplified models, with the mass difference between the $\tilde{t}_1$ and the lightest neutralino fixed to 20 GeV. The (0+1)-lepton combination provides the best sensitivity in these models. The 1L(S,H) search is complementary to the 0L search in that the expected limit for the single-lepton search is able to cover higher top squark masses at intermediate gluino masses (e.g. 80 GeV higher at $m_{\tilde{g}} = 900$ GeV). The resulting exclusion limit is presented in the $(m_{\tilde{g}}, m_{\tilde{t}_1})$ plane in figure 33, and reaches gluino masses up to 1260 GeV.

JHEP10(2015)054

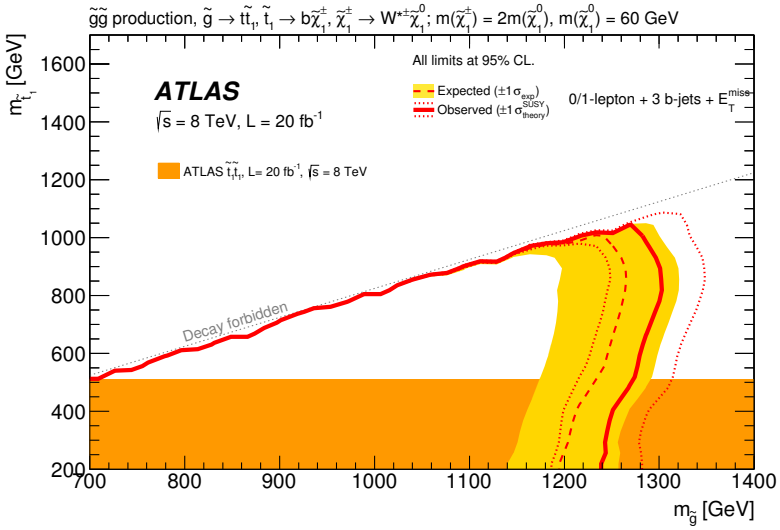

Figure 32. Exclusion limits in the $(m_{\tilde{g}}, m_{\tilde{t}_1})$ plane for the gluino-stop simplified models in which the top squarks are produced in the decay of pair-produced gluinos and decay via $\tilde{t}_1 \to b\tilde{\chi}_1^\pm$. The neutralino mass is set to 60 GeV and the mass of the chargino is assumed to be twice the mass of the neutralino. The solid red line and the dashed red line show respectively the combined observed and expected 95% CL exclusion limits. Also shown for reference is the limit from the ATLAS search for direct stop-pair production [18].

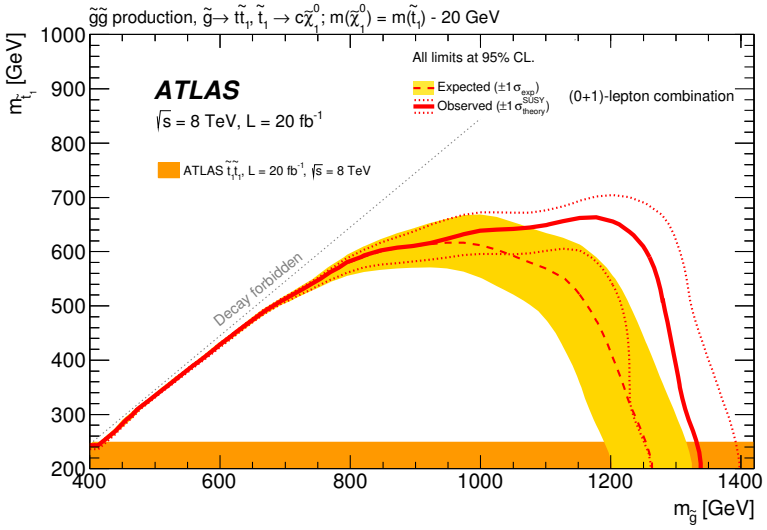

Figure 33. Exclusion limits in the $(m_{\tilde{g}}, m_{\tilde{t}_1})$ plane for the gluino-stop simplified models in which the top squarks are produced in the decay of pair-produced gluinos and decay via $\tilde{t}_1 \to c + \tilde{\chi}_1^0$. The mass difference between the $\tilde{t}_1$ and the lightest neutralino is fixed to 20 GeV. The solid red line and the dashed red line show respectively the combined observed and expected 95% CL exclusion limits. Also shown for reference is the limit from the ATLAS search for direct stop-pair production [18].

JHEP10(2015)054

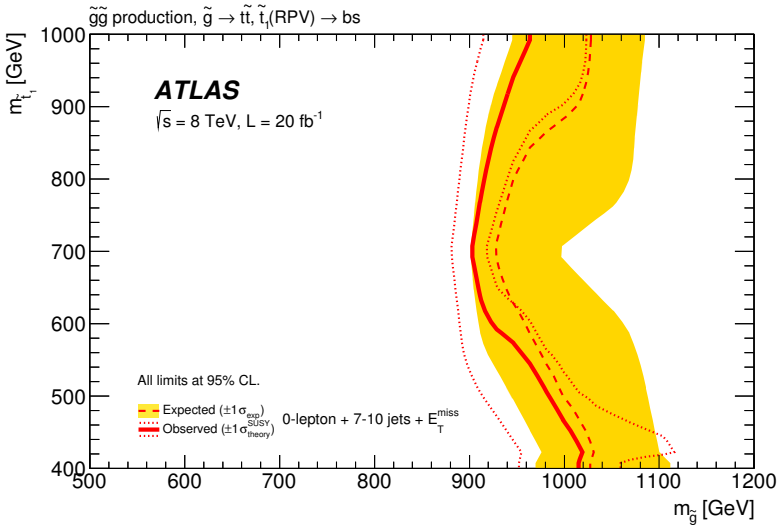

Figure 34. Exclusion limits in the $(m_{\tilde{g}}, m_{\tilde{t}_1})$ plane for the gluino-stop simplified models in which the top squarks are produced in the decay of pair-produced gluinos and decay via R-parity and baryon number violation $\tilde{t}_1 \to sb$. The solid red line and the dashed red line show respectively the combined observed and expected 95% CL exclusion limits. Expected limits from the individual analyses which contribute to the final combined limits are also shown for comparison.

A simplified model is also considered, in which the top squark decay, $\tilde{t}_1 \to sb$, involves R-parity and baryon number violation. The result is presented in the $(m_{\tilde{g}}, m_{\tilde{t}_1})$ plane in figure 34, where the best limit is obtained by the MULTJ search. Gluino masses below 880 GeV are excluded for top squark masses ranging from 400 GeV to 1000 GeV.

The sensitivity in the gluino-sbottom simplified models in which the branching ratio for $\tilde{g} \to \tilde{b}_1 b$ decays is 100% and the bottom squarks are assumed to decay exclusively via $\tilde{b}_1 \to b\tilde{\chi}_1^0$ is provided only by the 0/1L3B search [27] and the result is presented for completeness in figure 35. The search excludes gluino masses below 1200 GeV for sbottom masses up to about 1100 GeV.

The limits for the gluino-off-shell-sbottom simplified models, which assume 100% branching ratio for the gluino three-body decay $\tilde{g} \to b\bar{b}\tilde{\chi}_1^0$ via an off-shell sbottom, are given in the $(m_{\tilde{g}}, m_{\tilde{\chi}_1^0})$ plane in figure 36. The best sensitivities are provided by two searches, the 0/1L3B and the 0L search. The former is the most sensitive search in regions of the parameter space with a large mass splitting between the gluino and the lightest neutralino, and the latter in regions with a small mass splitting where softer jets and smaller $E_{\mathrm{T}}^{\mathrm{miss}}$ are expected in the final state. In these models, gluino masses below 1250 GeV are excluded for $m_{\tilde{\chi}_1^0} < 400$ GeV while neutralino masses below 600 GeV are excluded in the gluino mass range between 700 and 1200 GeV.

The sensitivity in the gluino-off-shell-stop/sbottom simplified models in which gluinos decay via virtual stops or sbottoms is provided only by the 0/1L3B search [27]. Here the mass difference between the particles is set such that the gluino decays result in an effectively three-body final state $(bt\tilde{\chi}_1^0)$. The exclusion limit is presented in figure 37 for completeness. For neutralino masses of 500 GeV, gluino masses are excluded between 750 and 1250 GeV.

JHEP10(2015)054

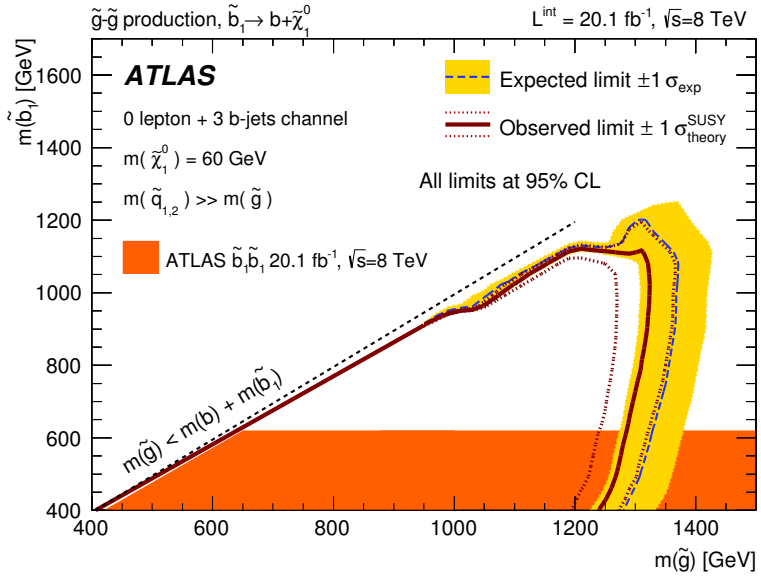

Figure 35. Exclusion limits in the $(m_{\tilde{g}}, m_{\tilde{b}_1})$ plane for the gluino-sbottom simplified models, taken from ref. [27]. Also shown for reference is the limit from the ATLAS search for direct sbottom-pair production [18].

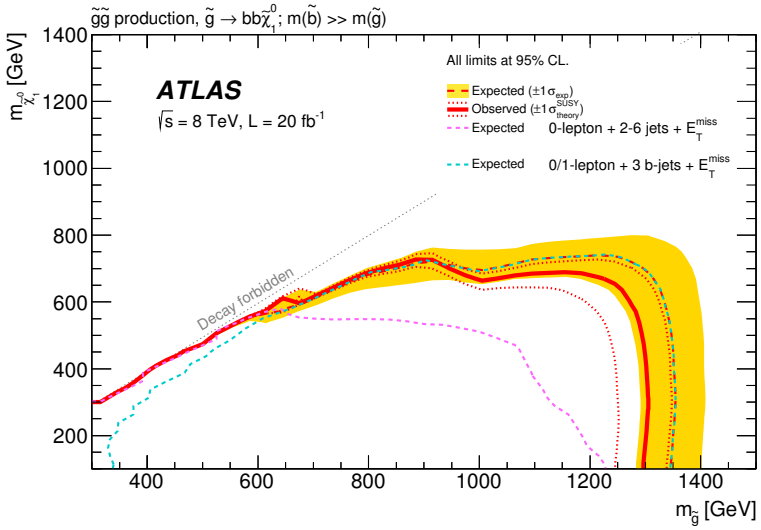

Figure 36. Exclusion limits in the $(m_{\tilde{g}}, m_{\tilde{\chi}_1^0})$ plane for the gluino-off-shell-sbottom simplified models in which the pair-produced gluinos decay via an off-shell sbottom as $\tilde{g} \to b\bar{b}\tilde{\chi}_1^0$. The solid red line and the dashed red line show respectively the combined observed and expected 95% CL exclusion limits. Expected limits from the individual analyses which contribute to the final combined limits are also shown for comparison.

JHEP10(2015)054

12 Conclusions

A search for squarks and gluinos in inclusive final states containing high-p_{T} jets and missing transverse momentum, with or without leptons or b-jets, is presented. The data were recorded in 2012 by the ATLAS experiment with $\sqrt{s} = 8\,\mathrm{TeV}$ proton-proton collisions at the Large Hadron Collider, with a total integrated luminosity up to $20.3\,\mathrm{fb}^{-1}$. Earlier ATLAS searches have been extended and combined with new search techniques, thus improving the sensitivity for supersymmetric models. Good agreement is found with the predictions from SM processes. The data are therefore used to set exclusion limits for a variety of simplified and phenomenological SUSY models.

Limits in simplified models with gluinos and squarks of the first and second generations are derived for direct and one- or two-step decays of squarks and gluinos, and gluino decays via third-generation squarks. In all the considered simplified models that assume R-parity conservation, the limit on the gluino mass exceeds 1150 GeV at 95% CL, for an LSP mass smaller than 100 GeV. Additional limits are set in a phenomenological MSSM model used in the search for left-handed squarks, a minimal Supergravity/Constrained MSSM model, R-parity-violation scenarios, a minimal gauge-mediated supersymmetry breaking model, a natural gauge mediation model, a non-universal Higgs mass model with gaugino mediation and a minimal model of universal extra dimensions. These limits are either new or extend the region of parameter space excluded by previous searches with the ATLAS detector.

Acknowledgments

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently.

A Extension of the $\tilde{g} \to t\bar{t}\tilde{\chi}_1^0$ simplified model to include decays with off-shell top quarks

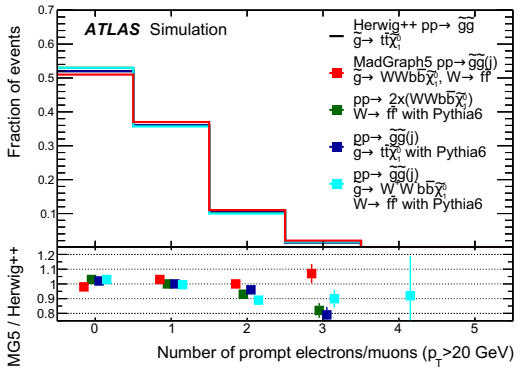
In this appendix, further details are provided about the extension of the gluino-mediated off-shell stop model $\tilde{g} \to t\bar{t}\tilde{\chi}_1^0$ to the region $m_t + m_W + m_b \leq m_{\tilde{g}} - m_{\tilde{\chi}_1^0} \leq 2m_t$, where three-body decays are replaced by more complex multi-body decays proceeding via off-shell top quarks and W bosons. This region is delimited by the kinematic boundaries corresponding to three- and four-body gluino decays. In principle, the extension could have been performed up to mass gaps as small as $m_{\tilde{g}} - m_{\tilde{\chi}_1^0} \geq 2m_b$, but it was found that for a 100% branching ratio hypothesis for the $\tilde{g} \to t\bar{t}\tilde{\chi}_1^0$ mode, mass gaps smaller than the four-body kinematic bound quickly lead to large gluino lifetimes, resulting in displaced gluino decays. This is verified even in the scenario leading to the smallest gluino lifetime ($m_{\tilde{t}_1} = m_{\tilde{g}}$, $\tilde{t}_1 = \tilde{t}_R$). Since the results of the various searches reported in this paper are all based on prompt objects, the expected sensitivity to these scenarios with small mass gaps is very small, and they are addressed by dedicated searches [157]. Therefore, the probed parameter space is limited to $m_{\tilde{g}} - m_{\tilde{\chi}_1^0} \geq m_t + m_W + m_b$.

Despite the restriction of the model parameter space to regions where four-body gluino decays $\tilde{g} \to tWb\tilde{\chi}_1^0$ are always kinematically allowed, more complex decays (mainly five-body) can occur concurrently with a significant branching ratio, and even become dominant when the mass gap approaches its lower bound. Consideration of these alternative decay modes also sometimes leads to large differences in kinematic distributions of the decay products. For example, the b-quark in the decay $\tilde{g} \to tWb\tilde{\chi}_1^0$ becomes too soft for ex-

JHEP10(2015)054

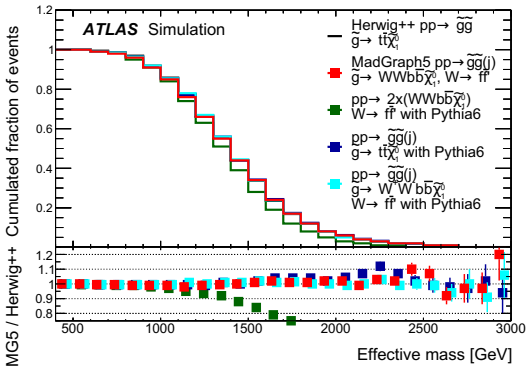
perimental detection when $m_{\tilde{g}} \approx m_t + m_W + m_b + m_{\tilde{\chi}_1^0}$, whereas it can still get sizeable momentum in the alternative decay $\tilde{g} \to WWbb\tilde{\chi}_1^0$. Since the most sensitive searches for this model rely on selections with at least three b-jets, one can see that the acceptance of these selections would vanish at the kinematic bound if considering only four-body decays, although it is not the case thanks to the alternative decay modes. To summarize, quantitative studies showed that it is important to consider at least the five-body decay as well in this region of the parameter space.

Finally, signal events were generated following a configuration defined and validated by comparing generator predictions for several observables in a region at low neutralino mass where only three-body decays contribute. The reference was provided by Herwig++ (the generator used for the $m_{\tilde{g}} - m_{\tilde{\chi}_1^0} > 2m_t$ region of this scenario), characterized notably by the use of a matrix element amplitude for the gluino decay, and the preservation of spin correlation between the decay products. It was first observed that narrow-width approximations for the gluino decay compared poorly to the reference, hence imposing the need for decay amplitudes computed from matrix elements for the four- and five-body decays, and as a consequence the choice of the Madgraph generator. However, the computing requirements to obtain the amplitude associated with such a $2 \to 10\,(+1)$ hard process (with an extra parton) are too demanding. An approximation is used instead, consisting in the separate generation of pair-produced gluinos, and gluino decays into fermions $\tilde{g} \to f\bar{f}'f''\bar{f}'''bb\tilde{\chi}_1^0$. The two stages are then combined by boosting the gluino decay products according to the gluino's directions and momenta defined by the hard process, while preserving the gluino spin orientations. The use of the inclusive seven-body gluino decay, instead of the minimally required five-body decay, came at no additional computing cost and allowed, in particular, proper propagation of the various spin correlations along the gluino decay chain. This setup provided agreement with the reference at the level of 5%, for the shapes of various generator-level kinematic distributions (a few of which are presented in figure 38), as well as for fiducial acceptances of typical event selections used as signal regions in the relevant SUSY searches.



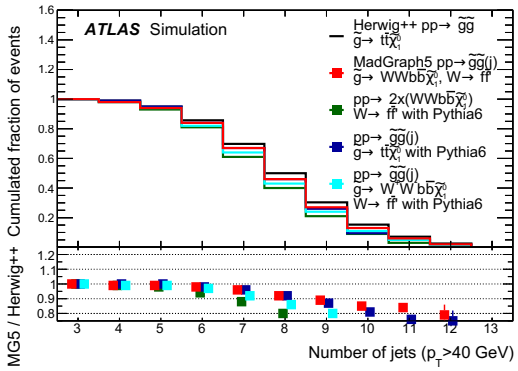
B Summary of selection criteria

Tables 14–22 summarize the selection criteria for signal regions listed in table 5 which have been defined in previous ATLAS publications [20–27].

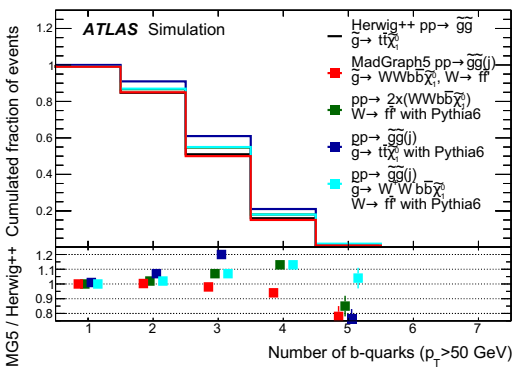


C 0-lepton Razor analysis details

Many kinematical variables have been used to search for SUSY at hadron colliders, typically making use of the expected heavy mass scale of the SUSY particles produced, and the missing transverse momentum originating from the LSP. The analysis described here searches for squarks in final states with high-p_{T} jets, missing transverse momentum and no electrons or muons, using the Razor variable set [19]. These variables provide longitudinal and transverse information about each event, contribute to the rejection of the background from the multi-jet processes that dominate hadronic collisions, and can be used as an approximation of the mass scale of the produced particles.



JHEP10(2015)054



(a) Distribution of the number of prompt leptons (electrons and muons), $p_{\mathrm{T}} > 20\,\mathrm{GeV}$, $|\eta| < 2.5$.

(b) Cumulative distribution of the effective mass built from selected leptons, jets and non-interacting particles.

(c) Cumulative distribution of the number of jets (anti-k_t algorithm, $R = 0.4$), $p_{\mathrm{T}} > 40\,\mathrm{GeV}$, $|\eta| < 2.8$.

(d) Cumulative distribution of the number of b-quarks, $p_{\mathrm{T}} > 50\,\mathrm{GeV}$, $|\eta| < 2.5$.

Figure 38. Validation of the MadGraph5+Pythia6 setup used to generate five-body gluino decays $\tilde{g} \to W^+W^-b\bar{b}\tilde{\chi}_1^0$: kinematic distributions obtained with the nominal configuration (red markers) are compared to the reference Herwig++ sample (black), for a signal scenario featuring only three-body gluino decays $\tilde{g} \to t\bar{t}\tilde{\chi}_1^0$ ($m_{\tilde{g}} = 1\,\mathrm{TeV}$, $m_{\tilde{\chi}_1^0} = 100\,\mathrm{GeV}$). A few alternative (and simpler) generator configurations are also shown (other coloured markers), but they fail to reach a satisfactory level of agreement with the reference, for the typical signal region requirements (cf. SR3b in table 20). The distributions are built from the outgoing particles provided by the generators.

The basic analysis approach relies on the definition of statistically independent regions in the Razor variable phase space, R and M_R', explained in details in the remainder of this section, that are rich in SUSY-like events, and other regions, each dominated by one SM background component. Following the strategy explained in section 6, the Monte Carlo expectations are normalized to the data in each background control region, and those normalization factors are then transferred to the MC prediction in the SUSY signal regions. The baseline object selection and event cleaning, as well as the choice of MC generators for SM background processes and the approach for calculating systematic uncertainties exactly follow those of the 0-lepton + 2–6 jets + $E_{\mathrm{T}}^{\mathrm{miss}}$ (0L) search [20], and are not discussed here.

$E_{\mathrm{T}}^{\mathrm{miss}}$ [GeV] >	220	340	450
$\Delta\phi(\mathrm{jet}, \boldsymbol{E}_{\mathrm{T}}^{\mathrm{miss}})$ >	0.4		

Table 14. Selection criteria used to define the three signal regions in the search with at least one high-p_{T} jet and large missing transverse momentum (Monojet) [21]. The azimuthal separation $\Delta\phi(\mathrm{jet}, \boldsymbol{E}_{\mathrm{T}}^{\mathrm{miss}})$ is calculated between the missing transverse momentum direction and each of the selected jets.

C.1 The Razor variables

The Razor variable set is designed to group together visible final-state particles associated with heavy produced sparticles, and in doing so contains information about the mass scale of the directly produced sparticles. The final-state jets are grouped into two hemispheres called "mega-jets", where all visible objects from one side of the di-sparticle decay are collected together to create a single four-vector, representing the decay products of a single sparticle. The mega-jet construction involves iterating over all possible combinations of the four-vectors of the visible reconstructed objects, with the favoured combination being that which minimizes the sum of the squared masses of the mega-jet four-vectors. Using this mega-jet configuration, with some simplifying assumptions (e.g. symmetric sparticle production), the rest frame of the sparticles (the so-called "R-frame" described in ref. [19]) can be reconstructed, and a characteristic mass M_R' can be defined in this frame:

$$M_R' = \sqrt{(j_{1,E} + j_{2,E})^2 - (j_{1,\mathrm{L}} + j_{2,\mathrm{L}})^2}, \tag{C.1}$$

where $j_{i,\mathrm{L}}$ denotes the longitudinal momentum, and $j_{i,E}$ the energy in the R-frame, of the mega-jet i.

To help reduce the SM backgrounds, a second variable, M_{T}^R, is defined that includes information about the transverse quantities, including the total missing transverse momentum and its angular distance to the two mega-jets. In the di-sparticle decay there are two mega-jets, each with associated $E_{\mathrm{T}}^{\mathrm{miss}}$ from the escaping LSPs. Assigning half of the missing transverse momentum per event to each of the LSPs, M_{T}^R is defined as

$$M_{\mathrm{T}}^R = \sqrt{\frac{E_{\mathrm{T}}^{\mathrm{miss}}(j_{1,\mathrm{T}} + j_{2,\mathrm{T}}) - \boldsymbol{E}_{\mathrm{T}}^{\mathrm{miss}} \cdot (\boldsymbol{j}_{1,\mathrm{T}} + \boldsymbol{j}_{2,\mathrm{T}})}{2}}, \tag{C.2}$$

where $\boldsymbol{j}_{i,\mathrm{T}}$ denotes the transverse momentum of the mega-jet i. The variable M_{T}^R is designed such that for small values of $E_{\mathrm{T}}^{\mathrm{miss}}$, M_{T}^R is also small. If the multi-jet event were perfectly re-

Table 15. Selection criteria used to define the fifteen signal regions in the search with at least two to at least six jets, significant $E_{\mathrm{T}}^{\mathrm{miss}}$ and the absence of isolated electrons or muons (0-lepton + 2–6 jets + $E_{\mathrm{T}}^{\mathrm{miss}}$) [20]. Each signal region is labelled with the inclusive jet multiplicity considered ('2j', '3j', etc.) together with the degree of background rejection. The latter is denoted by labels 'l-' ('very loose'), 'l' ('loose'), 'm' ('medium'), 't' ('tight') and 't+' ('very tight'). The $E_{\mathrm{T}}^{\mathrm{miss}}/m_{\mathrm{eff}}^{N_{\mathrm{j}}}$ requirement in any N_{j}-jet channel uses a value of m_{eff} constructed from only the leading N_{j} jets ($m_{\mathrm{eff}}^{N_{\mathrm{j}}}$). The final $m_{\mathrm{eff}}^{\mathrm{incl}}$ selection, which is used to define the signal regions, includes all jets with $p_{\mathrm{T}} > 40\,\mathrm{GeV}$. The variable H_{T} is defined as the scalar sum of the transverse momenta of all jets with $p_{\mathrm{T}} > 40\,\mathrm{GeV}$. The azimuthal separation $\Delta\phi(\mathrm{jet}, \boldsymbol{E}_{\mathrm{T}}^{\mathrm{miss}})_{\mathrm{min}}$ is defined to be the smallest of the azimuthal separations between $\boldsymbol{E}_{\mathrm{T}}^{\mathrm{miss}}$ and the reconstructed jets. In SR 2jW and SR 4jW a requirement $60\,\mathrm{GeV} < m(W_{\mathrm{cand}}) < 100\,\mathrm{GeV}$ is placed on the masses of candidate resolved or unresolved hadronically decaying W bosons. Candidate W bosons are reconstructed from single high-mass jets (unresolved candidates; $W \to j$ in the table) or from pairs of jets (resolved candidates; $W \to jj$ in the table.

Requirement	Signal regions in multi-jet + flavour stream														
	8j50			**9j50**			**10j50**	**7j80**			**8j80**				
$\|\eta\|^{\text{jet}}$ <	2.0														
$p_{\text{T}}^{\text{jet}}$ [GeV] >	50							80							
N_{jet}	= 8			= 9			≥ 10	= 7			≥ 8				
$N_{b-\text{jet}}$ ($p_{\text{T}} > 40\,\text{GeV}, \|\eta\| < 2.5$)	0	1	≥ 2	0	1	≥ 2	—	0	1	≥ 2	0	1	≥ 2		
$E_{\text{T}}^{\text{miss}}/\sqrt{H_{\text{T}}}$ [GeV$^{1/2}$] >	4														

Requirement	Signal regions in multi-jet + M_J^{Σ} stream		
	8j50	**9j50**	**10j50**
$\|\eta\|^{\text{jet}}$ <	2.8		
$p_{\text{T}}^{\text{jet}}$ [GeV] >	50		
N_{jet}	≥ 8	≥ 9	≥ 10
M_J^{Σ} [GeV]	> 340 and > 420 for each case		
$E_{\text{T}}^{\text{miss}}/\sqrt{H_{\text{T}}}$ [GeV$^{1/2}$] >	4		

Table 16. Selection criteria used to define the nineteen signal regions in the search with at least seven to at least ten jets, significant $E_{\text{T}}^{\text{miss}}$ and the absence of isolated electrons or muons (0-lepton + 7–10 jets + $E_{\text{T}}^{\text{miss}}$) [22]. The four-momenta of the R=0.4 jets satisfying $p_{\text{T}} > 20\,\text{GeV}$ and $|\eta| < 2.8$ are used as inputs to a second iteration of the anti-k_t jet algorithm, this time using the larger distance parameter R=1.0. The resulting larger objects are denoted as composite jets. The selection variable M_J^{Σ} is then defined to be the sum of the masses of the composite jets: $M_J^{\Sigma} \equiv \sum_j m_j^{R=1.0}$, where the sum is over the composite jets that satisfy $p_{\text{T}}^{R=1.0} > 100\,\text{GeV}$ and $|\eta^{R=1.0}| < 1.5$. The variable H_{T} is defined as the scalar sum of p_{T} of all jets with $p_{\text{T}} > 40\,\text{GeV}$ and $|\eta|$ <2.8.

constructed then $E_{\text{T}}^{\text{miss}} = 0$ and M_{T}^R would also be zero, while in the case where a jet is mis-calibrated, the fake $\boldsymbol{E}_{\text{T}}^{\text{miss}}$ tends to align with one of the mega-jets (that are back-to-back), also creating small values of M_{T}^R. For SUSY-like events where the mega-jets tend not to be back-to-back, and their vector sum is opposite to the $\boldsymbol{E}_{\text{T}}^{\text{miss}}$, the quantity M_{T}^R is large. The kinematic endpoint of M_{T}^R is the mass difference between the heavy and the light sparticles.

Finally, the razor variable is defined as:

$$R = \frac{M_{\text{T}}^R}{M_R'}. \tag{C.3}$$

For SUSY-like events, when the mass splitting between the heavier and light sparticles is large, M_R' peaks near the mass of the heavier sparticle and M_{T}^R has a kinematical endpoint at the mass of the heavier sparticle. For SM processes, R tends to have a low value, while it tends to have a broad distribution centred around 0.5 for SUSY-like events. Thus R can be used as a discriminant between signal and background.

Table 17. Selection criteria used to define the signal regions in the search requiring at least one isolated lepton (1-lepton (soft+hard) + jets + $E_{\mathrm{T}}^{\mathrm{miss}}$) and in the search requiring two soft muons (2-leptons + jets + $E_{\mathrm{T}}^{\mathrm{miss}}$) [23]. For each jet multiplicity in the single-lepton channel, two sets of requirements are defined: one single-bin signal region optimized for discovery reach, which is also used to place limits on the visible cross-section, and one signal region which is binned in an appropriate variable in order to exploit the expected shape of the distribution of signal events when placing model-dependent limits. The requirements of the binned signal region are shown in parentheses when they differ from those of the single-bin signal region. The transverse mass (m_{T}) of the lepton (ℓ) and $\boldsymbol{E}_{\mathrm{T}}^{\mathrm{miss}}$ is defined as $m_{\mathrm{T}} = \sqrt{2p_{\mathrm{T}}^{\ell}E_{\mathrm{T}}^{\mathrm{miss}}(1-\cos[\Delta\phi(\vec{\ell},\boldsymbol{E}_{\mathrm{T}}^{\mathrm{miss}})])}$. The inclusive effective mass ($m_{\mathrm{eff}}^{\mathrm{inc}}$) is computed as the scalar sum of the p_{T} of the lepton(s), the jets and $E_{\mathrm{T}}^{\mathrm{miss}}$: $m_{\mathrm{eff}}^{\mathrm{inc}} = \sum_{i=1}^{N_\ell} p_{\mathrm{T},i}^{\ell} + \sum_{j=1}^{N_{\mathrm{jet}}} p_{\mathrm{T},j} + E_{\mathrm{T}}^{\mathrm{miss}}$, where the index i identifies all the signal leptons and the index j all the signal jets in the event. The exclusive effective mass ($m_{\mathrm{eff}}^{\mathrm{excl}}$) is defined in a similar way to $m_{\mathrm{eff}}^{\mathrm{inc}}$, with the exception that only the three leading signal jets are considered. The minimum angular separation ΔR_{min} calculated between the signal lepton ℓ and all preselected jets is used to reduce the background coming from misidentified or non-prompt leptons in the soft-lepton signal region with three jets and in the soft dimuon signal region. In the latter case, the subleading signal muon is used to compute ΔR_{min}.

Table 19. Selection criteria used to define the signal regions in the search requiring two same-flavour opposite-sign electrons or muons (2-leptons off-Z) [24]. If more than two leptons are present, the two with the largest values of p_{T} are selected. The leading lepton in the event must have $p_{\mathrm{T}} > 25$ GeV and the subleading lepton is required to have $p_{\mathrm{T}} > 20$ GeV. These two leptons are used to define the dilepron invariant mass, $m_{\ell\ell}$. In addition, one SR with the same requirements as those used in the CMS search [148], which reported an excess of events above the SM background with a significance of 2.6 standard deviations, is defined (SR-loose) for comparison purposes.

Table 20. Selection criteria used to define the signal regions in the search with multiple jets, and either two leptons of the same electric charge (same-sign leptons) or at least three leptons (SS/3L + jets + $E_{\text{T}}^{\text{miss}}$) [25]. The effective mass (m_{eff}) is computed from all selected leptons and selected jets in event, as $m_{\text{eff}} = \sum_{i=1}^{N_\ell} p_{\text{T},i}^{\ell} + \sum_{j=1}^{N_{\text{jet}}} p_{\text{T},j} + E_{\text{T}}^{\text{miss}}$. The transverse mass ($m_{\text{T}}$) is computed from the highest-p_{T} lepton (ℓ_1) and $\boldsymbol{E}_{\text{T}}^{\text{miss}}$ as $m_{\text{T}} = \sqrt{2p_{\text{T}}^{\ell_1} E_{\text{T}}^{\text{miss}}(1 - \cos[\Delta\phi(\vec{\ell_1}, \boldsymbol{E}_{\text{T}}^{\text{miss}})])}$.

C.2 Signal regions

The SUSY models targeted by this search are expected to have final states characterized by the presence of jets, missing transverse momentum, and no leptons. In the simplest case of squark-pair production with direct decays to quarks and neutralinos, there are at least two jets visible in the detector, so the baseline inclusive signal regions require at least two jets. This is also the minimum number of visible objects in the final state necessary to construct the Razor variables. Figure 39 shows the values of R and M_R' for two simplified model signal points, one with $m_{\tilde{q}} = 450\,\text{GeV}$ and $m_{\text{LSP}} = 400\,\text{GeV}$, where the $\Delta m = 50\,\text{GeV}$ is small (referred to as small-Δm_{signal}) and the other with $m_{\tilde{q}} = 850\,\text{GeV}$ and $m_{\text{LSP}} = 100\,\text{GeV}$, where the $\Delta m = 750\,\text{GeV}$ is large (referred to as large-Δm_{signal}), after requiring no leptons and at least two jets in the final state.

Since the variable M_R' is related to the mass difference between the squark and the neutralino, going from the small-Δm_{signal} to the large-Δm_{signal}, the events tend to populate higher M_R' regions. Extending this to all points of the model with squark-pair production followed by the direct decay of squarks, the average value of M_R' is approximately constant for a fixed mass splitting between the LSP and the squark, and increases with increasing Δm, while the average R-value tends to be around 0.5.

To select events for this search, the combination of two $E_{\text{T}}^{\text{miss}}$ triggers, which are fully efficient in events having offline reconstructed $E_{\text{T}}^{\text{miss}} > 160\,\text{GeV}$ is used. Two signal regions which target different regions of the $(m_{\tilde{q}}, m_{\tilde{\chi}_1^0})$ plane are defined: SR_{loose} and SR_{tight}. Signal region SR_{loose} has a lower requirement on R and targets regions of the $(m_{\tilde{q}}, m_{\tilde{\chi}_1^0})$ plane with small mass splitting, which typically have softer visible objects. Signal region SR_{tight} was chosen to target high squark masses which typically contain harder visible objects. An overview of the selection criteria for these two signal regions is given in table 9.

Table 21. Selection criteria used to define the signal regions in the search requiring large missing transverse momentum, jets and at least one hadronically decaying tau lepton (taus + jets + $E_{\text{T}}^{\text{miss}}$) [26]. The transverse mass m_{T}^{τ} is formed from the $\boldsymbol{E}_{\text{T}}^{\text{miss}}$ and the p_{T} of the tau lepton in the 1τ channel as: $m_{\text{T}}^{\tau} = \sqrt{2p_{\text{T}}^{\tau}E_{\text{T}}^{\text{miss}}(1 - \cos(\Delta\phi(\tau, \boldsymbol{E}_{\text{T}}^{\text{miss}})))}$. In addition, the variable $m_{\text{T}}^{\tau_1}+m_{\text{T}}^{\tau_2}$ is used as a discriminating variable in the 2τ channel. The transverse mass m_{T}^{ℓ} is similarly formed from the $\boldsymbol{E}_{\text{T}}^{\text{miss}}$ and the p_{T} of the light leptons. The variable H_{T} is defined as the scalar sum of the transverse momenta of the tau, light lepton and jets ($p_{\text{T}}^{\text{jet}} > 30\,\text{GeV}$): $H_{\text{T}} = \sum_{i=1}^{N_\ell} p_{\text{T}}^{\ell} + \sum_{j=1}^{N_\tau} p_{\text{T}}^{\tau} + \sum_{k=1}^{N_{\text{jet}}} p_{\text{T}}^{\text{jet}}$. The variable H_{T}^{2j} is defined as the scalar sum of the transverse momenta of the tau and light lepton candidates, and the two jets with the largest transverse momenta in the event: $H_{\text{T}}^{\text{2j}} = \sum_{i=1}^{N_\ell} p_{\text{T}}^{\ell} + \sum_{j=1}^{N_\tau} p_{\text{T}}^{\tau} + \sum_{k=1,2} p_{\text{T}}^{\text{jet}_k}$. The effective mass ($m_{\text{eff}}$) is defined as $m_{\text{eff}} = H_{\text{T}}^{\text{2j}}+E_{\text{T}}^{\text{miss}}$.

Table 22. Selection criteria used to define the signal regions in the search that requires at least three jets tagged as b-jets, no or at least one lepton, jets and large missing transverse momentum (0/1-lepton + 3b-jets + $E_{\mathrm{T}}^{\mathrm{miss}}$) [27]. The jet p_{T} threshold requirements are also applied to b-jets. The notation SR-0ℓ-4j-C* means that the leading jet is required to fail the b-tagging requirements, in order to target the region close to the kinematic boundary in the gluino-sbottom simplified models. In the 0-lepton selection, the inclusive effective mass $m_{\mathrm{eff}}^{\mathrm{incl}}$ is defined as the scalar sum of the $E_{\mathrm{T}}^{\mathrm{miss}}$ and the p_{T} of all jets with $p_{\mathrm{T}} > 30\,\mathrm{GeV}$. In the 1-lepton selection the $m_{\mathrm{eff}}^{\mathrm{incl}}$ is defined as for the 0-lepton selection with the addition of the p_{T} of all selected leptons with $p_{\mathrm{T}} > 20\,\mathrm{GeV}$. The exclusive effective mass ($m_{\mathrm{eff}}^{\mathrm{4j}}$) is defined as the scalar sum of the $E_{\mathrm{T}}^{\mathrm{miss}}$ and the p_{T} of the four leading jets. The transverse mass (m_{T}) is computed from the leading lepton and the missing transverse momentum. The variable $H_{\mathrm{T}}^{\mathrm{4j}}$ is defined as the scalar sum of the transverse momenta of the four leading jets.

C.3 Control and validation regions for SM background processes

The dominant SM background processes which contribute to the event counts in the signal regions are: Z+jets, W+jets, top quark pairs, and multiple jets. For each of these processes a dedicated control region is defined. The production of boson (W/Z) pairs in which at least one boson decays to charged leptons and/or neutrinos (referred to as 'dibosons' below), the single-top production, and the $t\bar{t}+W/Z$ boson production are small components of the total background and are estimated with MC simulated data.

Figure 40 shows the values of R and M_R' for the major SM backgrounds in this search. As previously discussed, the SM backgrounds tend to occupy regions with lower values of M_R' and R, which is taken into account while defining control regions for the main background processes. A summary of the selection criteria used to define the control and validation regions in this search is shown in table 23.

The largest potential background for a search with no leptons is expected to originate from the QCD-induced multi-jet event. However, the Razor variables were constructed

Table 23. Overview of the selection criteria for the Z+jets, W+jets, semileptonic $t\bar{t}$ and multi-jet control regions (0LRaz_CRZ, 0LRaz_CRW, 0LRaz_CRT and 0LRaz_CRQ$_{\text{loose/tight}}$ respectively) and the corresponding validation regions (0LRaz_VRZ, 0LRaz_VRW, 0LRaz_VRT, 0LRaz_VRQ$_{\text{loose/tight}}$) used by the 0-lepton Razor analysis. Details of the construction of Razor variables $M_R^{'}$ and R can be found in the appendix C.1.

JHEP10(2015)054

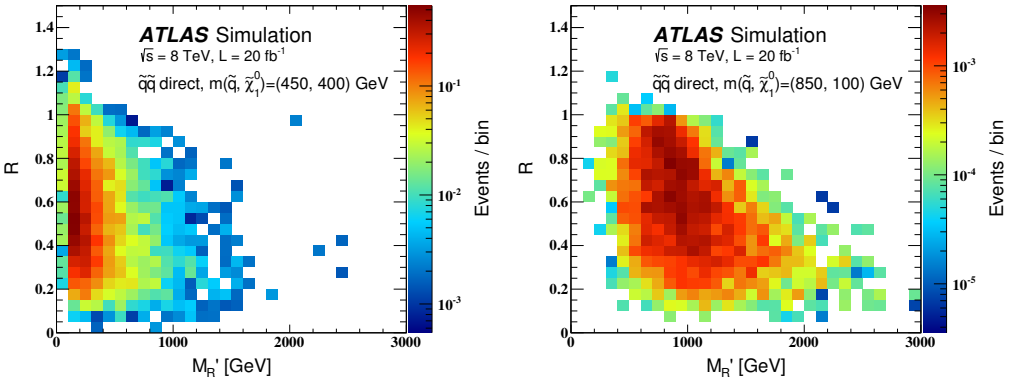

Figure 39. Distributions of the Razor variable R versus the characteristic mass in the R-frame M'_R for two points of the simplified model with squark-pair production assuming the direct decay of squarks, after requiring no leptons and at least two jets. Figure (a) shows the case where $m_{\tilde{q}} = 450\,\text{GeV}$ and $m_{\text{LSP}} = 400\,\text{GeV}$, and (b) where $m_{\tilde{q}} = 850\,\text{GeV}$ and $m_{\text{LSP}} = 100\,\text{GeV}$.

to be able to distinguish this background from a SUSY-like signal, which minimizes the contribution of the multi-jet events after the SR event selection has been applied. To estimate the contribution of multi-jet background events in the final signal region selection, a data-driven technique [156], which applies a resolution function to well-measured multi-jet events in order to estimate the impact of jet energy mis-measurement and heavy-flavour semileptonic decays on $E_{\text{T}}^{\text{miss}}$ and other variables, is used. Two dedicated control regions, $\text{CRQ}_{\text{loose}}$ and $\text{CRQ}_{\text{tight}}$, which use different selection criteria on R and $\Delta\phi(p_T^{j2}, E_{\text{T}}^{\text{miss}})$, correspond to the loose and tight signal regions respectively, and select samples of events with similar kinematics to the SR but enriched in multi-jet background events.

Since the QCD multi-jet background is significantly reduced by use of the Razor variables, the largest remaining backgrounds come from the production of W/Z bosons with additional jets and semileptonic $t\bar{t}$ decays, where the leptons can be mis-reconstructed as jets, non-prompt or be outside the lepton identification criteria. For each of these backgrounds a control region, rich in the respective process, is defined. The trigger requirements for these lepton-rich control regions follow those used by the corresponding control regions for the the 0L search [20]. The Razor variables are used to preselect a region which is dominated by the particular process. Following this preselection, to control the $t\bar{t}$ background, the control region CRT requires at least one jet tagged as a b-jet and exactly one electron or muon, while the W+jets control region, CRW, applies a veto on the presence of b-jets and requires exactly one electron or muon. In both cases the lepton is treated as a jet in the reconstruction of the Razor variables. This treatment of leptons as jets is motivated by the observation that ∼75% of $\text{W}(\rightarrow \ell\nu)$+jets and semileptonic $t\bar{t}$ events appearing in the SRs possess leptons which have fake jets, either through the misidentification of electrons or by the production of tau leptons decaying hadronically (identification of hadronic tau decays is not used in this analysis). The Z+jets control region, CRZ, is required to have exactly two opposite-sign same-flavour leptons. The Z+jets contribution to the signal region largely originates from Z decays to neutrinos. To mimic the behaviour of $Z \rightarrow \nu\nu$ in the

JHEP10(2015)054

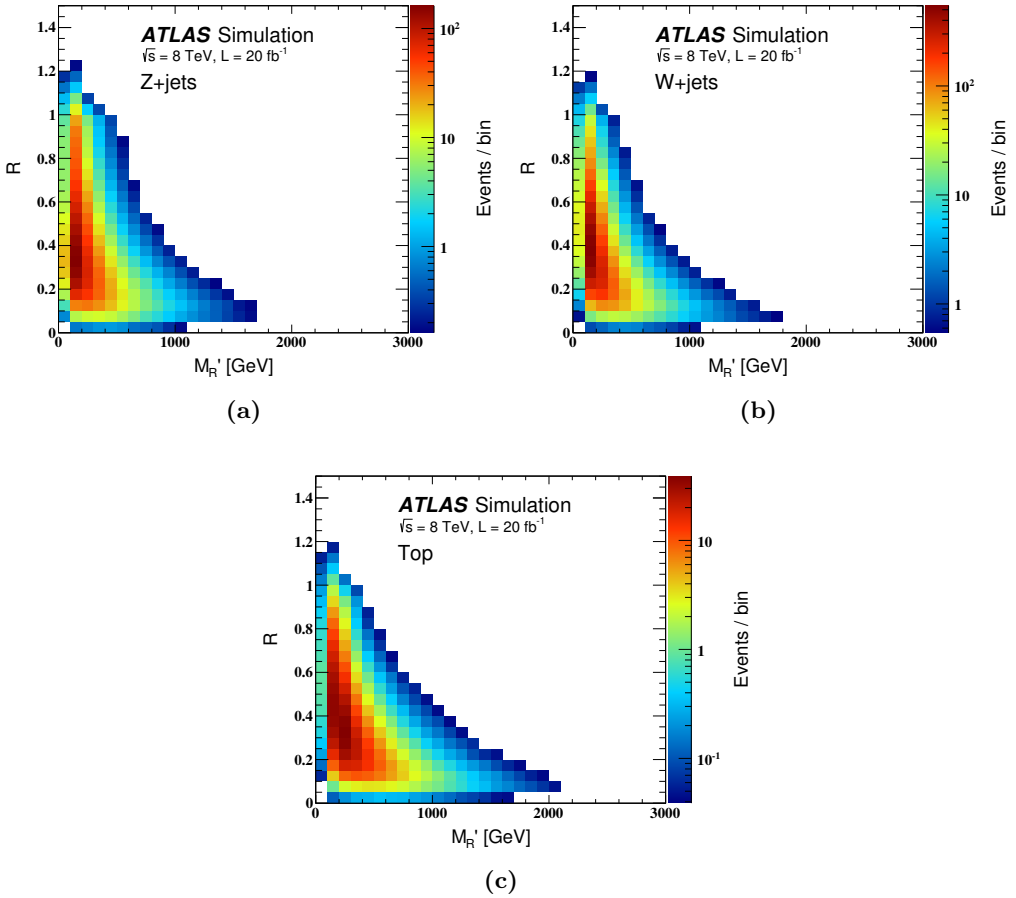

Figure 40. Distributions of the Razor variable R versus the characteristic mass in the R-frame M'_R for the dominant Standard Model backgrounds: (a) Z+jets, (b) W+jets and (c) $t\bar{t}$, after requiring no-leptons and at least two jets in the final state.

control region, the two leptons have been treated as invisible and are used to re-calculate $\boldsymbol{E}_{\mathrm{T}}^{\mathrm{miss}}$ as $\boldsymbol{E}_{\mathrm{T}}^{\mathrm{miss}'} = \boldsymbol{E}_{\mathrm{T}}^{\mathrm{miss}} + \boldsymbol{p}_{\mathrm{T}}(\ell\ell)$ with the invariant mass of the leptons falling within a Z-mass window, $66 < m(\ell\ell) < 116\,\mathrm{GeV}$. The Razor variables are also calculated with this methodology where the leptons are treated as invisible objects.

To validate the normalization parameters extracted in the background control regions, validation regions VRZ, VRW, VRT, $\mathrm{VRQ}_{\mathrm{loose}}$ and $\mathrm{VRQ}_{\mathrm{tight}}$ for Z+jets, W+jets, $t\bar{t}$ and multi-jet backgrounds respectively, are defined (table 23). These validation regions are statistically independent from the signal and control regions previously defined, and are expected to have minimal contribution from any signal, if present.

Following the definition of the control and validation regions, the backgrounds from Z+jets, W+jets, $t\bar{t}$ and multi-jet processes are estimated by using the background-only fit, as described in section 6. Figures 41 and 42 show the M'_R distributions for these control and validation regions after the fit. Good agreement is seen between the fitted and observed yields in all regions.

JHEP10(2015)054

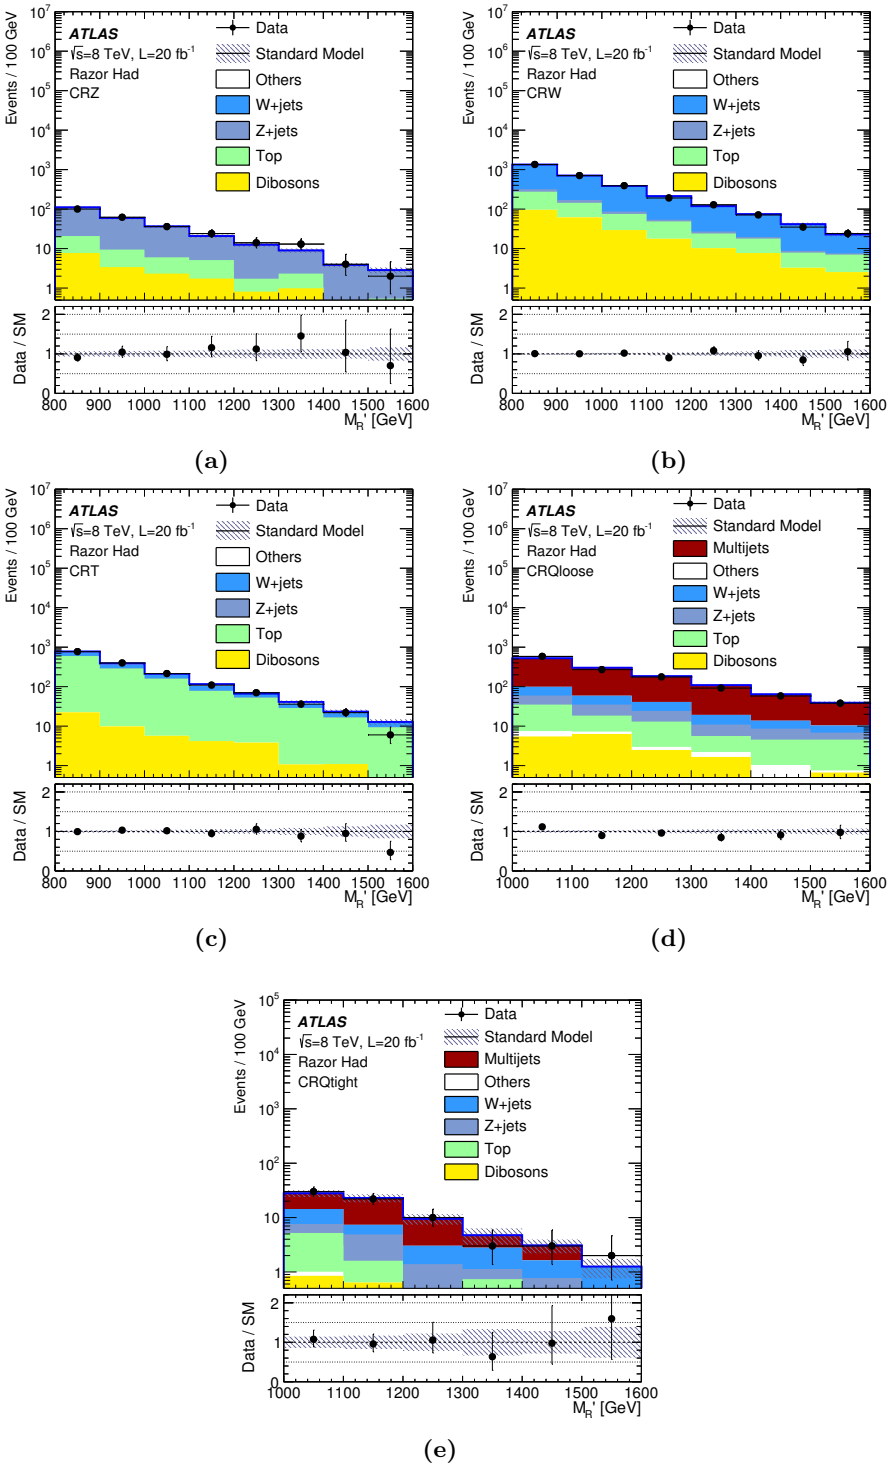

Figure 41. Observed M'_R distributions in control regions for (a) Z+jets, (b) W+jets, (c) $t\bar{t}$ and multi-jet backgrounds for (d) loose and (e) tight selection. The "Top" label includes all top-quark-related backgrounds ($t\bar{t}$, single top and $t\bar{t}+V$), while the "Others" includes the contributions of the jets misidentified as leptons or of non-prompt leptons, and the γ+jets background which is estimated with MC simulated data. All distributions are after the background-only fit has been performed.

JHEP10(2015)054

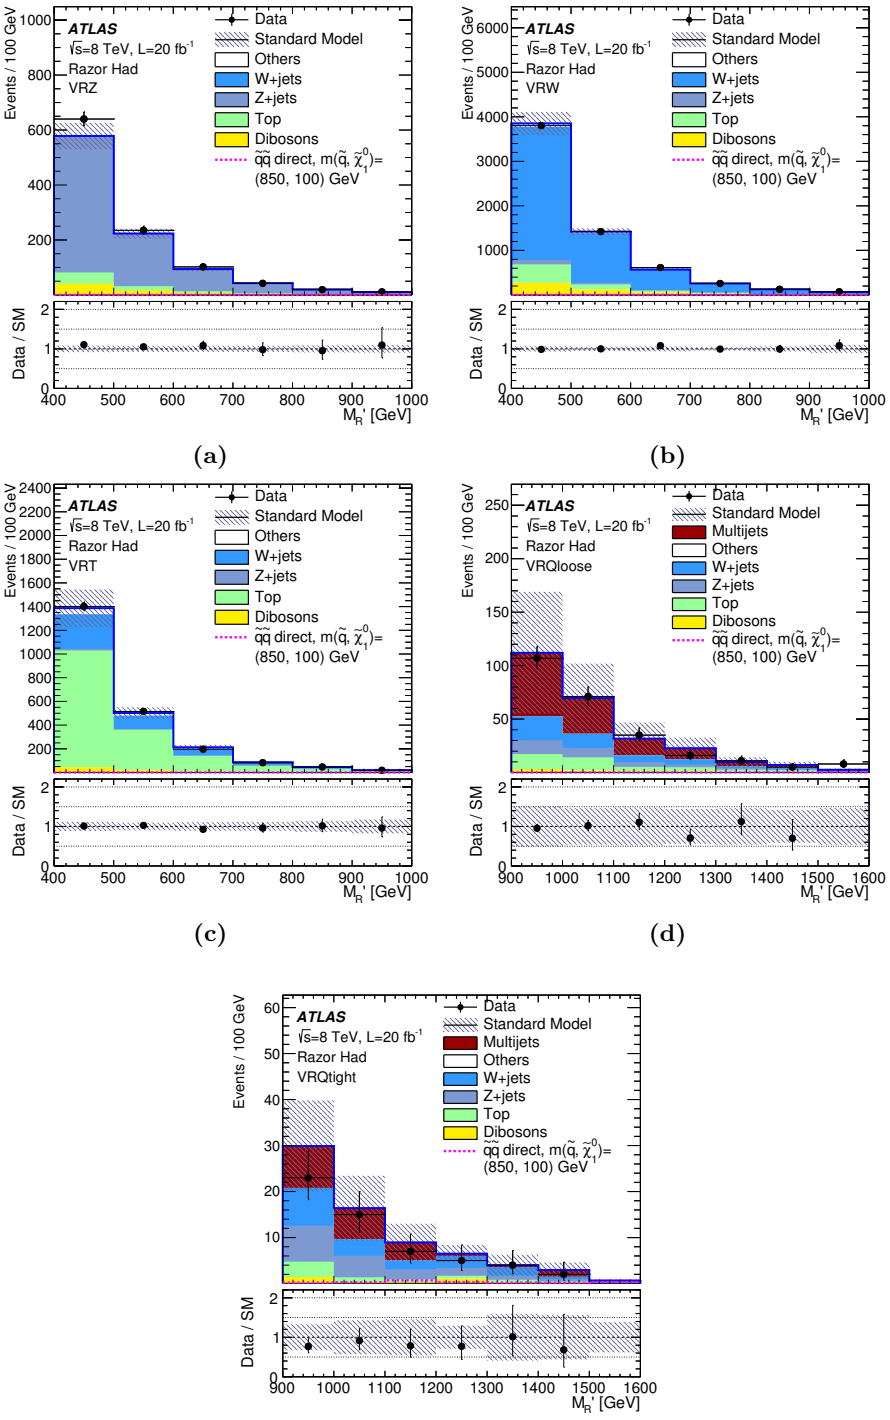

Figure 42. Observed M_R' distributions in validation regions for (a) Z+jets, (b) W+jets, (c) $t\bar{t}$ and multi-jet backgrounds for (d) loose and (e) tight selection. The "Top" label includes all top-quark-related backgrounds ($t\bar{t}$, single top and $t\bar{t}+V$), while the "Others" includes the contributions of the jets misidentified as leptons or of non-prompt leptons, and the γ+jets background which is estimated with MC simulated data. All distributions are after the background-only fit has been performed.

JHEP10(2015)054

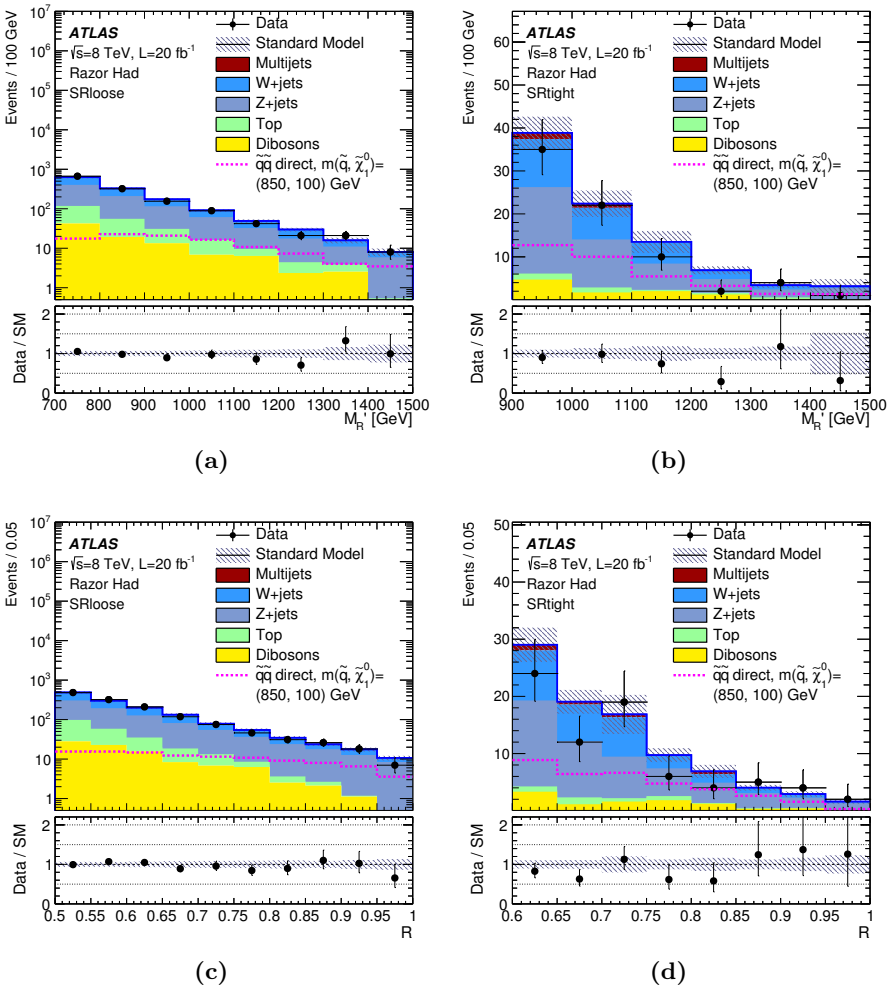

Figure 43. Observed (a, c) M_R' and (b, d) R distributions in (a, b) loose and (c, d) tight signal region selections listed in table 9. The "Top" label includes all top-quark-related backgrounds ($t\bar{t}$, single top and $t\bar{t}+V$). All distributions are after the background-only fit has been performed.

The Razor variable distributions, M_R' and R, for the SM backgrounds and a simplified model point with large-Δm_{signal} are shown in figure 43 for SR_{loose} and SR_{tight}.

ATLAS Run 1 searches for direct pair production of third-generation squarks at the Large Hadron Collider

ATLAS Collaboration[⋆]

CERN, 1211 Geneva 23, Switzerland

Received: 30 June 2015 / Accepted: 8 October 2015 / Published online: 29 October 2015
© CERN for the benefit of the ATLAS collaboration 2015. This article is published with open access at Springerlink.com

Abstract This paper reviews and extends searches for the direct pair production of the scalar supersymmetric partners of the top and bottom quarks in proton–proton collisions collected by the ATLAS collaboration during the LHC Run 1. Most of the analyses use 20 fb^{-1} of collisions at a centre-of-mass energy of $\sqrt{s} = 8$ TeV, although in some case an additional 4.7 fb^{-1} of collision data at $\sqrt{s} = 7$ TeV are used. New analyses are introduced to improve the sensitivity to specific regions of the model parameter space. Since no evidence of third-generation squarks is found, exclusion limits are derived by combining several analyses and are presented in both a simplified model framework, assuming simple decay chains, as well as within the context of more elaborate phenomenological supersymmetric models.

1 Introduction

In a theory with broken supersymmetry (SUSY) [1–9], the mass scale of the supersymmetric particles is undetermined. However, for SUSY to provide a solution to the hierarchy problem [10–13] some of the new SUSY particles masses are typically required to be below about one TeV [14,15], hence they could be within the reach of the LHC.

The scalar partners of the right-handed and left-handed chiral components of the top-quark state ($\tilde{t}_R$ and $\tilde{t}_L$ respectively) are among these particles. In many supersymmetric models, the large Yukawa coupling of the top quark to the Higgs sector makes the Higgs boson mass sensitive to the masses of the scalar top (referred to as stop in the following) states, such that, to avoid fine tuning, their masses are often required to be light. The $\tilde{t}_R$ and $\tilde{t}_L$ components mix to form the mass eigenstates $\tilde{t}_1$ and $\tilde{t}_2$, $\tilde{t}_1$ being defined as the lighter of the two. The scalar superpartner of the left-handed chiral component of the bottom quark ($\tilde{b}_L$) belongs to the same weak isospin doublet as the $\tilde{t}_L$, hence they usually share the same supersymmetry-breaking mass parameter: a light stop can therefore imply the existence of a light scalar bottom. The lightest sbottom mass eigenstate is referred to as $\tilde{b}_1$.

The ATLAS and CMS collaborations have searched for direct production of stops and sbottoms [16–35] using about 4.7 fb^{-1} of data from the proton–proton collisions produced by the LHC at $\sqrt{s} = 7$ TeV and 20 fb^{-1} at $\sqrt{s} = 8$ TeV. These searches have found no evidence of third-generation squark signals, leading to exclusion limits in many SUSY models. The aim of this paper is to sum-

⋆ e-mail: atlas.publications@cern.ch

marise the sensitivity of the ATLAS experiment to R-parity-conserving[1] [38–42] models including the direct pair production of stops and sbottoms using the full $\sqrt{s} = 8$ TeV proton–proton collision dataset collected during Run 1 of the LHC.[2] The third-generation squarks are assumed to decay to the stable lightest supersymmetric particle (LSP) directly or through one or more intermediate stages. The analyses considered are those previously published by the ATLAS collaboration on the topic, together with new ones designed to increase the sensitivity to scenarios not optimally covered so far. A wide range of SUSY scenarios are studied by combining different analyses to improve the global sensitivity.

The paper is organised as follows: Sect. 2 briefly reviews the expected phenomenology of third-generation squark production and decay; Sect. 3 reviews the general analysis approach followed by the ATLAS collaboration for SUSY searches; Sects. 4 and 5 present the exclusion limits obtained in specific models by combining the results of several analyses. Two different types of models have been considered: simplified models, where the third-generation squarks are assumed to decay into typically one or two different final states, and more complex phenomenological supersymmetric models, where the stop and sbottom have many allowed decay channels. Conclusions are drawn in Sect. 6.

For the sake of brevity, the body of the paper provides no details of the ATLAS detector and object reconstruction, of the analyses used in the limit derivation, or of how the signal Monte Carlo simulation samples were generated. However, a comprehensive set of appendices is provided to supply additional information to the interested reader. Appendix A briefly summarises the layout of the ATLAS detector and the general principles used in the reconstruction of electrons, muons, jets, jets containing b-hadrons (b-jets), and the missing transverse momentum vector $\mathbf{p}_{\mathrm{T}}^{\mathrm{miss}}$ (whose magnitude is referred to as $E_{\mathrm{T}}^{\mathrm{miss}}$). Appendix B discusses the analyses used to derive the exclusion limits presented in Sects. 4 and 5. The analyses that have already been published are only briefly reviewed, while those presented for the first time in this paper are discussed in detail. Appendix C provides further details of a combination of analyses which is performed for the first time in this paper. Finally, Appendix D provides details about the generation and simulation of the signal Monte Carlo samples used to derive the limits presented.

2 Third-generation squark phenomenology

The cross section for direct stop pair production in proton–proton collisions at $\sqrt{s} = 8$ TeV as a function of the stop mass as calculated with PROSPINO [43,44] is shown in Fig. 1a. It is calculated to next-to-leading order accuracy in the strong coupling constant, adding the resummation of soft gluon emission at next-to-leading-logarithmic accuracy (NLO+NLL) [45–47]. In this paper, the nominal cross section and its uncertainty are taken from an envelope of cross-section predictions using different parton distribution function (PDF) sets and factorisation and renormalisation scales described in Ref. [44]. The difference in cross section between the sbottom and stop pair production is known to be small [46], hence the values of Fig. 1a are used for both.

Searches for direct production of stops and sbottoms by the ATLAS collaboration have covered several possible final-state topologies. The experimental signatures used to identify these processes depend on the masses of the stop or sbottom, on the masses of the other supersymmetric particles they can decay into, and on other parameters of the model, such as the stop and sbottom left–right mixing and the mixing between the gaugino and higgsino states in the chargino–neutralino sector.

Assuming that the lightest supersymmetric particle is a stable neutralino ($\tilde{\chi}_1^0$), and that no other supersymmetric particle plays a significant role in the sbottom decay, the decay chain of the sbottom is simply $\tilde{b}_1 \to b\tilde{\chi}_1^0$ (Fig. 2a).

A significantly more complex phenomenology has to be considered for the stop, depending on its mass and on the $\tilde{\chi}_1^0$ mass. Figure 1b shows the three main regions in the $m_{\tilde{t}_1}$–$m_{\tilde{\chi}_1^0}$ plane that are taken into account. They are identified by different values of $\Delta m(\tilde{t}_1, \tilde{\chi}_1^0) = m_{\tilde{t}_1} - m_{\tilde{\chi}_1^0}$. In the region where $\Delta m(\tilde{t}_1, \tilde{\chi}_1^0) > m_t$, the favoured decay is $\tilde{t}_1 \to t\tilde{\chi}_1^0$ (Fig. 2b). The region where $m_W + m_b < \Delta m(\tilde{t}_1, \tilde{\chi}_1^0) < m_t$ is characterised by the three-body decay[3] ($\tilde{t}_1 \to Wb\tilde{\chi}_1^0$ through an off-shell top quark, Fig. 2c). The region where the value of $\Delta m(\tilde{t}_1, \tilde{\chi}_1^0)$ drops below $m_W + m_b$, sees the four-body decay $\tilde{t}_1 \to bff'\tilde{\chi}_1^0$, (where f and f' indicate generic fermions coming from the decay of an off-shell W boson, Fig. 2d) competing with the flavour-changing decay[4] $\tilde{t}_1 \to c\tilde{\chi}_1^0$ of Fig. 2e; the dominant decay depends on the details of the supersymmetric model chosen [50].

If the third-generation squark decay involves more SUSY particles (other than the $\tilde{\chi}_1^0$), then additional dependencies on

[1] It is also assumed that the decay of the third-generation squarks is prompt: long-lived and metastable stops/sbottoms are discussed elsewhere [36,37].

[2] The analysis exploiting the measurement of the $t\bar{t}$ cross section discussed in this paper also uses 4.7 fb^{-1} of proton–proton collisions at $\sqrt{s} = 7$ TeV.

[3] In scenarios that depart from the minimal flavour violation assumption, flavour-changing decays like $\tilde{t}_1 \to c\tilde{\chi}_1^0$ or $\tilde{t}_1 \to u\tilde{\chi}_1^0$ could have a significant branching ratio up to $\Delta m(\tilde{t}_1, \tilde{\chi}_1^0) \sim 100$ GeV [48].

[4] The decay $\tilde{t}_1 \to u\tilde{\chi}_1^0$, in the assumption of minimal flavour violation [49], is further suppressed with respect to $\tilde{t}_1 \to c\tilde{\chi}_1^0$ by corresponding factors of the CKM matrix.

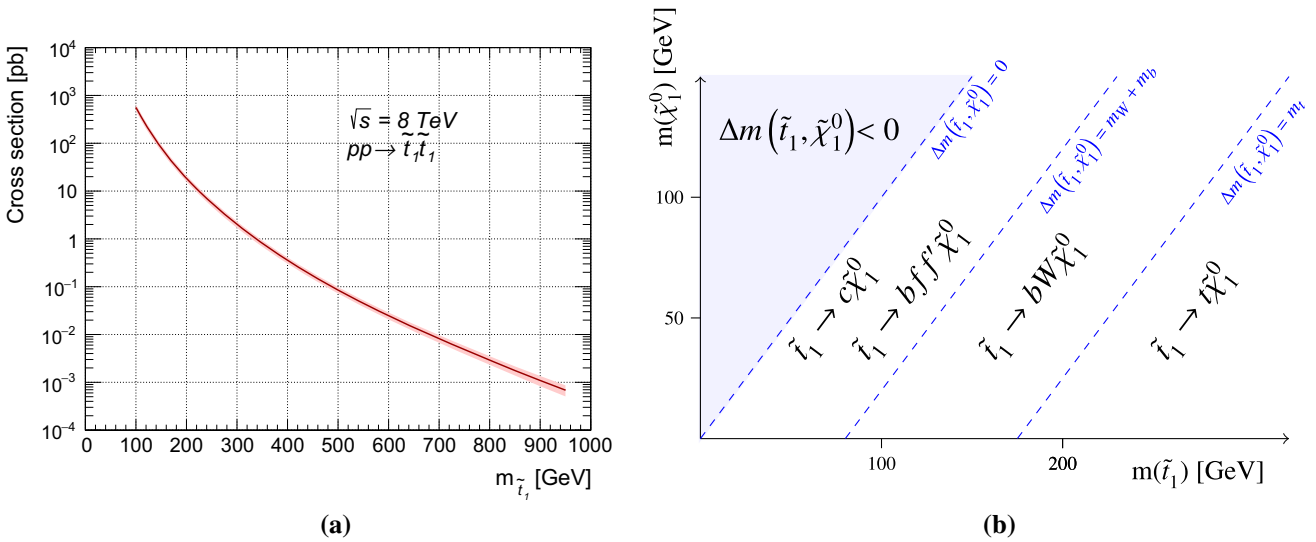

Fig. 1 **a** Direct stop pair production cross section at $\sqrt{s} = 8$ TeV as a function of the stop mass. The band around the cross section curve illustrates the uncertainty (which is everywhere about 15–20 %) on the cross section due to scale and PDF variations. **b** Illustration of stop decay modes in the plane spanned by the masses of the stop ($\tilde{t}_1$) and the lightest neutralino ($\tilde{\chi}_1^0$), where the latter is assumed to be the lightest supersymmetric particle and the only one present among the decay products. The *dashed blue lines* indicate thresholds separating regions where different processes dominate

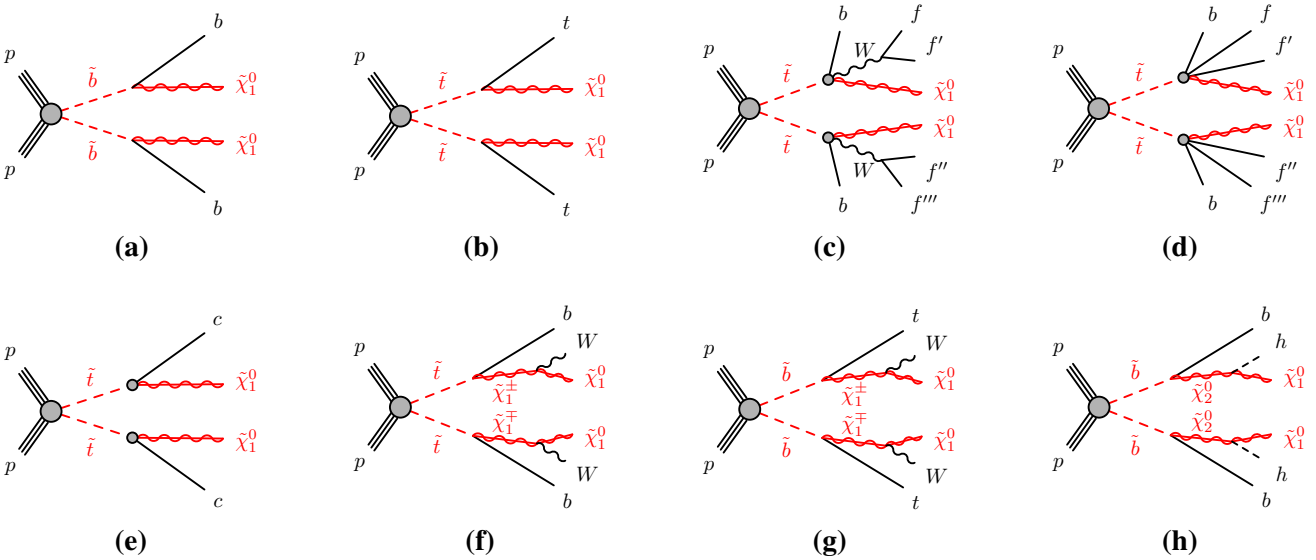

Fig. 2 Diagrams of $\tilde{t}_1$ and $\tilde{b}_1$ pair production and decays considered as simplified models: **a** $\tilde{b}_1\tilde{b}_1 \to b\tilde{\chi}_1^0 b\tilde{\chi}_1^0$; **b** $\tilde{t}_1\tilde{t}_1 \to t\tilde{\chi}_1^0 t\tilde{\chi}_1^0$; **c** three-body decay; **d** four-body decay; **e** $\tilde{t}_1\tilde{t}_1 \to c\tilde{\chi}_1^0 c\tilde{\chi}_1^0$; **f** $\tilde{t}_1\tilde{t}_1 \to b\tilde{\chi}_1^\pm b\tilde{\chi}_1^\pm$; **g** $\tilde{b}_1\tilde{b}_1 \to t\tilde{\chi}_1^\pm t\tilde{\chi}_1^\pm$; **h** $\tilde{b}_1\tilde{b}_1 \to b\tilde{\chi}_2^0 b\tilde{\chi}_2^0$. The diagrams do not show "mixed" decays, in which the two pair-produced third-generation squarks decay to different final states

SUSY parameters arise. For example, if the lightest chargino ($\tilde{\chi}_1^\pm$) is the next-to-lightest supersymmetric particle (NLSP), then the stop tends to have a significant branching ratio for $\tilde{t}_1 \to b\tilde{\chi}_1^\pm$ (Fig. 2f), or, for the sbottom, $\tilde{b}_1 \to t\tilde{\chi}_1^\pm$ if kinematically allowed (Fig. 2g). The presence of additional particles in the decay chain makes the phenomenology depend on their masses. Several possible scenarios have been considered, the most common ones being the gaugino universality inspired $m_{\tilde{\chi}_1^\pm} = 2m_{\tilde{\chi}_1^0}$, favoured, for example, in mSUGRA/CMSSM models [51–56]; other interpretations include the case of a chargino almost degenerate with the neutralino, a chargino almost degenerate with the squark, or a chargino of fixed mass. Another possible decay channel considered for the sbottom is $\tilde{b}_1 \to b\tilde{\chi}_2^0 \to bh\tilde{\chi}_1^0$ (Fig. 2h), which occurs in scenarios with a large higgsino component of the two lightest neutralinos.

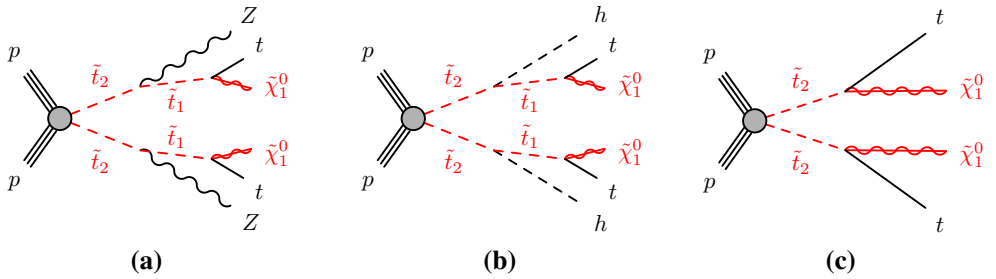

Fig. 3 Diagrams of $\tilde{t}_2$ decays considered as simplified models: **a** $\tilde{t}_2\tilde{t}_2 \to \tilde{t}_1 Z \tilde{t}_1 Z$; **b** $\tilde{t}_2\tilde{t}_2 \to \tilde{t}_1 h \tilde{t}_1 h$; **c** $\tilde{t}_2\tilde{t}_2 \to t\tilde{\chi}_1^0 t\tilde{\chi}_1^0$. The *diagrams* do not show "mixed" decays, in which the two pair-produced third-generation squarks decay to different final states. The decay $\tilde{t}_2 \to \gamma\tilde{t}_1$ is not an allowed process

Despite the lower production cross section and similar final states to $\tilde{t}_1$, the heavier stop state ($\tilde{t}_2$) pair production has also been studied: the search for it becomes interesting in scenarios where the detection of $\tilde{t}_1$ pair production becomes difficult (for example if $\Delta m(\tilde{t}_1, \tilde{\chi}_1^0) \sim m_t$). The diagrams of the investigated processes are shown in Fig. 3.

Two types of SUSY models are used to interpret the results in terms of exclusion limits. The simplified model approach assumes that either a stop or a sbottom pair is produced and that they decay into well-defined final states, involving one or two decay channels. Simplified models are used to optimise the analyses for a specific final-state topology, rather than the complex (and model-dependent) mixture of different topologies that would arise from a SUSY model involving many possible allowed production and decay channels. The sensitivity to simplified models is discussed in Sect. 4.

More complete phenomenological minimal supersymmetric extensions of the Standard Model (pMSSM in the following [57]) are also considered, to assess the performance of the analyses in scenarios where the stop and sbottom typically have many allowed decay channels with competing branching ratios. Three different sets of pMSSM models are considered, which take into account experimental constraints from LHC direct searches, satisfying the Higgs boson mass and dark-matter relic density constraints, or additional constraints arising from considerations of naturalness. The sensitivity to these models is discussed in Sect. 5.

3 General discussion of the analysis strategy

The rich phenomenology of third-generation supersymmetric particles requires several event selections to target the wide range of possible topologies. A common analysis strategy and common statistical techniques, which are extensively described in Ref. [58], are employed.

Signal regions (SR) are defined, which target one specific model and SUSY particle mass range. The event selection is optimised by relying on the Monte Carlo simulation of both the Standard Model (SM) background production processes and the signal itself. The optimisation process aims to maximise the expected significance for discovery or exclusion for each of the models considered.

For each SR, multiple control regions (CR) are defined: they are used to constrain the normalisation of the most relevant SM production processes and to validate the MC predictions of the shapes of distributions of the kinematic variables used in the analysis. The event selection of the CRs is mutually exclusive with that of the SRs. It is, however, chosen to be as close as possible to that of the signal region while keeping the signal contamination small, and such that the event yield is dominated by one specific background process.

A likelihood function is built as the product of Poisson probability functions, describing the observed and expected number of events in the control and signal regions. The observed numbers of events in the various CRs and SRs are used in a combined profile likelihood fit [59] to determine the expected SM background yields for each of the SRs. Systematic uncertainties are treated as nuisance parameters in the fit and are constrained with Gaussian functions with standard deviation equal to their value. The fit procedure takes into account correlations in the yield predictions between different regions due to common background normalisation parameters and systematic uncertainties, as well as contamination from SUSY signal events, when a particular model is considered for exclusion.

The full procedure is validated by comparing the background predictions and the shapes of the distributions of the key analysis variables from the fit results to those observed in dedicated validation regions (VRs), which are defined to be orthogonal to, and kinematically similar, to the signal regions, with low potential contamination from signal.

After successful validation, the observed yields in the signal regions are compared to the prediction. The profile likelihood ratio statistic is used first to verify the SM background-only hypothesis, and, if no significant excess is observed, to exclude the signal-plus-background hypothesis in specific signal models. A signal model is said to be excluded at 95 % confidence level (CL) if the CL_s [60,61] of the profile likeli-

hood ratio statistics of the signal-plus-background hypothesis is below 0.05.

Several publications, targeting specific stop and sbottom final-state topologies, were published by the ATLAS collaboration at the end of the proton–proton collision run at $\sqrt{s} = 8$ TeV, using a total integrated luminosity of about 20 fb^{-1}. Each of these papers defined one or more sets of signal regions optimised for different simplified models with different mass hierarchies and decay modes for the stop and/or sbottom. A few additional signal regions, focusing on regions of the parameter space not well covered by existing analyses have been defined since then. All signal regions that are used in this paper are discussed in detail in Appendix B, while Table 1 introduces their names and the targeted models. Each analysis is identified by a short acronym defined in the second column of Table 1. The signal region names of previously published analyses are retained, but, to avoid confusion and to ease the bookkeeping, the analysis acronym is prepended to their names. For example, SRA1 from the t0L analysis of Ref. [16], which is a search for stop pair production in channels with no leptons in the final state, is referred to as t0L-SRA1.

4 Interpretations in simplified models

The use of simplified models for analysis optimisation and result interpretation has become more and more common in the last years. The attractive feature of this approach is that it focuses on a specific final-state topology, rather than on a complex (and often heavily model-dependent) mixture of several different topologies: only a few SUSY particles are assumed to be produced in the proton–proton collision – often just one type – and only a few decay channels are assumed to be allowed. In the remainder of this section, several exclusion limits derived in different supersymmetric simplified models are presented. Details about how the MC signal samples used for the limit derivations were produced are available in Appendix D.

4.1 Stop decays with no charginos in the decay chain

A first series of simplified models is considered. It includes direct stop pair production as the only SUSY production process, and assumes that no supersymmetric particle other than the $\tilde{t}_1$ itself and the LSP, taken to be the lightest neutralino $\tilde{\chi}_1^0$, is involved in the decay. Under this assumption, there is little model dependence left in the stop phenomenology, as discussed in Sect. 2. The stop decay modes are defined mainly by the mass separation $\Delta m(\tilde{t}_1, \tilde{\chi}_1^0)$ between the stop and the neutralino, as shown in Fig. 1b. The corresponding diagrams are shown in Fig. 2.

Figure 4 shows the 95 % CL exclusion limits obtained in the $m_{\tilde{t}_1} - m_{\tilde{\chi}_1^0}$ plane by the relevant analyses listed in Table 1 and discussed in Appendix B, or by their combination. A detailed discussion of which analysis is relevant in each range of $\Delta m(\tilde{t}_1, \tilde{\chi}_1^0)$ follows.

$\boldsymbol{\Delta m(\tilde{t}_1, \tilde{\chi}_1^0) < m_W + m_b}$ This kinematic region is characterised by the presence of two competing decays: the flavour-violating decay $\tilde{t}_1 \to c\tilde{\chi}_1^0$ (Fig. 2e) and the four-body decay $\tilde{t}_1 \to bff'\tilde{\chi}_1^0$ (Fig. 2d). Which one of the two becomes dominant depends on the model details, in particular on the mass separation between the stop and the neutralino, and on the amount of flavour violation allowed in the model [50]. Several analyses have sensitivity in this region of the $m_{\tilde{t}_1} - m_{\tilde{\chi}_1^0}$ plane. The monojet-like signal regions (tc-M1-3) dominate the sensitivity in the region with $\Delta m(\tilde{t}_1, \tilde{\chi}_1^0) \gtrsim m_b$, regardless of the decay of the stop pair, which goes undetected: their selection is based on the presence of an initial-state radiation (ISR) jet recoiling against the stop-pair system, which is assumed to be invisible. At larger values of $\Delta m(\tilde{t}_1, \tilde{\chi}_1^0)$, signal regions requiring the presence of a c-tagged jet (tc-C1-2) complement the monojet-like signal regions by targeting the $\tilde{t}_1 \to c\tilde{\chi}_1^0$ decay. Limits on four-body decays can be set using signal regions which include low transverse momentum electrons and muons (t1L-bCa_low and WW).

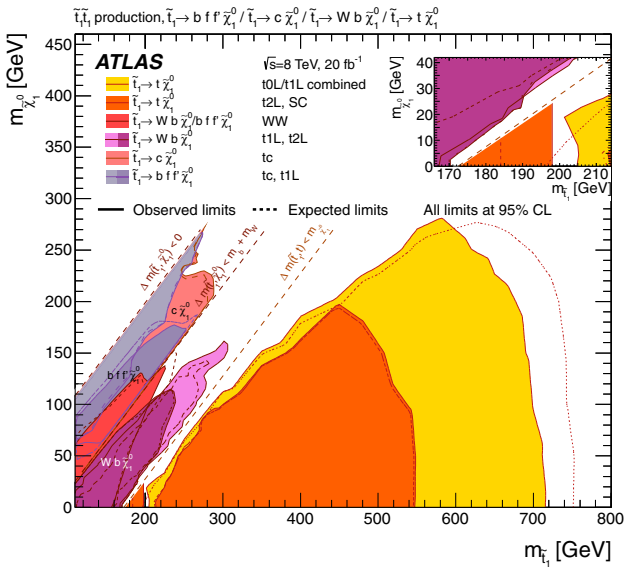
The limits reported in Fig. 4 for these values of Δm all assume that the branching ratio of the stop decay into either $\tilde{t}_1 \to c\tilde{\chi}_1^0$ or $\tilde{t}_1 \to bff'\tilde{\chi}_1^0$ is 100 %. However, this assumption can be relaxed, and exclusion limits derived as a function of the branching ratio of the $\tilde{t}_1 \to c\tilde{\chi}_1^0$ decay, $\mathrm{BR}(\tilde{t}_1 \to c\tilde{\chi}_1^0)$, assuming that $\mathrm{BR}(\tilde{t}_1 \to c\tilde{\chi}_1^0) + \mathrm{BR}(\tilde{t}_1 \to bff'\tilde{\chi}_1^0) = 1$. Two different scenarios, with $\Delta m(\tilde{t}_1, \tilde{\chi}_1^0) = 10, 80$ GeV, are considered. The first compressed scenario is characterised by low-p_{T} stop decay products, and the set of signal regions which have sensitivity is the tc-M, independently of the decay of the stop. In the second scenario, the phase space available for the $\tilde{t}_1$ decay is larger, and the full set of tc-M, tc-C, t1L-bCa_low, t1L-bCa_med and WW-SR selections have different sensitivity, depending on $\mathrm{BR}(\tilde{t}_1 \to c\tilde{\chi}_1^0)$.

The cross-section limit is derived by combining the analyses discussed above. The SR giving the lowest expected exclusion CL_s for each signal model and for each value of $\mathrm{BR}(\tilde{t} \to c\tilde{\chi}_1^0)$ is chosen.

Figure 5 shows the result of these combinations. For $\Delta m(\tilde{t}_1, \tilde{\chi}_1^0) = 10$ GeV, the sensitivity is completely dominated by the tc-M signal regions, hence no significant dependence on $\mathrm{BR}(\tilde{t} \to c\tilde{\chi}_1^0)$ is observed. In this case, stop masses up to about 250 GeV are excluded. For $\Delta m(\tilde{t}_1, \tilde{\chi}_1^0) = 80$ GeV, the sensitivity is dominated by the tc-C signal regions at high values of $\mathrm{BR}(\tilde{t} \to c\tilde{\chi}_1^0)$. For lower values of $\mathrm{BR}(\tilde{t} \to c\tilde{\chi}_1^0)$, the "soft-lepton" and WW signal regions both become competitive, the latter yielding a higher sensitivity at smaller

Table 1 Summary of the ATLAS analyses and signal regions used in this paper. Each signal region is identified by the acronym of the corresponding analysis followed by the original name of the signal region defined either in the published paper or in Appendix B.2. A dash in the signal region name column indicates that the analysis does not use the concept of signal region

Analysis name and corresponding reference	Analysis acronym	Original signal region name	Model targeted
Multijet final states [16]	t0L	SRA1-4	$\tilde{t}_1 \to t\tilde{\chi}_1^0$
		SRB	
		SRC1-3	$\tilde{t}_1\tilde{t}_1 \to bt\tilde{\chi}_1^0\tilde{\chi}_1^\pm$ with $m_{\tilde{\chi}_1^\pm} = 2m_{\tilde{\chi}_1^0}$
One-lepton final states [17]	t1L	tN_diag	$\tilde{t}_1 \to t\tilde{\chi}_1^0$ with $m_{\tilde{t}_1} \sim m_t + m_{\tilde{\chi}_1^0}$
		tN_med, tN_high, tN_boost	$\tilde{t}_1 \to t\tilde{\chi}_1^0$
		bCa_low, bCa_med, bCb_med1,	$\tilde{t}_1 \to b\tilde{\chi}_1^\pm$
		bCb_high, bCb_med2, bCc_diag	
		bCd_bulk, bCd_high1, bCd_high2	
		3body	$\tilde{t}_1 \to bW\tilde{\chi}_1^0$ (three-body decay)
		tNbC_mix	$\tilde{t}_1\tilde{t}_1 \to bt\tilde{\chi}_1^0\tilde{\chi}_1^\pm$ with $m_{\tilde{\chi}_1^\pm} = 2m_{\tilde{\chi}_1^0}$
Two-lepton final states [18]	t2L	L90, L100, L110, L120, H160	$\tilde{t}_1 \to b\tilde{\chi}_1^\pm$, three-body decay
		M1-4	$\tilde{t}_1 \to t\tilde{\chi}_1^0$
Final states from compressed stop decays [19]	tc	M1-3	$\tilde{t}_1/\tilde{b}_1 \to$ anything with $m_{\tilde{t}_1} \sim m_{\tilde{\chi}_1^0}$
		C1-2	$\tilde{t}_1 \to c\tilde{\chi}_1^0$
Final states with a Z boson [20]	t2t1Z	SR2A, SR2B, SR2C, SR3A, SR3B	$\tilde{t}_2 \to \tilde{t}_1 Z$ and $\tilde{t}_2 \to \tilde{t}_1 h$
Final states with two b-jets and $E_{\mathrm{T}}^{\mathrm{miss}}$ [21]	b0L	SRA, SRB	$\tilde{b}_1 \to b\tilde{\chi}_1^0$ and $\tilde{t}_1 \to b\tilde{\chi}_1^\pm$ with $m_{\tilde{\chi}_1^\pm} \sim m_{\tilde{\chi}_1^0}$
Final states with two leptons at intermediate m_{T2} (Appendix B.2.1)	WW	SR1–7	$\tilde{t}_1 \to b\tilde{\chi}_1^\pm$ with $m_{\tilde{\chi}_1^\pm} = m_{\tilde{t}_1} - 10$ GeV and
			$\tilde{t}_1 \to b\ell\nu\tilde{\chi}_1^0$ (three- and four-body decays)
Final states containing two top quarks and a Higgs boson (Appendix B.2.2)	t2t1h	–	$\tilde{t}_2 \to \tilde{t}_1 h$
Final states containing a top and a b-quark (Appendix B.2.3)	tb	SR1-5	$\tilde{t}_1\tilde{t}_1 \to b\tilde{\chi}_1^\pm t\tilde{\chi}_1^0$ with $m_{\tilde{\chi}_1^\pm} \sim m_{\tilde{\chi}_1^0}$ and pMSSM models
Final states with three b-jets [62]	g3b	SR-0ℓ-4j-A, SR-0ℓ-4j-B, SR-0ℓ-4j-C,	Gluino-mediated $\tilde{t}_1$ and $\tilde{b}_1$ production,
		SR-0ℓ-7j-A, SR-0ℓ-7j-B, SR-0ℓ-7j-C,	$\tilde{b}_1 \to \tilde{\chi}_2^0 b \to \tilde{\chi}_1^0 hb$
		SR-1ℓ-6j-A, SR-1ℓ-6j-B, SR-1ℓ-7j-C	
Strongly produced final states with two same-sign or three leptons [63]	SS3L	SR3b, SR0b, SR1b, SR3Llow, S3Lhigh	Generic gluino and squark production, $\tilde{b}_1 \to t\tilde{\chi}_1^\pm$
Spin correlation in $t\bar{t}$ production events [64]	SC	–	$\tilde{t}_1 \to t\tilde{\chi}_1^0$ with $m_{\tilde{t}_1} \sim m_t + m_{\tilde{\chi}_1^0}$
$t\bar{t}$ production cross section [65]	xsec	–	$\tilde{t}_1 \to t\tilde{\chi}_1^0$, three-body decay



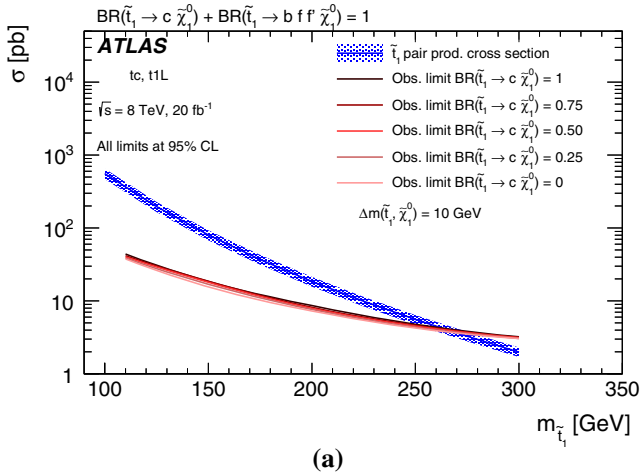


Fig. 4 Summary of the ATLAS Run 1 searches for direct stop pair production in models where no supersymmetric particle other than the $\tilde{t}_1$ and the $\tilde{\chi}_1^0$ is involved in the $\tilde{t}_1$ decay. The 95 % CL exclusion limits are shown in the $m_{\tilde{t}_1}$–$m_{\tilde{\chi}_1^0}$ mass plane. The *dashed* and *solid lines* show the expected and observed limits, respectively, including all uncertainties except the theoretical signal cross-section uncertainty (PDF and scale). Four decay modes are considered separately with a branching ratio of 100 %: $\tilde{t}_1 \to t\tilde{\chi}_1^0$, where the $\tilde{t}_1$ is mostly $\tilde{t}_R$, for $\Delta m(\tilde{t}_1, \tilde{\chi}_1^0) > m_t$; $\tilde{t}_1 \to Wb\tilde{\chi}_1^0$ (three-body decay) for $m_W + m_b < \Delta m(\tilde{t}_1, \tilde{\chi}_1^0) < m_t$; $\tilde{t}_1 \to c\tilde{\chi}_1^0$ and $\tilde{t}_1 \to bff'\tilde{\chi}_1^0$ (four-body decay) for $\Delta m(\tilde{t}_1, \tilde{\chi}_1^0) < m_W + m_b$. The latter two decay modes are superimposed

values of the stop mass. The maximum excluded stop mass ranges from about 180 GeV for $\mathrm{BR}(\tilde{t} \to c\tilde{\chi}_1^0) = 25\,\%$ to about 270 GeV for $\mathrm{BR}(\tilde{t} \to c\tilde{\chi}_1^0) = 100\,\%$.

$\boldsymbol{m_W + m_b < \Delta m(\tilde{t}_1, \tilde{\chi}_1^0) < m_t}$ In this case, the three-body decay of Fig. 2c is dominant. The signal regions that are sensitive to this decay are the dedicated signal region defined in the analysis selecting one-lepton final states (the t1L-3body) and the combination of several signal regions from the analysis selecting two-lepton final states, the t2L. The exclusion limits shown in Fig. 4 assume $\mathrm{BR}(\tilde{t}_1 \to bW\tilde{\chi}_1^0) = 1$. The WW signal regions are found to be sensitive to the kinematic region separating the three-body from the four-body stop decay region.

$\boldsymbol{\Delta m(\tilde{t}_1, \tilde{\chi}_1^0) \sim m_t}$ In this case, the neutralinos are produced with low p_{T}, and the kinematic properties of the signal are similar to those of SM $t\bar{t}$ production. Exclusion limits in this region were obtained by two analyses performing precision SM measurements. The first one is the measurement of the $t\bar{t}$ inclusive production cross section $\sigma_{t\bar{t}}$. Limits on $\tilde{t}_1$ pair production were already set in Ref. [65], which measured $\sigma_{t\bar{t}}$ in the different-flavour, opposite-sign channel $e\mu$. They were derived assuming a $\tilde{t}_1$ decay into an on-shell top quark, $\tilde{t}_1 \to t\tilde{\chi}_1^0$. An extension of the limits into the three-body stop decay is discussed in Appendix B.1. For a massless neutralino, the analysis excludes stop masses from about 150 GeV to about m_t. The limit deteriorates for higher neutralino masses, mainly because of the softer b-jet spectrum and the consequent loss in acceptance. The second analysis considered is that of the top quark spin correlation (SC) which considers SM $t\bar{t}$ production with decays to final states containing two leptons (electrons or muons). The shape and normalisation of the distribution of the azimuthal angle between the two leptons is sensitive to the spin of the produced particles,

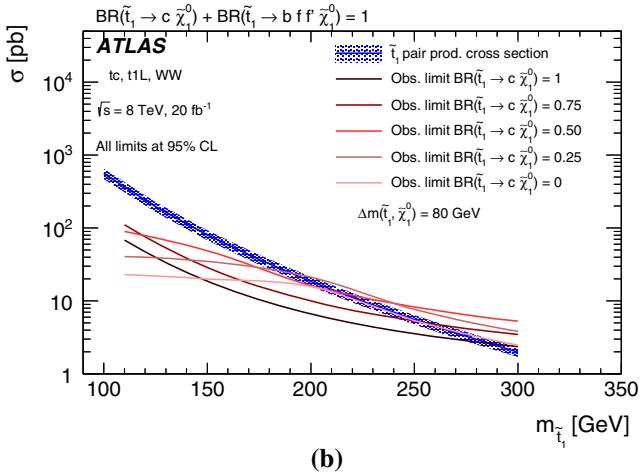

Fig. 5 Upper limits on the stop pair production cross sections for different values of the BRs for the decays $\tilde{t}_1 \to c\tilde{\chi}_1^0$ and $\tilde{t}_1 \to ff'b\tilde{\chi}_1^0$. Signal points with $\Delta m(\tilde{t}_1, \tilde{\chi}_1^0)$ of 10 GeV (**a**) and 80 GeV (**b**) are shown. The limits quoted are taken from the best performing, based on expected exclusion CL_s, signal regions from the tc-M, tc-C, t1L-bCa_low and WW analyses at each mass point. The *blue line* and corresponding *hashed band* correspond to the mean value and uncertainty on the production cross section of the stop as a function of its mass. The *pink lines*, whose *darkness* indicate the value of $\mathrm{BR}(\tilde{t} \to c\tilde{\chi}_1^0)$ according to the legend, indicate the observed limit on the production cross section

hence it allows the analysis to differentiate between stop pair and $t\bar{t}$ production. The limit obtained is shown in the bottom middle (dark orange) of the inset of Fig. 4. A small region of $\Delta m(\tilde{t}_1, \tilde{\chi}_1^0) \approx 180$ GeV is excluded with this measurement assuming a small neutralino mass.

$\Delta m(\tilde{t}_1, \tilde{\chi}_1^0) > m_t$ In this kinematic region, the decay $\tilde{t}_1 \to t\tilde{\chi}_1^0$ (see Fig. 2b) is dominant. The best results in this region are obtained by a statistical combination of the results of the multijet (t0L) and one-lepton (t1L) analyses. They both have dedicated signal regions targeting this scenario and the expected sensitivity is comparable for the two analyses. The number of required leptons makes the two signal regions mutually exclusive.

To maximise the sensitivity to the $\tilde{t}_1 \to t\tilde{\chi}_1^0$ decays a statistical combination of the t0L and t1L signal regions is performed. The details of the combination are given in Appendix C and the final limit is shown in Fig. 4 by the largest shaded region (yellow). The expected limit on the stop mass is about 50 GeV higher at low $m_{\tilde{\chi}_1^0}$ than in the individual analyses. The observed limit is increased by roughly the same amount and stop masses between 200 and 700 GeV are excluded for small neutralino masses.[5]

A similar combination is performed to target a scenario where the stop can decay as $\tilde{t}_1 \to t\tilde{\chi}_1^0$ with branching ratio x and as $\tilde{t}_1 \to b\tilde{\chi}_1^\pm$ with branching ratio $1-x$. Assuming gauge universality, the mass of the chargino is set to be twice that of the neutralino. Neutralino masses below 50 GeV are not considered, to take into account limits on the lightest chargino mass obtained at LEP [66–70]. The exclusion limits are derived for $x = 75, 50, 25$ and 0 %.[6] Regardless of the branching ratio considered, it is always assumed that $m_{\tilde{t}_1} > m_t + m_{\tilde{\chi}_1^0}$ and $m_{\tilde{t}_1} > m_b + m_{\tilde{\chi}_1^\pm}$, such that the two decays $\tilde{t} \to t\tilde{\chi}_1^0$ and $\tilde{t} \to b\tilde{\chi}_1^\pm$ are both kinematically allowed. A statistical combination, identical to the one described above, is used for $x = 75$ %. For smaller values of x, no combined fit is performed, as the sensitivity is dominated by the t1L analysis almost everywhere: rather either the t0L or the t1L analysis is used, depending which one gives the smaller expected CL_s value.

Figure 6 shows the result of the combination in the $m_{\tilde{t}_1} - m_{\tilde{\chi}_1^0}$ plane. The limit is improved, with respect to the individual analyses, by about 50 GeV for $m_{\tilde{\chi}_1^0} = 50$ GeV and $x = 75$ %. For other x values, the t1L analysis is used on the full plane, with the exception of the point at the highest stop mass for $m_{\tilde{\chi}_1^0} = 50$ GeV at $x = 50$ and 25 %. Stop masses

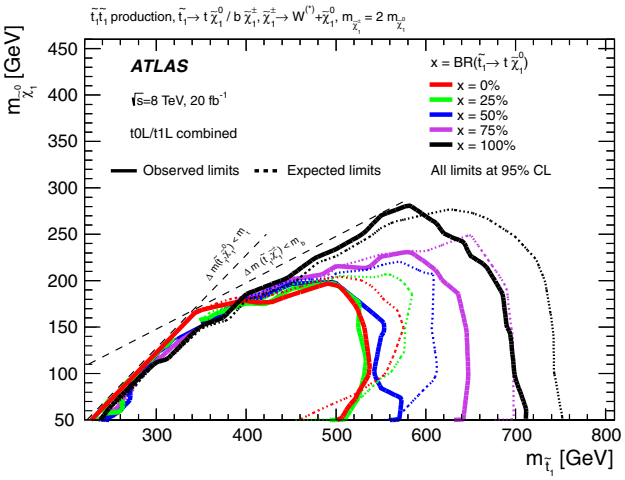

Fig. 6 Combined exclusion limits assuming that the stop decays through $\tilde{t}_1 \to t\tilde{\chi}_1^0$ with different branching ratios x and through $\tilde{t}_1 \to b\tilde{\chi}_1^\pm$ with branching ratios $1-x$. The limits assume $m_{\tilde{\chi}_1^\pm} = 2m_{\tilde{\chi}_1^0}$, and values of x from 0 to 100 % are considered. For each branching ratio, the observed (with *solid lines*) and expected (with *dashed lines*) limits are shown

below 500 GeV are excluded for $m_{\tilde{\chi}_1^0} < 160$ GeV for any value of x.

4.2 Stop decays with a chargino in the decay chain

In the pMSSM, unless the higgsino–gaugino mass parameters are related by $M_1 \ll \mu, M_2$, the mass difference between the lightest neutralino and the lightest chargino cannot be too large. The mass hierarchy $m_{\tilde{\chi}_1^0} < m_{\tilde{\chi}_1^\pm} < m_{\tilde{t}_1}$ is, hence, well motivated, leading to the decay chain shown in Fig. 2f.

If additional particles beside the stop and the lightest neutralino take part in the stop decay, the stop phenomenology quickly becomes complex. Even if the chargino is the only other relevant SUSY particle, the stop phenomenology depends on the chargino mass, on the stop left–right mixing, and on the composition of the neutralino and chargino in terms of bino, wino and higgsino states.

Figure 7 shows the exclusion limits obtained by the analyses listed in Table 1 and discussed in Appendix B if a branching ratio of 100 % for $\tilde{t} \to b\tilde{\chi}_1^\pm$ is assumed. The exclusion limits are presented in a number of $m_{\tilde{t}_1}$–$m_{\tilde{\chi}_1^0}$ planes, each characterised by a different hypothesis on the chargino mass. For all scenarios considered, the chargino is assumed to decay as $\tilde{\chi}_1^\pm \to W^{(*)}\tilde{\chi}_1^0$, where the $(*)$ indicates a possibly virtual W boson.

$\Delta m(\tilde{\chi}_1^\pm, \tilde{\chi}_1^0) = 5, 20$ GeV This scenario assumes that the difference in mass between the lightest chargino and the neutralino is small (Fig. 7a), which is a rather common feature of models where, for example, the LSP has a large wino or higgsino component. Two hypotheses have been considered,

[5] This result holds if the top quark produced in the $\tilde{t}_1$ decay has a right-handed chirality. The dependence of the individual limits on the top quark chirality is discussed in Refs. [16,17].

[6] A value of $x = 0$ % is in fact not achievable in a real supersymmetric model. Nevertheless, this value has been considered as the limiting case of a simplified model.

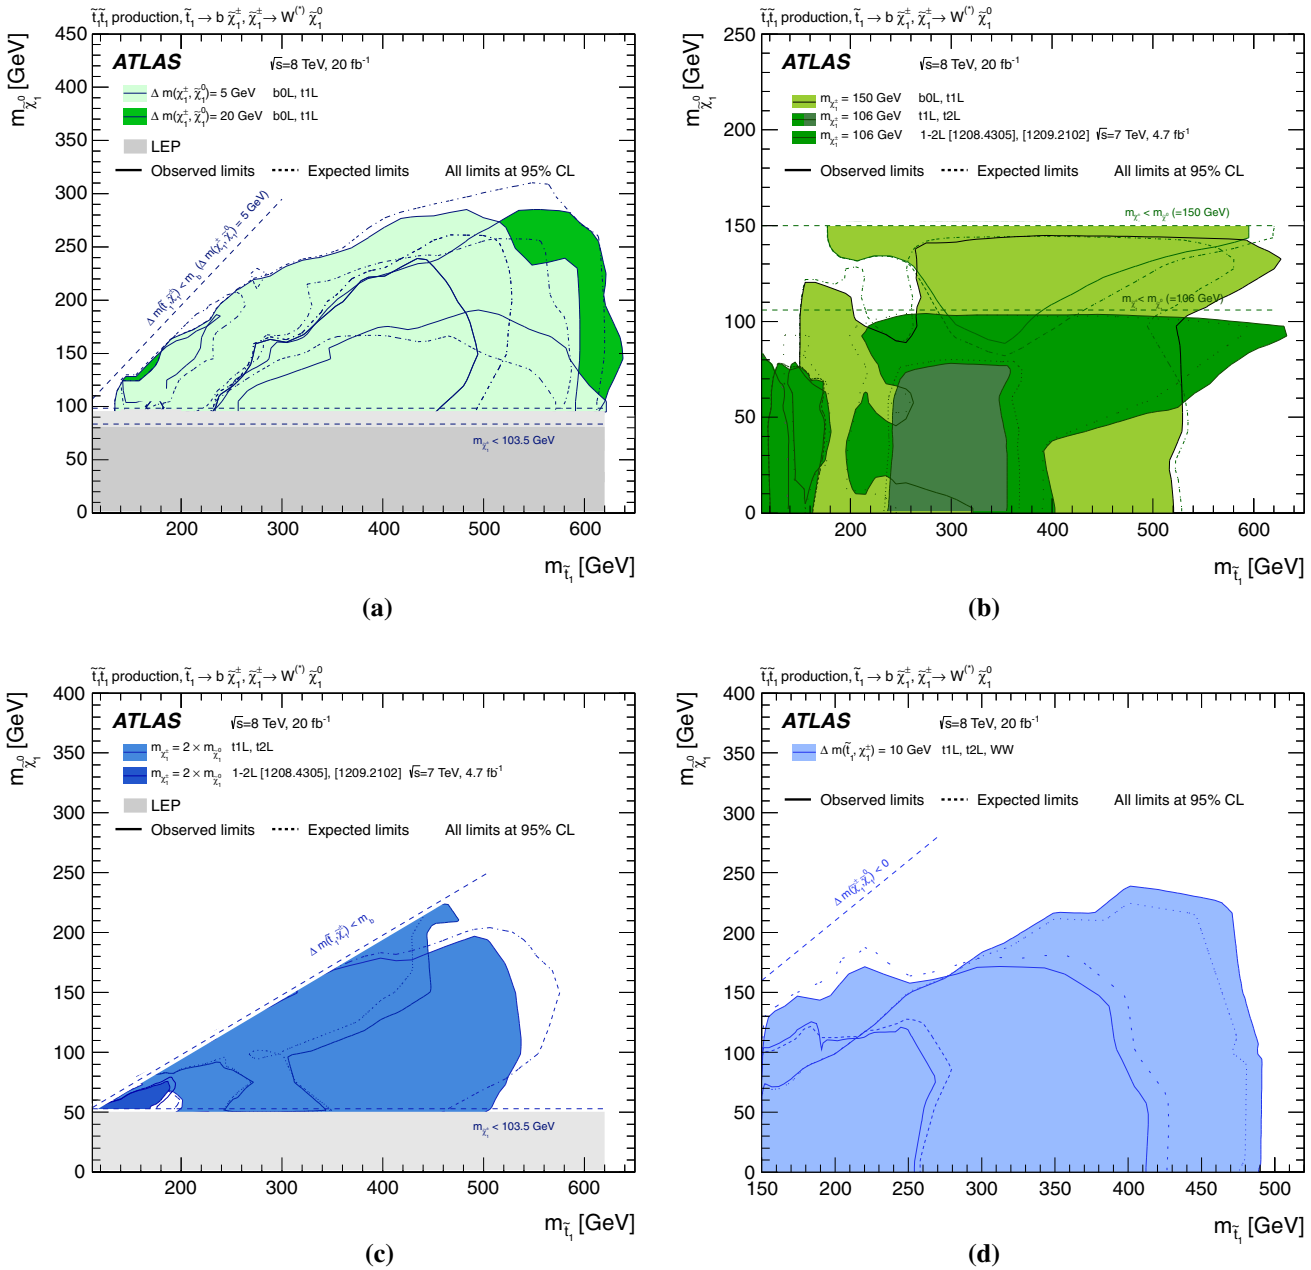

Fig. 7 Summary of the ATLAS Run 1 searches for direct stop pair production in models where the decay mode $\tilde{t}_1 \to b\tilde{\chi}_1^{\pm}$ with $\tilde{\chi}_1^{\pm} \to W^*\tilde{\chi}_1^0$ is assumed with a branching ratio of 100 %. Various hypotheses on the $\tilde{t}_1$, $\tilde{\chi}_1^{\pm}$, and $\tilde{\chi}_1^0$ mass hierarchy are used. Exclusion limits at 95 % CL are shown in the $\tilde{t}_1 - \tilde{\chi}_1^0$ mass plane. The *dashed* and *solid lines* show the expected and observed limits, respectively, including all uncertainties except the theoretical signal cross-section uncertainty (PDF and scale). Wherever not superseded by any $\sqrt{s} = 8$ TeV analysis, results obtained by analyses using 4.7 fb^{-1} of proton–proton collision data taken at $\sqrt{s} = 7$ TeV are also shown, with the corresponding reference. The four *plots* correspond to interpretations of **a** the b0L and t1L soft-lepton analyses in two scenarios ($\Delta m(\tilde{\chi}_1^{\pm}, \tilde{\chi}_1^0) = 5$ GeV in *light green* and $\Delta m(\tilde{\chi}_1^{\pm}, \tilde{\chi}_1^0) = 20$ GeV in *dark green*), for a total of four limits; **b** the b0L, t1L and t2L analyses in scenarios with a fixed chargino mass $m_{\tilde{\chi}_1^{\pm}} = 106$ GeV (*dark green*) and $m_{\tilde{\chi}_1^{\pm}} = 150$ GeV (*light green*); **c** the t1L and t2L analyses in scenarios with $m_{\tilde{\chi}_1^{\pm}} = 2m_{\tilde{\chi}_1^0}$; **d** interpretations of the t1L, t2L and WW analyses in senarios with $\Delta m\left(\tilde{t}_1, \tilde{\chi}_1^{\pm}\right) = 10$ GeV

with $\Delta m(\tilde{\chi}_1^{\pm}, \tilde{\chi}_1^0) = 5$ GeV and $\Delta m(\tilde{\chi}_1^{\pm}, \tilde{\chi}_1^0) = 20$ GeV. For both, the complete decay chain is $\tilde{t}_1 \to b\tilde{\chi}_1^{\pm} \to bff'\tilde{\chi}_1^0$, where the transverse momenta of the fermions f and f' depend on $\Delta m(\tilde{\chi}_1^{\pm}, \tilde{\chi}_1^0)$ and on the stop mass, given the dependency on the chargino boost. If $\Delta m(\tilde{\chi}_1^{\pm}, \tilde{\chi}_1^0) = 5$ GeV, the fermions have momenta too low to be efficiently reconstructed. The observed final state then consists of two b-jets and $E_{\mathrm{T}}^{\mathrm{miss}}$. This final state is the direct target of the b0L signal

regions. For $\Delta m(\tilde{\chi}_1^{\pm}, \tilde{\chi}_1^0) = 20$ GeV, the signal efficiencies of the b0L signal regions decrease because of the lepton and jet veto applied. The t1L signal regions with soft leptons, instead, gain in sensitivity, profiting from the higher transverse momentum of the fermions from the off-shell W decay produced in the chargino decay.

$\boldsymbol{m_{\tilde{\chi}_1^{\pm}} = 106, 150\,\text{GeV}}$ This scenario (Fig. 7b) assumes a fixed chargino mass. The SR yielding the lowest expected exclusion CL_s for this scenario depends on the value of $\Delta m(\tilde{\chi}_1^{\pm}, \tilde{\chi}_1^0)$. For $\Delta m(\tilde{\chi}_1^{\pm}, \tilde{\chi}_1^0) < 20$ GeV, the b0L signal regions provide the best sensitivity; for larger values of $\Delta m(\tilde{\chi}_1^{\pm}, \tilde{\chi}_1^0)$, the t1L and t2L signal regions provide better sensitivity because of the same mechanism as in the $\Delta m(\tilde{\chi}_1^{\pm}, \tilde{\chi}_1^0) = 5, 20$ GeV scenario above. The exclusion extends up to about 600 GeV for small values of $\Delta m(\tilde{\chi}_1^{\pm}, \tilde{\chi}_1^0)$. A region of the parameter space with $m_{\tilde{t}_1}$ up to about 260 GeV and $m_{\tilde{\chi}_1^0}$ between 100 GeV and $m_{\tilde{\chi}_1^{\pm}}$ is not yet excluded.

$\boldsymbol{m_{\tilde{\chi}_1^{\pm}} = 2m_{\tilde{\chi}_1^0}}$ Inspired by gauge-universality considerations, the third scenario (Fig. 7c) is characterised by a relatively large $\Delta m(\tilde{\chi}_1^{\pm}, \tilde{\chi}_1^0)$. The t2L signal regions dominate the sensitivity for $m_{\tilde{t}_1} \sim m_{\tilde{\chi}_1^{\pm}}$. The sensitivity of the dedicated t1L-bC is dominant in a large region of the plane, and determines the exclusion reach for moderate to large values of $\Delta m(\tilde{t}_1, \tilde{\chi}_1^0)$.

$\boldsymbol{\Delta m(\tilde{t}_1, \tilde{\chi}_1^{\pm}) = 10\,\text{GeV}}$ The fourth scenario (Fig. 7d) assumes a rather compressed $\tilde{t}_1 - \tilde{\chi}_1^{\pm}$ spectrum. The region at low $m_{\tilde{t}_1}$ and large $m_{\tilde{\chi}_1^0}$ is characterised by low mass separations between all particles involved, and it is best covered by the t1L-bCc_diag, the t1L soft lepton, and the WW signal regions. At larger values of the stop mass, the leptons emitted in the $\tilde{\chi}_1^{\pm}$ decay have larger p_{T}, and the t2L signal regions provide the best sensitivity.

$\boldsymbol{m_{\tilde{t}_1} = 300\,\text{GeV}}$ The final scenario considered is one where the stop mass is fixed at 300 GeV, and the exclusion limits are expressed in the $m_{\tilde{\chi}_1^{\pm}}$–$m_{\tilde{\chi}_1^0}$ plane. In the case of the compressed scenario, corresponding to a small mass difference $\Delta m(\tilde{\chi}_1^{\pm}, \tilde{\chi}_1^0)$, the fermions from the $W^{(*)}$ decay can escape detection and only the two b-jets and $E_{\text{T}}^{\text{miss}}$ would be identified in the final state. Thus, the b0L signal regions are expected to have a large sensitivity in this case, while for larger values of $\Delta m(\tilde{\chi}_1^{\pm}, \tilde{\chi}_1^0)$, the lepton can be observed, yielding a final-state signature investigated by the t1L soft-lepton signal region. A combination of the b0L and t1L signal regions is performed by choosing, for each point of the plane, the SR giving the lowest CL_s for expected exclusion. The result, reported in Fig. 8, shows that a large portion of the plane is excluded, with the exception of a region where the mass separations between the $\tilde{t}_1$, the $\tilde{\chi}_1^{\pm}$ and the $\tilde{\chi}_1^0$ are small.

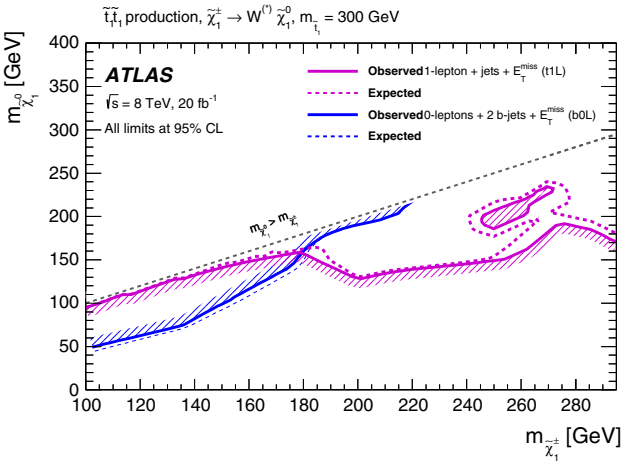

Fig. 8 Exclusion limits assuming that the stop decays through $\tilde{t}_1 \to b + \tilde{\chi}_1^{\pm} \to b + W^{(*)} + \tilde{\chi}_1^0$ with branching ratio of 100 % assuming a fixed stop mass of $m_{\tilde{t}_1} = 300$ GeV. The region *below the purple line* and *above the blue line*, indicated by a *light shading*, is excluded

Summarising, in the simplified models with $\tilde{t}_1 \to b\tilde{\chi}_1^{\pm} \to bW^{(*)}\tilde{\chi}_1^0$, stop masses up to 450–600 GeV are generally excluded. Scenarios where $\Delta m(\tilde{t}_1, \tilde{\chi}_1^0)$ is small are particularly difficult to exclude and in these compressed scenarios, stop masses as low as 200 GeV are still allowed (Fig. 7b). A small unexcluded area is also left for a small region around $(m_{\tilde{t}_1}, m_{\tilde{\chi}_1^{\pm}}, m_{\tilde{\chi}_1^0}) = (180, 100, 50)$ GeV (Fig. 7c), where the sensitivity of the analyses is poor because the signal kinematics are similar to SM $t\bar{t}$ production.

4.3 Limits on pair production of $\tilde{t}_2$

Although the pair production of $\tilde{t}_1$ has a cross section larger than that of $\tilde{t}_2$, and although the decay patterns of the two particles can be similar, it can be convenient to search for the latter in regions where the sensitivity to the former is limited. This is the case, for example, in the region where $\Delta m(\tilde{t}_1, \tilde{\chi}_1^0) \sim m_t$ of Fig. 4, where the separation of $\tilde{t}_1$ pair production from SM top quark pair production is difficult. The t2t1Z and t2t1h analyses are designed to detect $\tilde{t}_2$ pair production in this region of the $m_{\tilde{t}_1} - m_{\tilde{\chi}_1^0}$ plane, followed by the decays $\tilde{t}_2 \to \tilde{t}_1 Z$ and $\tilde{t}_2 \to \tilde{t}_1 h$. The Higgs boson h is assumed to have a mass of 125 GeV and SM branching ratios.

The exclusion limits were first derived in a scenario in which the pair-produced $\tilde{t}_2$ decays either through $\tilde{t}_2 \to Z\tilde{t}_1$ with a branching ratio of 100 % (Fig. 3a), or through $\tilde{t}_2 \to h\tilde{t}_1$ (again with a branching ratio of 100 %; Fig. 3b). In both cases, the $\tilde{t}_1$ is assumed to decay through $\tilde{t}_1 \to t\tilde{\chi}_1^0$, and its mass is set to be 180 GeV above that of the neutralino (assumed to be the LSP), which is the region not excluded in Fig. 4. The final state contains two top quarks, two neutralinos, and either two Z or two h bosons.

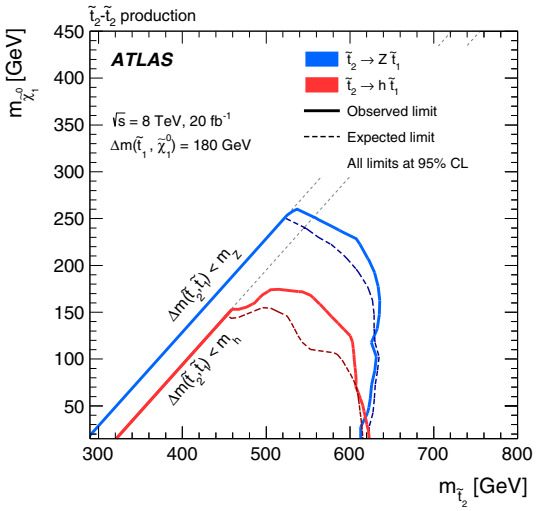

Fig. 9 Exclusion limits at 95 % CL in the scenario where $\tilde{t}_2$ pair production is assumed, followed by the decay $\tilde{t}_2 \to Z\tilde{t}_1$ (*blue*) or $\tilde{t}_2 \to \tilde{t}_1 h$ (*red*) and then by $\tilde{t}_1 \to t\tilde{\chi}_1^0$ with a branching ratio of 100 %, as a function of the $\tilde{t}_2$ and $\tilde{\chi}_1^0$ mass. The $\tilde{t}_1$ mass is determined by the relation $m_{\tilde{t}_1} - m_{\tilde{\chi}_1^0} = 180$ GeV. The *dashed lines* indicate the expected limit and the *solid lines* indicate the observed limit

Figure 9 shows the exclusion limits for the t2t1h and the t2t1Z analyses. In both cases, a limit on $m_{\tilde{t}_2}$ is set at about 600 GeV for a massless neutralino. In the case of a $\tilde{t}_2$ decay through a Higgs boson, the limit covers neutralino masses lower than in the case of the decay through a Z boson.

The assumption on the branching ratio of the $\tilde{t}_2$ has also been relaxed, and limits have been derived assuming that the three decays $\tilde{t}_2 \to Z\tilde{t}_1$, $\tilde{t}_2 \to h\tilde{t}_1$ and $\tilde{t}_2 \to t\tilde{\chi}_1^0$ (Fig. 3c) are the only possible ones. The limits are shown in Fig. 10 as a function of the three BRs, for different combinations of the $\tilde{t}_2$ and $\tilde{\chi}_1^0$ masses. Three analyses have been considered: the t2t1Z, t2t1h and the combination of the t0L and t1L discussed in Sect. 4.1.[7] The three analyses have complementary sensitivities. Together, they exclude $\tilde{t}_2$ pair production with a mass of 350 and 500 GeV for $m_{\tilde{\chi}_1^0} = 20$ GeV. A non-excluded region appears for $m_{\tilde{t}_2} = 500$ GeV if larger $\tilde{\chi}_1^0$ masses are considered.

4.4 Sbottom decays

Under the assumption that no supersymmetric particle takes part in the sbottom decay apart from the lightest neutralino, the sbottom decays as $\tilde{b}_1 \to b\tilde{\chi}_1^0$ with a branching ratio of 100 % (Fig. 2a). The final state arising from sbottom pair production hence contains two b-jets and $E_{\mathrm{T}}^{\mathrm{miss}}$. The b0L signal regions were explicitly optimised to be sensitive to this scenario. In case of a mass degeneracy between the sbottom and the neutralino, the general consideration that the monojet-like tc-M selection is almost insensitive to the details of the decay of the produced particles still holds: the tc-M signal regions offer the best sensitivity for scenarios where $m_{\tilde{b}_1} \sim m_{\tilde{\chi}_1^0}$.

Figure 11 shows the limits of the tc and b0L analyses on the $m_{\tilde{b}_1} - m_{\tilde{\chi}_1^0}$ plane. The monojet-like (tc-M) SRs exclude models up to a value of $m_{\tilde{b}_1} \sim m_{\tilde{\chi}_1^0} \sim 280$ GeV. Sbottom masses are excluded up to about 600 GeV for neutralino masses below about 250 GeV.

If other supersymmetric particles enter into the decay chain, then multiple decay channels would be allowed. Similarly to the stop, the case in which other neutralinos or charginos have a mass below the sbottom is well motivated. The branching ratios of the sbottom to the different decay channels depend on the supersymmetric particle mass hierarchy, on the mixing of the left–right components of the sbottom, and on the composition of the charginos and neutralinos in terms of bino, wino, and higgsino states.

An exclusion limit is derived under the assumption that the sbottom decays with a branching ratio of 100 % into $\tilde{b}_1 \to t\tilde{\chi}_1^{\pm}$ (Fig. 2g). The chargino is assumed to decay through $\tilde{\chi}_1^{\pm} \to W^{(*)}\tilde{\chi}_1^0$ with a branching ratio of 100 %. The final state is a complex one, and offers many handles for background rejection: it potentially contains up to ten jets, two b-jets, and up to four leptons. The limits of Fig. 12a, shown in the $m_{\tilde{b}_1} - m_{\tilde{\chi}_1^0}$ plane, were obtained by using the three-lepton signal regions SS3L, either fixing the mass of the neutralino to $m_{\tilde{\chi}_1^0} = 60$ GeV or by making the assumption that $m_{\tilde{\chi}_1^{\pm}} = 2m_{\tilde{\chi}_1^0}$. In the two scenarios considered, sbottom masses up to about 440 GeV are excluded, with a mild dependency on the neutralino mass.

The last case considered is one where the pair-produced sbottoms decay through $\tilde{b}_1 \to b\tilde{\chi}_2^0$, followed by the decay of $\tilde{\chi}_2^0$ into a $\tilde{\chi}_1^0$ and a SM-like Higgs boson h (Fig. 2h). The final state contains up to six b-jets, four of which are produced by the two Higgs bosons decays. Since multiple b-jets are present in the final state, the three-b-jets signal regions (g3b) are used to place limits in this model.

The limit, derived as a function of $m_{\tilde{b}_1}$ and $m_{\tilde{\chi}_2^0}$ assuming a fixed neutralino mass of $\tilde{\chi}_1^0 = 60$ GeV, is shown in Fig. 12b. Sbottom masses between about 300 and 650 GeV are excluded for $\tilde{\chi}_2^0$ masses above 250 GeV.

5 Interpretations in pMSSM models

The interpretation of the results in simplified models is useful to assess the sensitivity of each signal region to a specific topology. However, this approach fails to test signal regions on the complexity of the stop and sbottom phenomenology

[7] For the combination of the t0L and t1L analyses, the limits extracted for the $\tilde{t}_1 \to t\tilde{\chi}_1^0$ decay with branching ratio of 100 % have simply been rescaled by appropriate factors depending on the branching ratio of $\tilde{t}_2 \to t\tilde{\chi}_1^0$ considered here.

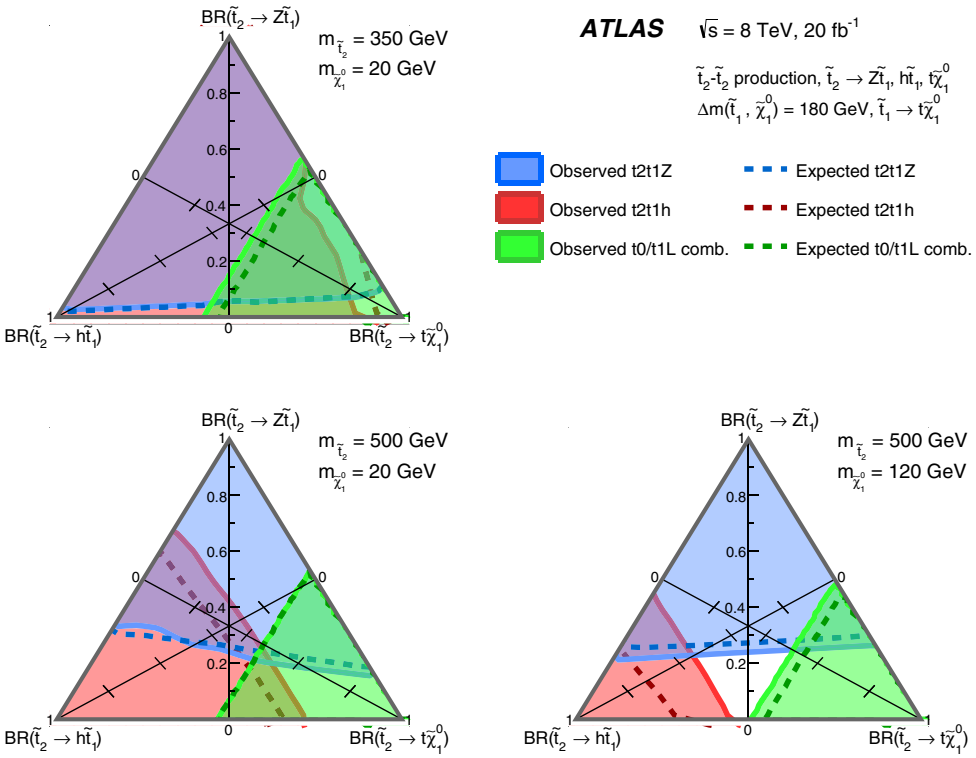

Fig. 10 Exclusion limits as a function of the $\tilde{t}_2$ branching ratio for $\tilde{t}_2 \to \tilde{t}_1 h$, $\tilde{t}_2 \to \tilde{t}_1 Z$ and $\tilde{t}_2 \to t\tilde{\chi}_1^0$. The *blue*, *red* and *green limit* refers to the t2t1Z, t2t1h and combination of t0L and t1L analyses respectively. The limits are given for three different values of the $\tilde{t}_2$ and $\tilde{\chi}_1^0$ masses

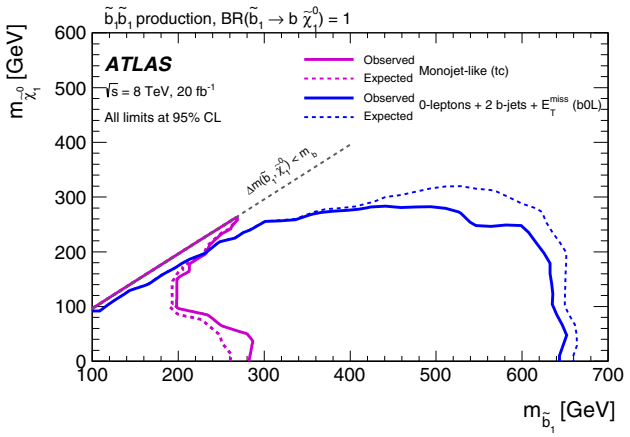

Fig. 11 Observed (*solid lines*) and expected (*dashed lines*) 95 % CL limits on sbottom pair production where the sbottom is assumed to decay as $\tilde{b}_1 \to b\tilde{\chi}_1^0$ with a branching ratio of 100 %. The *purple lines* refer to the limit of the tc analysis, while the *blue lines* refer to the b0L analysis

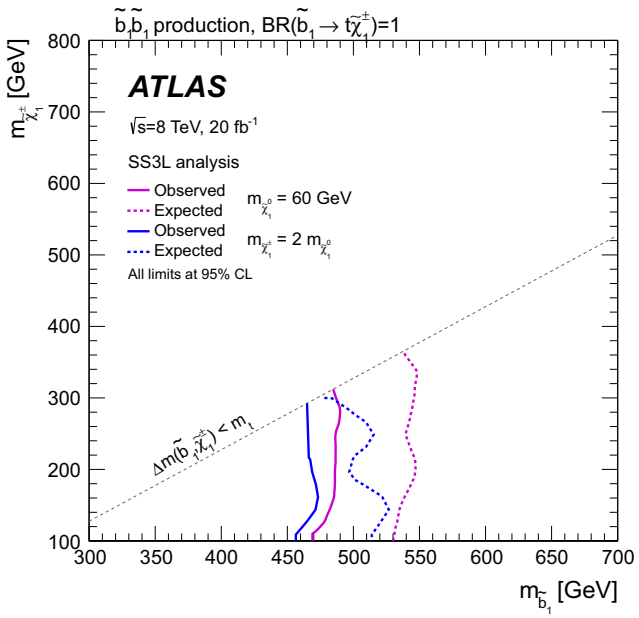
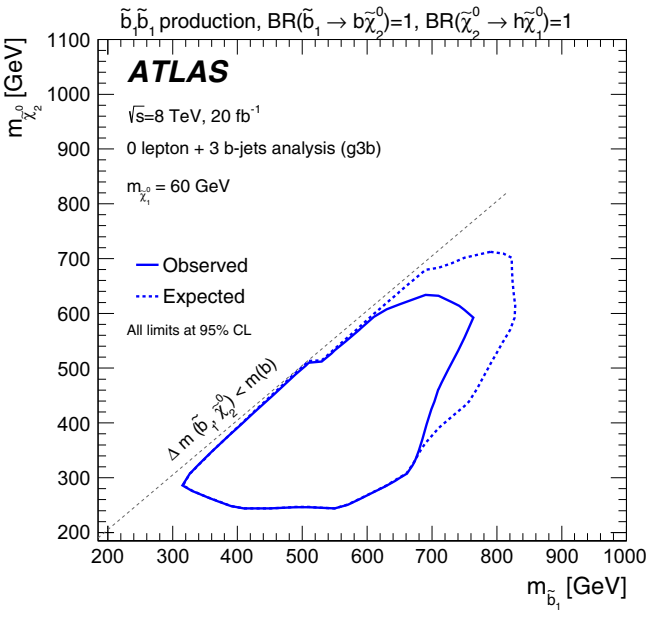
that appears in a realistic SUSY model. To this extent, the signal regions are used to derive exclusion limits in the context of specific pMSSM models.



The pMSSM [57] is obtained from the more general MSSM by making assumptions based on experimental results:

– No new source of CP violation beyond the Standard Model. New sources of CP violation are constrained by experimental limits on the electron and neutron electric dipole moments.
– No flavour-changing neutral currents. This is implemented by requiring that the matrices for the sfermion masses and trilinear couplings are diagonal.
– First- and second-generation universality. The soft-SUSY-breaking mass parameters and the trilinear couplings for the first and second generation are assumed to be the same based on experimental data from, e.g., the neutral kaon system [71].



With the above assumptions, and with the choice of a neutralino as the LSP, the pMSSM adds 19 free parameters on top of those of the SM. The complete set of pMSSM parameters is shown in Table 2.

A full assessment of the ATLAS sensitivity to a scan of the 19-parameters space has been performed in Ref. [72]. Here, a set of additional hypotheses are made, to focus on the sensitivity to a specific, well-motivated set of models with enhanced third generation squark production:

– The common masses of the first- and second-generation squarks have been set to a multi-TeV scale, making these quarks irrelevant for the processes studied at the energies investigated in this paper. This choice is motivated by the

(a)

(b)

Fig. 12 Exclusion limits at 95 % CL for a scenario where sbottoms are pair produced and decay as **a** $\tilde{b}_1 \to t\tilde{\chi}_1^{\pm}$ with a BR of 100 % or **b** $\tilde{b}_1 \to b\tilde{\chi}_2^0$ with a BR of 100 %. The signal regions used in **a** are the SS3L, and two different models are considered: a fixed neutralino mass of 60 GeV (in *purple*) or $m_{\tilde{\chi}_1^{\pm}} = 2m_{\tilde{\chi}_1^0}$ (in *blue*). The limits are shown in the $m_{\tilde{b}_1}$–$m_{\tilde{\chi}_1^{\pm}}$ plane. The signal regions used in **b** are the g3b-SR-0j. A fixed neutralino mass of 60 GeV is assumed, and the limit is shown in the $m_{\tilde{b}_1}$–$m_{\tilde{\chi}_2^0}$ plane

Table 2 Description of the 19 additional parameters of the pMSSM model with a neutralino LSP

Parameter	Description
$m_{\tilde{u}R}, m_{\tilde{d}R}, m_{\tilde{q}L1}, m_{\tilde{e}R}, m_{\tilde{\ell}L1}$	First- and second-generation common mass parameters
$m_{\tilde{b}R}, m_{\tilde{t}R}, m_{\tilde{q}L3}, m_{\tilde{\tau}R}, m_{\tilde{\ell}L3}$	Third-generation mass parameters
M_1, M_2, M_3	Gaugino mass parameters
A_b, A_τ, A_t	Trilinear couplings
μ, M_A	Higgs/higgsino mass parameters
$\tan\beta$	Ratio of vacuum expectation values of the two Higgs doublets

absence of any signal from squark or gluino production in dedicated SUSY searches performed by the ATLAS [62,63,73–76] and CMS [29,34,77–82] collaborations.

– All slepton mass parameters have been set to the same scale as the first- and second-generation squarks. This choice has no specific experimental or theoretical motivation, and should be regarded as an assumption.
– A decoupling limit with $M_A = 3$ TeV and large $\tan\beta$ values ($\tan\beta > 15$) has been assumed. This is partially motivated by results of the LHC searches for higher mass Higgs boson states [83,84].
– For $\tan\beta \gg 1$, the Higgs boson mass depends heavily on the product of the stop-mass parameters $M_S = \sqrt{m_{\tilde{t}_1} m_{\tilde{t}_2}}$ and the mixing between the left- and right-handed states $X_t = A_t - \mu/\tan\beta$ [85]. The stop sector is therefore completely fixed, given the Higgs boson mass, the value of X_t and one of the two stop mass parameters.[8]
– The trilinear couplings A_b in the sbottom sector are found to have limited impact on the phenomenology, and are therefore set to zero.
– The gluino mass parameter M_3 is set such to evade LHC constraints on gluino-pair production.

These assumptions reduce the number of additional free parameters of the model to the mass parameters of the electroweak sector (μ, M_1, M_2) and two of the three third-generation squark mass parameters ($m_{\tilde{q}L3}, m_{\tilde{t}R}, m_{\tilde{b}R}$). All the assumptions made either have a solid experimental basis, or are intended to simplify the interpretation in terms of direct production of stops and sbottoms (as, for example, the assumption on the slepton mass parameters).

Three types of models have been chosen, that, by implementing in different ways constraints arising from naturalness arguments and the dark-matter relic density measurement, further reduce the number of parameters to be scanned over. They are described below, and summarised in Table 3

[8] In particular, a minimum value of $M_S \sim 800$ GeV is allowed if the maximal mixing condition $X_t/M_S = \sqrt{6}$ is realised.

Table 3 Details of parameters scanned in the three pMSSM models used for interpretations. The settings of additional parameters that are fixed for each model are also given together with the main production and decay channels targeted

Model name	Parameters scanned	Other parameter settings	Production channels	Typical decays
Naturalness-inspired pMSSM	$350\ \text{GeV} < m_{\tilde{q}L3} < 900\ \text{GeV}$	$M_2 = 3\mu$	$pp \to \tilde{t}_1\tilde{t}_1$	For $\mu = 110$ GeV, $m_{\tilde{q}L3} = 400$ GeV
	$100\ \text{GeV} < \mu < m_{\tilde{q}L3} - 150\ \text{GeV}$	$m_{\tilde{t}_R}$ such that $M_S = 800$ GeV	$pp \to \tilde{b}_1\tilde{b}_1$	$\tilde{t}_1 \to t\tilde{\chi}_1^0$ (33 %); $\tilde{t}_1 \to t\tilde{\chi}_2^0$ (36 %)
		A_t such that $X_t/M_S = \sqrt{6}$		$\tilde{t}_1 \to b\tilde{\chi}_1^\pm$ (26 %); $\tilde{b}_1 \to t\tilde{\chi}_1^\pm$ (70 %)
				$\tilde{b}_1 \to b\tilde{\chi}_1^0$ (16 %); $\tilde{b}_1 \to b\tilde{\chi}_2^0$ (13 %)
Well-tempered neutralino pMSSM	$310\ \text{GeV} < m_{\tilde{q}L3} < 810\ \text{GeV}$		$pp \to \tilde{t}_1\tilde{t}_1$	For $M_1 = 110$ GeV, $m_{\tilde{q}L3} = 410$ GeV
	$110\ \text{GeV} < M_1 < m_{\tilde{q}L3} - 50\ \text{GeV}$		$pp \to \tilde{b}_1\tilde{b}_1$	$\tilde{t}_1 \to t\tilde{\chi}_2^0$ (35 %); $\tilde{t}_1 \to t\tilde{\chi}_3^0$ (38 %)
		$\mu \sim -M_1$		$\tilde{t}_1 \to b\tilde{\chi}_1^\pm$ (20 %); $\tilde{b}_1 \to t\tilde{\chi}_1^\pm$ (85 %)

				$\tilde{\chi}_3^0 \to Z\tilde{\chi}_1^0$ (85 %); $\tilde{\chi}_3^0 \to h\tilde{\chi}_1^0$ (15 %)
	$500\ \text{GeV} < m_{\tilde{q}L3} < 800\ \text{GeV}$	$M_1 = 100$ GeV; $M_2 = 1$ TeV	$pp \to \tilde{t}_1\tilde{t}_1$	For $\mu = 300$ GeV, $m_{\tilde{q}L3} = 600$ GeV
	$100\ \text{GeV} < M_1 < m_{\tilde{q}L3}$ GeV	$m_{\tilde{b}_R} = 3$ TeV; $m_{\tilde{t}_R} = 2$ TeV	$pp \to \tilde{b}_1\tilde{b}_1$	$\tilde{t}_1 \to t\tilde{\chi}_2^0$ (46 %); $\tilde{t}_1 \to t\tilde{\chi}_3^0$ (39 %)
		A_t fixed by $m_h \sim 125$ GeV		$\tilde{t}_1 \to b\tilde{\chi}_1^\pm$ (11 %); $\tilde{b}_1 \to t\tilde{\chi}_1^\pm$ (87 %)
				$\tilde{\chi}_2^0 \to Z\tilde{\chi}_1^0$ (24 %); $\tilde{\chi}_2^0 \to h\tilde{\chi}_1^0$ (76 %)
				$\tilde{\chi}_3^0 \to Z\tilde{\chi}_1^0$ (88 %); $\tilde{\chi}_3^0 \to h\tilde{\chi}_1^0$ (12 %)

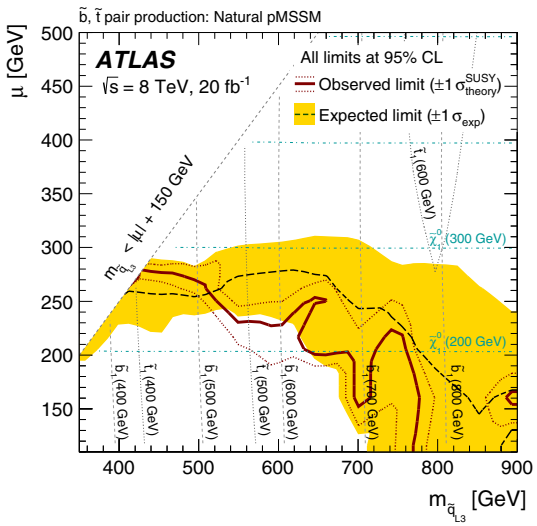
together with additional information on the most relevant production and decay channels.

Naturalness-inspired pMSSM The model is inspired by naturalness criteria, which require a value of μ in the range of a few hundred GeV, favour stop masses below one TeV, place weak constraints on the gluino mass and give no constraints on the mass of other SUSY particles [86]. The exclusion limits are determined as a function of the higgsino mass parameter μ and the left-handed squark mass parameter $m_{\tilde{q}L3}$. The parameter $m_{\tilde{q}L3}$ is scanned in the range 350 GeV $< m_{\tilde{q}L3} <$ 900 GeV. The parameter μ is scanned in the range 100 GeV $< \mu < m_{\tilde{q}L3} - 150$ GeV, where the lower bound is determined by limits on the chargino mass arising from LEP [66–70]. The right-handed stop mass parameter $m_{\tilde{t}R}$ and the stop mixing parameter X_t are determined by choosing the maximal mixing scenario $X_t/M_S = \sqrt{6}$ and by the requirement of having a Higgs boson mass of about 125 GeV. The other squark and slepton masses, as well as the bino mass parameter M_1, are set to 3 TeV. The wino mass parameter M_2 is set such that $M_2 = 3\mu$. The gluino mass parameter M_3 is set to 1.7 TeV.

With this choice of the model parameters, the spectrum is characterised by two light neutralinos $(\tilde{\chi}_1^0, \tilde{\chi}_2^0)$ and one chargino $(\tilde{\chi}_1^{\pm})$, all with masses of the order of μ, a light $\tilde{b}_1$ with a mass of the order of $m_{\tilde{q}L3}$, and a light $\tilde{t}_1$ with mass of the order of $m_{\tilde{q}L3}$ up to $m_{\tilde{q}L3} \sim 700$ GeV (the constraint on M_S does not allow the mass of $\tilde{t}_1$ to increase beyond about 650 GeV). The production processes considered are direct pair production of $\tilde{b}_1$ and $\tilde{t}_1$ with similar masses. Because of the abundance of light higgsino states, many different decays can occur.

Well-tempered neutralino pMSSM The models are designed to loosely satisfy dark-matter thermal-relic density constraints ($0.09 < \Omega_c h^2 < 0.15$, where h is the Hubble constant), while keeping fine tuning (defined as in Ref. [87]) to less than 1 %. The exclusion limits are determined as a function of M_1 and $m_{\tilde{q}L3}$, or M_1 and $m_{\tilde{t}R}$, with $\mu \sim -M_1$ in both cases to satisfy the dark-matter constraints through the presence of well-tempered neutralinos [88]. The constraints on the Higgs boson mass are satisfied in a way similar to the naturalness-inspired pMSSM model above. All other parameters are the same as in the naturalness-inspired pMSSM model. These models tend to have three neutralinos and two charginos with masses lower than $\tilde{t}_1$ or $\tilde{b}_1$, giving rise to a diverse phenomenology.

h/Z-enriched pMSSM These models are defined such that Higgs and Z bosons are produced abundantly in the SUSY particles' decay chains. The assumption of $M_1 = 100$ GeV ensures the presence of a bino-like neutralino LSP, while $M_3 = 2.5$ TeV ensures that direct gluino production is highly suppressed compared to third-generation squark production. Two sets of models have been defined: in the first one, μ and the right-handed sbottom mass parameter $m_{\tilde{b}R}$ are scanned while keeping $M_2 = \mu$, $m_{\tilde{q}L3} = 1.2$ TeV, $m_{\tilde{t}R} = 1.6$ TeV; in the second one, μ and $m_{\tilde{q}L3}$ are scanned while keeping $M_2 = 1$ TeV, $m_{\tilde{b}R} = 3$ TeV, $m_{\tilde{t}R} = 2$ TeV. The former is dominated by sbottom pair production, while both sbottom and stop pair production are relevant for the latter. Stop mixing parameters are chosen with maximal mixing to satisfy Higgs boson mass constraints. In these models, the decays of the third generation squarks into the heavier neutralino states ($\tilde{\chi}_2^0$ and $\tilde{\chi}_3^0$) are followed by decays to the lightest neutralino with the emission of a Z or a h boson. Typically the $\tilde{\chi}_2^0$ ($\tilde{\chi}_3^0$) decays into a Z boson 30 % (85 %) of the times, and into a Higgs boson 70 % (15 %) of the times. The subsequent decays of the Higgs boson into b-quark pairs (happening with the same branching ratio as in the Standard Model) lead to final states rich in b-jets.



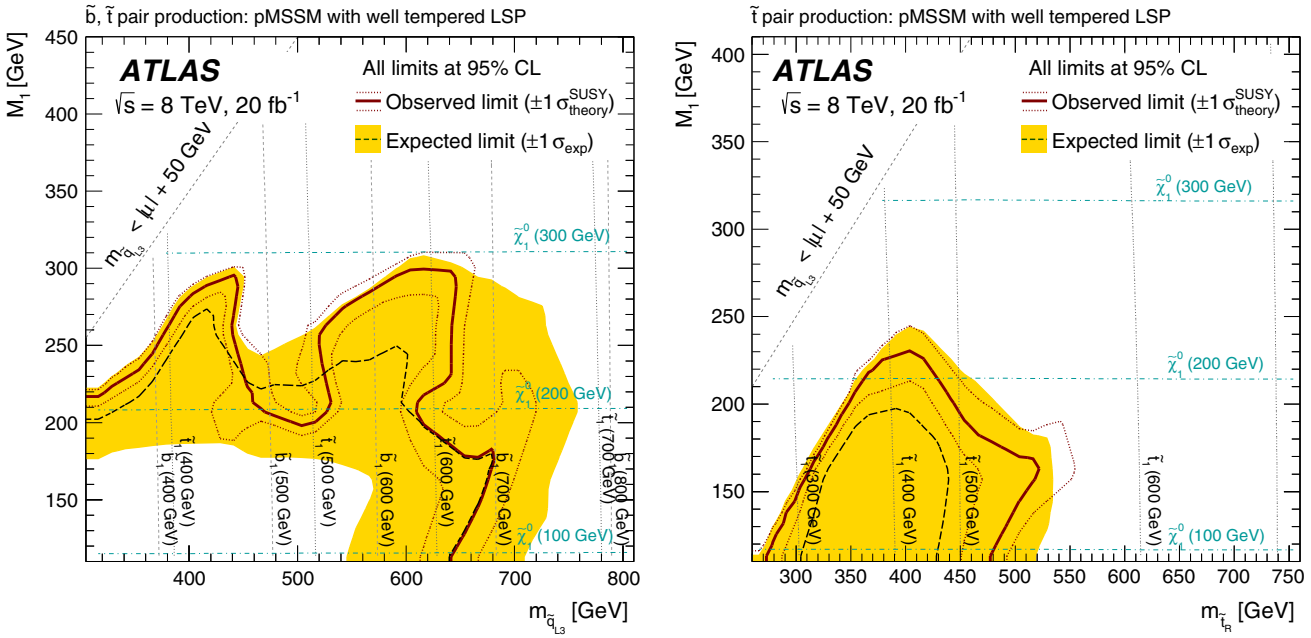


Fig. 13 Expected and observed 95 % CL exclusion limits for the naturalness-inspired set of pMSSM models from the combination t0L, t1L and tb analyses using the signal region yielding the smallest CL_s value for the signal-plus-background hypothesis. The *dashed black line* indicates the expected limit, and the *yellow band* indicates the $\pm 1\sigma$ uncertainties, which include all uncertainties except the theoretical uncertainties in the signal. The *red solid line* indicates the observed limit, and the *red dotted lines* indicate the sensitivity to $\pm 1\sigma$ variations of the signal theoretical uncertainties. The *dashed* and *dotted grey lines* indicate a constant value of the stop and sbottom masses, while the *dashed light-blue line* indicates a constant value of the neutralino mass

Exclusion limits for these pMSSM models are determined by combining many of the SRs defined for the searches discussed in this paper (t0L, t1L, tb,[9] t2t1Z, g3b, tc). For each

[9] The tb signal region, discussed in detail in Appendix B.2.3, implement a one-lepton selection, designed to be sensitive to final states containing a top quark, a b-quark and $E_{\mathrm{T}}^{\mathrm{miss}}$. It complements the selections of the $t0L$ and $t1L$ signal regions targeting $tt\,E_{\mathrm{T}}^{\mathrm{miss}}$ final states.

(a) **(b)**

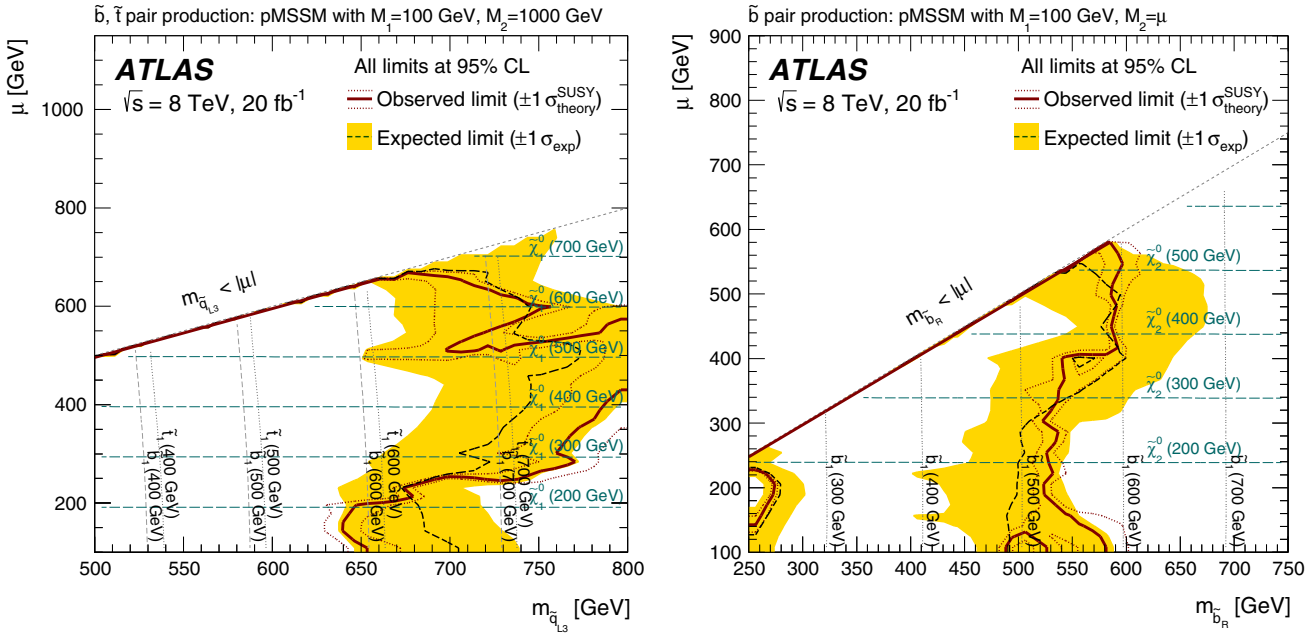

Fig. 14 Expected and observed 95 % CL exclusion limits for the pMSSM model with well-tempered neutralinos as a function of M_1 and **a** $m_{\tilde{q}L3}$ or **b** $m_{\tilde{t}_R}$. The limit of **a** is obtained as the combination of the t0L, t1L, tb and SS3L analyses, while the t0L analysis is used for **b**. The signal region yielding the smallest CL_s value for the signal-plus-background hypothesis is used for each point. The *dashed black line* indicates the expected limit, and the *yellow band* indicates the $\pm 1\sigma$ uncertainties, which include all uncertainties except the theoretical uncertainties in the signal. The *red solid line* indicates the observed limit, and the *red dotted lines* indicate the sensitivity to $\pm 1\sigma$ variations of the signal theoretical. The *dashed* and *dotted grey lines* indicate a constant value of the stop and sbottom masses, while the *dashed light-blue line* indicates a constant value of the neutralino mass

set of parameters the individual 95 % CL expected limit is evaluated. The combined exclusion contour is determined by choosing, for each model point, the signal region having the smallest expected CL_s value of the test statistic for the signal-plus-background hypothesis.

Figure 13 shows the exclusion limit for the naturalness-inspired set of pMSSM models based on the t0L, t1L and tb analyses. The t0L and t1L analyses have a similar expected sensitivity. These SRs were optimised assuming a 100 % BR for $\tilde{t}_1 \to t\tilde{\chi}_1^0$ or $\tilde{t}_1 \to b\tilde{\chi}_1^\pm$, while for these pMSSM models, the stop decays to $\tilde{t}_1 \to t\tilde{\chi}_1^0$, $\tilde{t}_1 \to b\tilde{\chi}_1^\pm$ and $\tilde{t}_1 \to b\tilde{\chi}_2^0$ with similar branching ratios (and the sbottom to both $\tilde{b}_1 \to b\tilde{\chi}_1^0$ and $\tilde{b}_1 \to t\tilde{\chi}_1^\pm$). The tb signal regions, discussed in detail in Appendix B.2.3, are designed to be sensitive to final states containing a top quark, a b-quark and missing transverse momentum and address such mixed-decay scenarios by requiring a lower jet multiplicity.

The signal regions that dominate the sensitivity are the tb, t0L-SRC1 and t1L-bCd_bulk at low values of $m_{\tilde{q}L3}$, and tb, t0L-SRA1, t0L-SRA2 and t1L-tNbC_mix at intermediate and high values of $m_{\tilde{q}L3}$. The excluded region for models with $m_{\tilde{q}L3} \sim 900$ GeV and $\mu \sim 150$ GeV is due to the saturation of $m_{\tilde{t}_1}$ at high $m_{\tilde{q}L3}$ values: to satisfy the Higgs boson mass constraint requires $M_S \sim 800$ GeV, hence $m_{\tilde{t}_1}$ at $m_{\tilde{q}L3} \sim 900$ GeV is smaller than that at $m_{\tilde{q}L3} \sim 800$ GeV. The large fluctuations of the observed limit with respect to the expected one are due to transitions between different signal regions providing the best expected exclusion in different regions of the plane.

Figure 14a, b show the exclusion limit obtained for the set of pMSSM models with well-tempered neutralinos as a function of $m_{\tilde{q}L3}$ and $m_{\tilde{t}R}$, respectively. In both cases, the exclusion is largely dominated by the t0L analysis. For Fig. 14a, the signal region dominating the sensitivity at low $m_{\tilde{q}L3}$ is t0L-SRC1, while at higher $m_{\tilde{q}L3}$ values t0L-SRA1 and t0L-SRA2 dominate the sensitivity. The drop in sensitivity at $m_{\tilde{q}L3} = 410$ GeV, $M_1 = 260$ GeV is due to the opening of the $\tilde{t}_1 \to t\tilde{\chi}_2^0$ and $\tilde{t}_1 \to t\tilde{\chi}_3^0$ transition, kinematically suppressed for smaller values of the difference $m_{\tilde{q}L3} - M_1$. Such decays introduce more intermediate states in the decay, effectively reducing the transverse momenta of the final state objects. The large fluctuations of the observed limit are again due to transitions between different signal regions. For Fig. 14b, the sensitivity is entirely dominated by the various t0L-SRC. The difference in sensitivity between these two scenarios is due to the presence of both a stop and

(a) (b)

Fig. 15 Expected and observed 95 % CL exclusion limits for the set of h/Z-enriched pMSSM models as a function of μ and **a** $m_{\tilde{q}L3}$ and **b** $m_{\tilde{b}_R}$. The limit of **a** is obtained as the combination of the t0L, g3b, t2t1Z and SS3L analyses, while the t0L, t2t1Z and tb analysis are used for **b**. The signal region yielding the smallest CL_s value for the signal-plus-background hypothesis is used for each point. The *dashed black line* indicates the expected limit, and the *yellow band* indicates the $\pm 1\sigma$ uncertainties, which include all uncertainties except the theoretical uncertainties in the signal. The *red solid line* indicates the observed limit, and the *red dotted lines* indicate the sensitivity to $\pm 1\sigma$ variations of the signal theoretical. The *dashed* and *dotted grey lines* indicate a constant value of the stop and sbottom masses, while the *dashed light-blue line* indicates a constant value of the neutralino mass

a sbottom for small $m_{\tilde{q}L3}$, while only a stop is present for low values of $m_{\tilde{t}R}$.

Finally, Fig. 15a, b show the exclusion limit obtained for the set of h/Z-enriched pMSSM models. These models yield large b-jet multiplicities to the final state through direct sbottom decays, top-quark decays and $\tilde{\chi}_2^0 \to h/Z\tilde{\chi}_1^0$. The exclusion is dominated by the t0L and g3b analyses for Fig. 15a and by and the t0L analysis for Fig. 15b.

More informations about the limits obtained, including the SLHA files for the points mentioned in Table 3, can be found in Refs. [89] and [90].

6 Conclusions

The search programme of the ATLAS collaboration for the direct pair production of stops and sbottoms is summarised and extended by new analyses targeting scenarios not optimally covered by previously published searches. The paper is based on 20 fb^{-1} of proton–proton collisions collected at the LHC by ATLAS in 2012 at a centre-of-mass energy $\sqrt{s}$ = 8 TeV. Exclusion limits in the context of simplified models are presented. In general, stop and sbottom masses up to several hundred GeV are excluded, although the exclusion limits significantly weaken in the presence of compressed SUSY mass spectra or multiple allowed decay chains. Three classes of pMSSM models, based on general arguments of Higgs boson mass naturalness and compatibility with the observed dark-matter relic density have also been studied and exclusion limits have been set. Large regions of the considered parameter space are excluded.

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently.

Acknowledgments We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWFW and FWF, Austria; ANAS, Azerbaijan; SSTC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR and VSC CR, Czech Republic; DNRF, DNSRC and Lundbeck Foundation, Denmark; EPLANET, ERC and NSRF, European Union; IN2P3-CNRS, CEA-DSM/IRFU, France; GNSF, Georgia; BMBF, DFG, HGF, MPG and AvH Foundation, Germany; GSRT and NSRF, Greece; RGC, Hong Kong SAR, China; ISF, MINERVA, GIF, I-CORE and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; BRF and RCN, Norway; MNiSW and NCN, Poland; GRICES and FCT, Portugal; MNE/IFA, Romania; MES of Russia and NRC KI, Russian Federation; JINR; MSTD, Serbia; MSSR, Slovakia; ARRS and MIZŠ, Slovenia; DST/NRF, South Africa; MINECO, Spain; SRC and Wallenberg Foundation, Sweden; SER, SNSF and Cantons of Bern and

A The ATLAS detector and object reconstruction

The ATLAS detector [91] consists of inner tracking devices surrounded by a superconducting solenoid, electromagnetic and hadronic calorimeters and a muon spectrometer immersed in a toroidal magnetic field. The inner detector (ID), in combination with a superconducting solenoid magnet with a central field of 2 T, provides precision tracking and momentum measurements of charged particles in a pseudorapidity[10] range $|\eta| < 2.5$. The ID consists of a silicon pixel detector, a silicon microstrip detector and a straw tube tracker ($|\eta| < 2.0$) that also provides transition radiation measurements for electron identification. A high-granularity electromagnetic calorimeter system, with acceptance covering $|\eta| < 3.2$, uses liquid argon (LAr) as the active medium. A scintillator-tile calorimeter provides hadronic coverage for $|\eta| < 1.7$. The end-cap and forward regions, spanning $1.5 < |\eta| < 4.9$, are instrumented with LAr electromagnetic and hadronic calorimeters. The muon spectrometer has separate trigger and high-precision tracking chambers which provide trigger coverage for $|\eta| < 2.4$ and muon identification and momentum measurements for $|\eta| < 2.7$.

The data sample used in this analysis was taken during the period from March to December 2012 with the LHC operating at a pp centre-of-mass energy of $\sqrt{s} = 8$ TeV.[11] Following requirements based on beam, detector conditions and data quality, the complete dataset corresponds to an integrated luminosity of 20.3 fb^{-1}, with an associated uncertainty of 2.8 %. The uncertainty is derived following the same methodology as that detailed in Ref. [92]. Events used in the analyses presented in this paper were selected using the ATLAS three-level trigger following different chains based on the signatures being considered. A common set of cleaning cuts, aimed at rejecting events heavily contaminated by non-collision backgrounds, or events containing badly measured or fake jets is applied to all analyses.

The experimental signature of third-generation supersymmetric particles includes the production of b-jets in association with missing transverse momentum and possibly additional jets and charged leptons. Different signatures are investigated in this paper to gain sensitivity to a variety of possible topologies arising from the production and decay of stops and sbottoms. Different event selections share common definitions of the final reconstructed objects, which are detailed in the remainder of this Appendix. Analysis-specific departures from those definitions are detailed for each case in Appendix B or in the specific analysis paper.

The reconstructed primary vertex [93] is required to be consistent with the luminous region and to have at least five associated tracks with $p_{\mathrm{T}} > 400$ MeV; when more than one such vertex is found, the vertex with the largest summed p_{T}^2 of the associated tracks is chosen.

Jets are constructed from three-dimensional clusters of noise-suppressed calorimeter cells [94] using the anti-k_t algorithm [95–97] with a distance parameter $R = 0.4$ and calibrated with a local cluster weighting algorithm [98]. An area-dependent correction is applied for energy from additional proton–proton collisions based on an estimate of the pileup activity in a given event using the method proposed in Ref. [99]. Jets are calibrated as discussed in Ref. [100] and required to have $p_{\mathrm{T}} > 20$ GeV and $|\eta| < 4.5$. Events containing jets arising from detector noise, cosmic-ray muons, or other non-collision sources are removed from consideration [100].

Jets arising from a b-quark fragmentation and within the acceptance of the inner detector ($|\eta| < 2.5$) are identified with an algorithm that exploits both the track impact parameters and secondary vertex information [101]; this algorithm is based on a neural network using the output weights of the IP3D, JetFitter+IP3D, and SV1 algorithms (defined in Refs. [102,103]). A lower cut on the output of the neural network defines the b-tagged jets. Three different working points are used, with a nominal efficiency of 60, 70 and 80 % as evaluated on simulated top quark pair production events. The corresponding rejection factors against jets originating from light (c) quarks are 25 (3), 135 (5) and 600 (8).

Electrons are reconstructed from energy clusters in the electromagnetic calorimeter matched to a track in the inner detector [104] and are required to have $|\eta| < 2.47$. Several criteria, including calorimeter shower shape, quality

[10] ATLAS uses a right-handed system with its origin at the nominal interaction point (IP) in the centre of the detector and the z-axis along the beam pipe. The x-axis points from the IP to the centre of the LHC ring, and the y-axis points upward. Cylindrical coordinates (r, ϕ) are used in the transverse plane, ϕ being the azimuthal angle around the beam pipe. The pseudorapidity is defined in terms of the polar angle θ as $\eta = -\ln\tan(\theta/2)$. The distance ΔR in the η–ϕ space is defined as $\Delta R = \sqrt{(\Delta\eta)^2 + (\Delta\phi)^2}$.

[11] The limits derived using a measurement of the $t\bar{t}$ production cross section discussed in Sect. 4.1 and Appendix B.1 also uses 4.7 fb^{-1} of pp collisions data collected at a centre-of-mass energy of $\sqrt{s} = 7$ TeV.

of the match between the track and the cluster, and the amount of transition radiation emitted in the TRT detector, are used to define three selections with decreasing efficiency and increasing purity, named respectively 'loose', 'medium' and 'tight' [104]. These three electron selections are used throughout this paper in the definitions of various signal and control regions. Muons, which are identified either as a combined track in the muon spectrometer and inner detector systems, or as an inner detector track matched with a muon spectrometer track segment [105,106], are required to have $|\eta| < 2.4$.

Electrons and muons (generically referred to by the symbol ℓ) are usually required to have transverse momentum $p_{\mathrm{T}} > 10$ GeV. For specific scenarios with compressed mass spectra, low-p_{T} leptons are expected and the p_{T} threshold is lowered to 6 GeV for muons and to 7 GeV for electrons.

The missing transverse momentum $\mathbf{p}_{\mathrm{T}}^{\mathrm{miss}}$ (with magnitude $E_{\mathrm{T}}^{\mathrm{miss}}$) is the negative vector sum of the p_{T} measured in the clusters of calorimeter cells, which are calibrated according to their associated reconstructed object (e.g. jets and electrons), and the p_{T} of the muons. Calorimeter cells not associated with any reconstructed object are also used in the calculation of $\mathbf{p}_{\mathrm{T}}^{\mathrm{miss}}$. The missing transverse momentum from the tracking system (denoted by $\mathbf{p}_{\mathrm{T}}^{\mathrm{miss,track}}$, with magnitude $E_{\mathrm{T}}^{\mathrm{miss,track}}$) is computed from the vector sum of the reconstructed inner detector tracks with $p_{\mathrm{T}} > 500$ MeV and $|\eta| < 2.5$, associated with the primary vertex in the event.

B Analyses used in the paper

Several signal regions are used in this paper, either standalone or in combination with others, to derive exclusion limits in the many models considered. This Appendix provides a review of the already published analyses and a more extended documentation of the signal regions not previously published.

B.1 Review of already published signal regions

The discussion of analyses that have already been published is reduced to a summary for the sake of brevity. Table 1 provides a reference to the papers where full details of the signal, control and validation region selections, together with the strategies adopted for the estimation of the background processes are found.

Multijet final states (t0L) The analysis is designed to be sensitive to final states arising from all-hadronic decays of directly pair-produced stops [16]. Two sets of signal regions were optimised to maximise the sensitivity to topologies arising from $\tilde{t}_1 \to t\tilde{\chi}_1^0$ decays, assumed to happen with a branching ratio of one. The first set of signal regions, named t0L-SRA, assumes that both top quark hadronic decays can be fully resolved by indentifying the six final-state jets. The SM background [dominated by $t\bar{t}$ and $Z+$ heavy flavour (HF) jets production] is rejected based on the presence of two hadronic systems consistent with top quarks and large $E_{\mathrm{T}}^{\mathrm{miss}}$. The second set of signal regions, named t0L-SRB targets a similar scenario, but aims at topologies where the top quarks have a large boost, and some of the decay products are merged into a single jet. The event selection is designed to select final states with a maximum of five $R = 0.4$ anti-k_t jets, to be mutually exclusive with t0L-SRA, and relies on the presence of $R = 0.8$ and $R = 1.2$ anti-k_t jets containing the hadronic decay products of the two top quarks. The jet masses, the transverse mass of the $E_{\mathrm{T}}^{\mathrm{miss}}$ and the nearest b-jet, and other variables are used to discriminate against the dominant SM $t\bar{t}$, Z + HF jets and W + HF jets production background processes.

Finally, a third set of signal regions, named t0L-SRC, is designed to increase the analysis sensitivity to the decay $\tilde{t}_1 \to b\tilde{\chi}_1^{\pm}$. The presence of the intermediate chargino state tends to decrease the jet multiplicity: these signal regions require five anti-k_t jets with $R = 0.4$, and base the signal selection on a set of transverse mass variables aimed at rejecting the dominant SM $t\bar{t}$ production process.

One-lepton final states (t1L) The large number of signal regions defined in this analysis stems from the variety and complexity of the possible stop final states considered [17]. All signal regions are characterised by the presence of one lepton, a second-lepton veto, a minimum of two jets and large $E_{\mathrm{T}}^{\mathrm{miss}}$. A first set of four signal regions (t1L-tN) were optimised assuming a branching ratio of 100 % for the decay $\tilde{t} \to t\tilde{\chi}_1^0$. These signal regions aim at having sensitivity to different $\Delta m(\tilde{t}, \tilde{\chi}_1^0)$, in particular t1L-tN_diag targets scenarios with small $\Delta m(\tilde{t}_1, \tilde{\chi}_1^0)$ and makes use of the shape information of the $E_{\mathrm{T}}^{\mathrm{miss}}$ and m_{T} distributions.[12] The t1L-tN_boost SR targets models with the largest $\Delta m(\tilde{t}, \tilde{\chi}_1^0)$, where the top quark produced by the stop decay has a large boost and large-R jets are used to reconstruct the top quark decays.

The decay $\tilde{t} \to \tilde{\chi}_1^{\pm} b$ introduces additional degrees of freedom in the decay. The final-state kinematics is largely driven by the mass separation between the stop and the chargino $\Delta m(\tilde{t}, \tilde{\chi}_1^{\pm})$, and by that between the chargino and the neutralino $\Delta m(\tilde{\chi}_1^{\pm}, \tilde{\chi}_1^0)$. Several signal regions, identified by the

[12] The transverse mass m_{T} of the lepton with transverse momentum $\mathbf{p}_{\mathrm{T}}$ and the missing transverse momentum vector $\mathbf{p}_{\mathrm{T}}^{\mathrm{miss}}$ with magnitude $E_{\mathrm{T}}^{\mathrm{miss}}$ is defined as

$$m_{\mathrm{T}} = \sqrt{2\left(|\mathbf{p}_{\mathrm{T}}| E_{\mathrm{T}}^{\mathrm{miss}} - \mathbf{p}_{\mathrm{T}} \cdot \mathbf{p}_{\mathrm{T}}^{\mathrm{miss}}\right)} \quad (1)$$

and it is extensively used in one-lepton final states to reject SM background processes containing a W boson decaying leptonically.

prefix t1L-bC were designed and optimised depending on the mass hierarchy and, consequently, on the different kinematics of the lepton and b-jets.

The four signal regions t1L-bCa_low, t1L-bCa_med, t1L-bCb_med1 and t1L-bCb_high target small values of $\Delta m(\tilde{\chi}_1^{\pm}, \tilde{\chi}_1^0)$ and have the common feature of making use of a dedicated soft-lepton selection: muons and electrons are identified down to a p_{T} threshold of 6 and 7 GeV, respectively, requiring a special treatment for the estimate of possible background processes arising from lepton misidentification. They are collectively referred to as "soft-lepton" signal regions. Both t1L-bCa signal regions require a hard ISR jet to boost the stop pair system and produce a sizeable $E_{\mathrm{T}}^{\mathrm{miss}}$. The t1L-bCb targets large values of $\Delta m(\tilde{t}_1, \tilde{\chi}_1^{\pm})$ and exploits the presence of two relatively hard b-jets in the event.

The signal region t1L-bCc_diag targets a mass hierarchy complementary to that of the t1L-bCb. The small value of $\Delta m(\tilde{t}, \tilde{\chi}_1^{\pm})$ gives rise to soft b-jets that go undetected, hence b-tagged jets are vetoed for this region.

Topologies arising from scenarios where both $\Delta m(\tilde{t}, \tilde{\chi}_1^{\pm})$ and $\Delta m(\tilde{\chi}_1^{\pm}, \tilde{\chi}_1^0)$ are sizeable are targeted by the three t1L-bCd regions: they all require four jets in the final state, are characterised by different b-jet multiplicities, and apply different selections on the $E_{\mathrm{T}}^{\mathrm{miss}}$, m_{T} and am_{T2}[13] variables. A veto on additional isolated tracks and τ lepton candidates identified with loose criteria helps to suppress the dominant SM background from dileptonic $t\bar{t}$ decays.

The last two signal regions listed in Table 1, t1L-3body and t1L-tNbC_mix, were optimised for two additional possible scenarios. If $\Delta m(\tilde{t}, \tilde{\chi}_1^0) < m_t$ and the mass hierarchy or the model parameters suppress the decay through a chargino, then the dominant stop decay is $\tilde{t} \rightarrow bW\tilde{\chi}_1^0$, through an off-shell top quark (three-body decay). The dedicated signal region relies on the shape information from the m_{T} and am_{T2} variable distributions. Finally, t1L-tNbC_mix is designed to recover sensitivity in scenarios where the stop is assumed to decay with similar probabilities to $t\tilde{\chi}_1^0$ and $b\tilde{\chi}_1^{\pm}$: the selection aims to reject the dominant dileptonic $t\bar{t}$ background by making use of the topness [109] variable.

Two-lepton final states (t2L) If the SUSY mass hierarchy forbids the presence of sleptons in the stop decay chain, final states containing two leptons (e or μ) and a large amount of $E_{\mathrm{T}}^{\mathrm{miss}}$ would arise from stop pair production. The main background is given by SM processes containing two W bosons in the final state (mainly $t\bar{t}$ and WW) [18]. To discriminate the stop signal from the SM background, the stransverse mass variable m_{T2} [107,108] is used. The stransverse mass, computed using the two leptons as visible particles and the missing transverse momentum vector, exhibits a kinematical end-point at m_W for most SM processes. Because of the presence of additional $E_{\mathrm{T}}^{\mathrm{miss}}$ due to the LSP, the end-point for a SUSY signal can be at larger values, depending on the mass separation between the particles involved in the decay. The analysis is optimised assuming $\tilde{t}_1 \rightarrow \tilde{\chi}_1^{\pm} b$ with BR = 100 % and $\Delta m(\tilde{\chi}_1^{\pm}, \tilde{\chi}_1^0) > m_W$, but it is also sensitive to the three-body decay mode of the stop. To derive exclusion limits, five signal regions (t2L) have been defined, requiring different jet multiplicities and different m_{T2} thresholds. A selection requiring two b-jets and based on m_{T2} computed using them as visible particles is sensitive to the chargino decay mode with $\Delta m(\tilde{t}_1, \tilde{\chi}_1^{\pm}) > m_t$. Finally, a multivariate discriminant is built which targets the $\tilde{t}_1 \rightarrow t\tilde{\chi}_1^0$ decay mode.

Final states from compressed stop decays (tc) If the difference in mass between the stop and the neutralino is smaller than the W boson mass, then the only possible decay channels are $\tilde{t} \rightarrow \tilde{\chi}_1^0 c$ or $\tilde{t} \rightarrow W^* b$, where the decay products of the off-shell W^* would, in general, be soft. This analysis [19] has defined two sets of signal regions, both optimised for the $\tilde{t} \rightarrow \tilde{\chi}_1^0 c$ decay. A common preselection requires the presence of a high-p_{T} jet, large $E_{\mathrm{T}}^{\mathrm{miss}}$ and applies a lepton veto. The first set of signal regions named tc-M, targets scenarios with the stop mass almost degenerate with the neutralino mass, and applies a selection that exploits a monojet-like signature arising from the presence of an ISR jet. Three different signal regions have been designed, characterised by increasing thresholds on the leading jet p_{T} and $E_{\mathrm{T}}^{\mathrm{miss}}$. The second set of signal regions, named tc-C, targets less compressed scenarios, and exploits the presence of jets originating from the fragmentation of c-quarks in the final state. A dedicated c-tagging algorithm was used to reject the dominant SM background processes arising mostly from $t\bar{t}$ and $Z \rightarrow \nu\bar{\nu}$ (produced in association with heavy-flavour jets) production. As in the case of the tc-M signal regions, different thresholds on the leading jet p_{T} and on $E_{\mathrm{T}}^{\mathrm{miss}}$ are used to identify a looser and a tighter tc-C region.

Final states with a Z boson (t2t1Z) A Z boson can be emitted in the decay of $\tilde{t}_2 \rightarrow \tilde{t}_1 Z$, producing final states with large lepton multiplicities. It can be useful to look for $\tilde{t}_2$ (rather than $\tilde{t}_1$) production if, for example, the mass of $\tilde{t}_1$ is very close to the sum of the top quark and neutralino masses, which would lead to $\tilde{t}_1$ pair production final states difficult to distinguish from SM $t\bar{t}$ production. Models are investigated with $\Delta m(\tilde{t}_1, \tilde{\chi}_1^0) = 180$ GeV with the decay $\tilde{t}_1 \rightarrow t\tilde{\chi}_1^0$. The final state would contain, beyond the Z boson, several jets arising from the $\tilde{t}_1$ decay. Similar final states can be obtained in GMSB models where the Z boson is emitted

[13] The asymmetric stransverse mass variable is a variant of the stransverse mass variable [107,108] defined to efficiently reject dileptonic $t\bar{t}$ decays. It assumes that the undetected particle is the W boson for the branch with the lost lepton and the neutrino is the missing particle for the branch with the observed charged lepton. For the dileptonic $t\bar{t}$events, am_{T2} is bounded from above by the top quark mass, whereas new physics can exceed this bound.

in the $\tilde{\chi}_1^0 \to \tilde{G}Z$ decay if the gravitino $\tilde{G}$ is the LSP and the neutralino the NLSP.

This analysis [20] defines five different signal regions divided into two sets. The first set, named t2t1Z-SR2, requires two same-flavour leptons whose invariant mass is consistent with that of a Z boson, m_Z, and at least one b-tagged jet. The three signal regions are characterised by the different selection thresholds applied to the $E_{\mathrm{T}}^{\mathrm{miss}}$, to the transverse momentum of the dilepton system p_{T} $(\ell\ell)$ and to the jet multiplicity. The second set of signal regions, named t2t1Z-SR3, requires three leptons, two of which must form an opposite-sign same-flavour pair whose invariant mass is consistent with m_Z. Both signal regions require at least five jets, among which at least one has to be b-tagged. The two signal regions are characterised by the different selection thresholds applied to p_{T} $(\ell\ell)$ and to the leading lepton p_{T}.

Final states with two b-jets and $E_{\mathrm{T}}^{\mathrm{miss}}$ (b0L) This signature arises naturally from the sbottom decay $\tilde{b}_1 \to b\tilde{\chi}_1^0$. Moreover, one expects the same final state from $\tilde{t}_1 \to \tilde{\chi}_1^{\pm} b$ followed by $\tilde{\chi}_1^{\pm} \to ff'\tilde{\chi}_1^0$ in the limit of small $\Delta m(\tilde{\chi}_1^{\pm}, \tilde{\chi}_1^0)$. This analysis [21] defines two sets of signal regions, b0L-SRA and b0L-SRB, targeting scenarios with large and small squark–neutralino mass separations, respectively.

The event selection of b0L-SRA requires large $E_{\mathrm{T}}^{\mathrm{miss}}$, exactly two b-jets and vetoes the presence of additional jets; the rejection of the SM $t\bar{t}$production background is carried out by making use of the contransverse mass [110] of the two b-jets. Its distributions shows a kinematical end-point at about 135 GeV for $t\bar{t}$ production, while extending to higher values for the signal.

A selection relying on the presence of an ISR jet is instead needed if the third-generation squark mass is almost degenerate with that of the neutralino. This is the purpose of b0L-SRB, which selects a hard, non-b-tagged leading jet recoiling against the squark pair system. The selection includes the requirement of two b-tagged jets, a veto on additional hadronic activity, and the presence of large $E_{\mathrm{T}}^{\mathrm{miss}}$.

Final states with three b-jets (g3b) This analysis [62] is designed to search for gluino-mediated sbottom and stop production in events with no leptons or one lepton (electron or muon) in the final state. However, it was found to have sensitivity for direct $\tilde{b}_1$ production followed by $\tilde{b}_1 \to \tilde{\chi}_2^0 b \to \tilde{\chi}_1^0 hb$, where h is the SM Higgs boson with mass $m_h = 125$ GeV, and also sensitivity to some of the pMSSM models considered in this paper. Such final states are characterised by a large multiplicity of b-jets both in $\tilde{g}\tilde{g} \to \tilde{t}_1\tilde{t}_1 tt$ and $\tilde{g}\tilde{g} \to \tilde{b}_1\tilde{b}_1 bb$ where there are up to four b-jets in the final state.

Three sets of signal regions have been designed to target different mass hierarchies of the gluino-mediated sbottom and stop production models. All signal regions have at least four jets with $p_{\mathrm{T}} > 30$ GeV, three identified b-jets, large $E_{\mathrm{T}}^{\mathrm{miss}}$ and a large m_{eff}, defined as the scalar sum of the p_{T} of the jets and $E_{\mathrm{T}}^{\mathrm{miss}}$.

Strongly produced final states with two same sign or three leptons (SS3L) Final states containing many leptons or same-sign (SS) leptons can arise from the pair production of gluinos and squarks, when the produced particles decay to the LSP through multiple intermediate stages, or when several top quarks appear as part of the decay chain. The analysis was developed for the gluino-mediated stop production process $\tilde{g}\tilde{g} \to \tilde{t}_1\tilde{t}_1 tt$ followed by $\tilde{t}_1 \to t\tilde{\chi}_1^0$, which can yield final states containing up to four leptons, including SS pairs. Similar final states arise from the sbottom decay $\tilde{b}_1 \to t\tilde{\chi}_1^{\pm}$, which are studied in this paper.

This analysis [63] concentrates on final states containing either three leptons or a SS lepton pair produced in association with many jets. Five signal regions (identified by the prefix SS3L) are defined, which are characterised by different light- and heavy-flavour jet multiplicities, high selection thresholds on $E_{\mathrm{T}}^{\mathrm{miss}}$ and m_{eff}, and different thresholds on the transverse mass of the lepton with the highest transverse momentum and the $E_{\mathrm{T}}^{\mathrm{miss}}$.

Spin correlation in $t\bar{t}$ production events (SC) If the mass of the $\tilde{t}_1$ is such that $m_{\tilde{t}_1} \sim m_{\tilde{\chi}_1^0} + m_t$, the final-state kinematics are similar to that of Standard Model $t\bar{t}$ production. One possible approach is to derive exclusion limits on the stop mass by performing SM precision measurements. This analysis has measured the azimuthal angle difference between the two leptons arising from the dileptonic $t\bar{t}$ decay [64]. The events are required to contain, beside the two leptons, at least two additional jets, one of which is required to be b-tagged. In events containing two leptons of the same flavour, the Z production background is suppressed by applying a selection on the dilepton invariant mass. The distribution of the azimuthal angle between the two leptons is sensitive to the spin correlations of the $t\bar{t}$ system: it is hence used to extract limits on possible contaminations from direct scalar top production events.

***$t\bar{t}$* production cross section (xsec)** The measurement of the $t\bar{t}$ production cross section using events containing two different-flavour leptons $e\mu$ and b-tagged jets is used in Ref. [65] to extract limits on the direct pair production of $\tilde{t}_1$ with mass close to the top quark. The assumed decay is $\tilde{t}_1 \to t\tilde{\chi}_1^0$.

The $t\bar{t}$ production cross section $\sigma_{t\bar{t}}$ is obtained by using the equations

$$N_1 = L\sigma_{t\bar{t}}\epsilon_{e\mu} 2\epsilon_b(1 - C_b\epsilon_b) + N_1^{\mathrm{bkg}} \quad (2)$$

$$N_2 = L\sigma_{t\bar{t}}\epsilon_{e\mu} C_b\epsilon_b^2 + N_2^{\mathrm{bkg}} \quad (3)$$

where N_1 and N_2 are the number of events with two different flavour leptons having exactly one or two b-tagged jets, respectively, L is the integrated luminosity, $\epsilon_{e\mu}$ the efficiency for a $t\bar{t}$ event to pass the lepton selection, ϵ_b is the probability of having a b-jet within acceptance and for it to be tagged, C_b is a correlation coefficient which is close to unity, and N_1^{bkg} and N_2^{bkg} are the number of events with one or two b-tagged jets from SM events different from $t\bar{t}$ production. The values of $\sigma_{t\bar{t}}$ and ϵ_b are extracted from the data by solving the two simultaneous Eqs. (2) and (3), avoiding the need to estimate ϵ_b from simulation.

Stop-pair production events with $m_{\tilde{t}_1} > m_t + m_{\tilde{\chi}_1^0}$ have similar $\epsilon_{e\mu}$ and b-jet kinematics to SM $t\bar{t}$ production events, so the fitted value of ϵ_b in a combined sample is compatible with that from $t\bar{t}$ production events alone, and the fitted cross section corresponds closely to the sum of $t\bar{t}$ and stop-pair production cross sections. Limits on stop pair production are extracted by calculating 95 % CL limits on the stop pair production signal strength μ (defined as the ratio of the obtained stop cross section to the theoretical prediction) based on the comparison of the measured cross section with that predicted for SM $t\bar{t}$ production events alone. A 95 % CL signal strength smaller than unity for a given signal point implies its exclusion.

This interpretation, which made use of collision data with both $\sqrt{s} = 7$ and 8 TeV, is extended here to the three-body decay $\tilde{t}_1 \to Wb\tilde{\chi}_1^0$. The main difference with respect to the scenario considered in Ref. [65] is that the three-body decay tends to yield b-jets with lower p_{T}, leading to a fitted ϵ_b for the combined sample which is different from that expected for $t\bar{t}$ events alone. The limits obtained are summarised in Fig. 16 for a neutralino mass of 1 GeV. A 95 % CL limit that excludes stop masses below 175 GeV is obtained. The figure also shows the effect on the limit of a "sneaky top squark" scenario [111]: the presence of a $\tilde{t}_1$ with mass similar to that of the top quark could bias the measurement of the top-quark mass itself. The bias in the top-mass measurement introduced by the existence of a $\tilde{t}_1$ with mass $m_{\tilde{t}_1} = 170$ GeV depends on the analysis technique and channel, and was evaluated to be at most 1 GeV for the two- and three-dimensional template techniques used in the ATLAS top mass measurement in the lepton+jets channel [112]. The effect of a potential bias of 1 and 2.5 GeV on the top-mass measurement was studied by recalculating the observed 95 % CL limit on μ when reducing the predicted SM $t\bar{t}$ production cross section from the baseline value of $m_t = 172.5 \pm 1.0$ GeV to those obtained for top mass central values of 173.5 and 175 GeV. The corresponding limit on the stop mass is reduced by about 5 and 15 GeV, respectively.

The dependence of the exclusion limits on the neutralino mass was studied and found to be important: the effect of an increasing neutralino mass is to decrease the p_{T} of the b-jets,

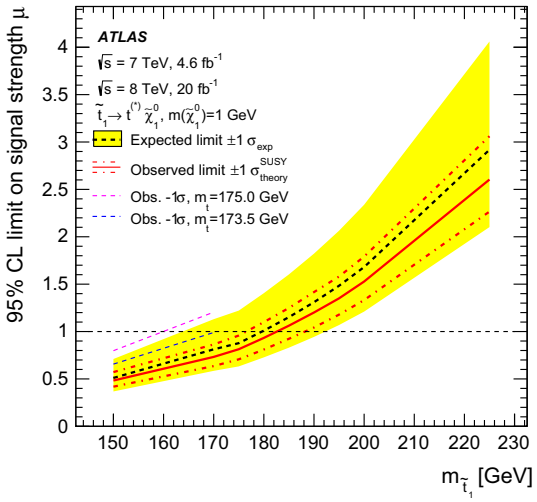

Fig. 16 Expected and observed 95 % CL limits on the signal strength μ (defined as the ratio of the obtained stop cross section to the theoretical prediction) for the production of $\tilde{t}_1$ pairs as a function of $m_{\tilde{t}_1}$. The stop is assumed to decay as $\tilde{t}_1 \to t\tilde{\chi}_1^0$ or through its three-body decay depending on its mass. The neutralino is assumed to have a mass of 1 GeV. The *black dotted line* shows the expected limit with $\pm 1\sigma$ uncertainty band *shaded in yellow*, taking into account all uncertainties except the theoretical cross-section uncertainties on the signal. The *red solid line* shows the observed limit, with *dotted lines* indicating the changes as the nominal signal cross section is scaled *up* and *down* by its theoretical uncertainty. The *short blue* and *purple dashed lines* indicate how the observed limits with the signal cross section reduced by one standard deviation of its theoretical uncertainty for $m_{\tilde{t}_1} < m_t$ when the top quark mass is assumed instead to be 173.5 ± 1.0 and 175.0 ± 1.0 GeV

and hence to lower the value of ϵ_b for the stop pair production signal. For a neutralino mass of 30 GeV, only a small range of stop masses around 150 GeV is excluded.

The sensitivity of the $t\bar{t}$ cross-section measurement to $\tilde{t}_1$ pair production assuming a branching ratio of 100 % into $\tilde{t}_1 \to b\tilde{\chi}_1^{\pm}$, followed by $\tilde{\chi}_1^{\pm} \to W^{(*)}\tilde{\chi}_1^0$ with $m_{\tilde{\chi}_1^{\pm}} = 2m_{\tilde{\chi}_1^0}$ was also investigated. The presence of the intermediate chargino state tends to lower the p_{T} of the leptons and of the b-jets significantly, hence decreasing both $\epsilon_{e\mu}$ and ϵ_b. No exclusion limit can be derived for this scenario.

Summarising, the limits on stop pair production obtained in Ref. [65] have been extended by considering the stop three-body decay. Stop masses between 150 GeV and m_t can be excluded for a neutralino mass of 1 GeV. The exclusion holds provided that any bias in the top-quark mass measurement by a nearby stop is not significant. Studies indicate that this potential bias would affect the limit on the stop mass by less than 5 GeV.

B.2 Description of the new signal regions

New analyses were developed to target topologies and regions of the SUSY parameter space not well covered

by previously published signal regions. They are identified throughout this paper and in Table 1 with the acronym WW, tb and t2t1h. Their contribution to the exclusion limits derived both in simplified and pMSSM models is outlined in Sects. 4 and 5 respectively. In this Appendix, further details about these analyses are provided for the interested reader. Additional informations about selection efficiencies, sensitivities of the different signal regions and individual limit plots, please refer to Refs. [89,90].

B.2.1 Final states with two leptons at intermediate values of $m_{T2}(WW)$

The measurement of the production cross section of non-resonant WW pairs in the two-lepton channel at the LHC [113–115] has given rise to theoretical speculations [116–118] which interpret the possible excess as due to the production of a light stop. The mass hierarchy favoured by these speculations includes a $\tilde{t}_1$ with mass around 200 GeV, a $\tilde{\chi}_1^\pm$ degenerate with it, and $m_{\tilde{\chi}_1^\pm} - m_{\tilde{\chi}_1^0}$ of a few tens of GeV: possible hadronic decay products of the $\tilde{t}_1 \to b\tilde{\chi}_1^\pm$ transition would have low p_{T} and would allow the events to survive the tight jet-veto selections applied in the SM cross-section measurement. Dedicated signal regions, defined by requiring two different-flavour opposite-sign leptons in the final states, are designed to have maximum sensitivity to such scenarios. The approach is also sensitive to scenarios where the stop decays predominantly through the three-body $\tilde{t}_1 \to bW\tilde{\chi}_1^0$ or four-body $\tilde{t}_1 \to b\ell\nu\tilde{\chi}_1^0$ decay.

MC simulated events are used to model the signal and to describe all backgrounds that produce two prompt leptons from W, Z or h decay. For processes whose predicted yield in the signal regions is small, or whose topology resembles very closely that of the signal, making it hard to define a proper control region, the background estimate is fully based on MC simulation. For $t\bar{t}$, Z + jets and WW production processes, which are the dominant backgrounds, the acceptance of the signal regions selection is estimated with MC simulation, while the normalisation is estimated in dedicated control regions. The MC samples used are the same as in Ref. [18].

The identification criteria for electrons, muons and jets follow the strategy defined in Appendix A: baseline electrons, which are used in the estimation of the fake-lepton background, are selected by applying the "medium" identification criteria. Signal electrons are identified using the "tight" criteria, and they are further required to be isolated. Signal muons correspond to baseline muons with an additional calorimeter- and track-based isolation requirement applied. Jets that have $|\eta| < 2.5$ and $p_{\mathrm{T}} > 20$ GeV are used for the event selection, although all jets up to $|\eta| < 4.5$ are retained for the computation of the missing transverse momentum.

Candidate stop production events, preselected by the same trigger and data quality requirements used in Ref. [18], are further required to contain one electron and one muon of opposite charge, with an invariant mass $m_{\ell\ell} > 20$ GeV. The leading (in p_{T}) and next-to-leading leptons are required to have $p_{\mathrm{T}} > 25$ GeV and $p_{\mathrm{T}} > 20$ GeV, respectively.

At this stage of the selection, the background is dominated by production of top-quark pairs and $Z \to \tau\tau$, followed by WW and Wt production.

A requirement of $m_{\mathrm{T2}} > 20$ GeV, where m_{T2} is the stransverse mass of the two leptons, strongly reduces the $Z \to \tau\tau$ background, which is expected to have a kinematical end-point at $m_{\mathrm{T2}} = m_\tau$. The ratio R_1 of the $E_{\mathrm{T}}^{\mathrm{miss}}$ and the effective mass, defined as the scalar p_{T} sum of the $E_{\mathrm{T}}^{\mathrm{miss}}$, the leptons and the jets, is useful in suppressing the $t\bar{t}$ background, which is typically characterised by a larger hadronic activity than in signal events. The selection chosen is $R_1 > 0.3 + m_{\mathrm{eff}}$ (with m_{eff} in TeV).

After the above selections, the SM background is dominated by WW production. Two differences between this process and the stop pair production signal are further exploited: firstly, the WW production is dominated by quark-antiquark scattering, while stop pair production is mostly initiated by gluon-gluon processes, and secondly the stop pair production signal has four invisible (two neutralinos and two neutrinos) and two undetected (the two b-jets) objects, while the WW process has only two. The first difference implies a higher longitudinal boost of the system emerging from the hard scattering in signal events than in background events. The variable

$$\Delta X = 2\left|\frac{(p_z(\ell_1) + p_z(\ell_2))}{\sqrt{s}}\right| \tag{4}$$

was defined in Ref. [119], and it is an estimator of the boost. The second difference implies a higher $E_{\mathrm{T}}^{\mathrm{miss}}$ for signal events. This is exploited by making use of

$$R_2 = \frac{E_{\mathrm{T}}^{\mathrm{miss}}}{E_{\mathrm{T}}^{\mathrm{miss}} + p_{\mathrm{T}}(\ell_1) + p_{\mathrm{T}}(\ell_2)}. \tag{5}$$

Finally, the variable $\cos\theta_{\mathrm{b}}$, the cosine of the angle between the direction of motion of one of the two leptons and the beam axis in the centre-of-mass frame of the two visible leptons [119], is sensitive to the spin of the produced particles, hence it provides additional rejection power against the WW production process.

A set of seven signal regions were optimised for the discovery of stop pair production, with the stop decaying either as $\tilde{t}_1 \to \tilde{\chi}_1^\pm b$ with a branching ratio of 100 % (assuming $m_{\tilde{t}_1} - m_{\tilde{\chi}_1^\pm} < 10$ GeV), or as $\tilde{t}_1 \to bW^{(*)}\tilde{\chi}_1^0$. The definitions of the signal regions are shown in Table 4.

Table 4 Summary of signal regions used in the analysis. The upper part of the table shows the preselection requirements

SR	WW-SR1	WW-SR2	WW-SR3	WW-SR4	WW-SR5	WW-SR6	WW-SR7
$p_{\mathrm{T}}(\ell_1)$	>25 GeV						
$p_{\mathrm{T}}(\ell_2)$	>20 GeV						
R_1	$>0.3+m_{\mathrm{eff}}$ (TeV)						
m_{T2}	>20 GeV						
ΔX	<0.02						
R_2	>0.5						
$\lvert\cos\theta_{\mathrm{b}}\rvert$	<0.8	<0.8	<0.8	–	–	<0.8	–
m_{T2}	<45 GeV	>25, <55 GeV	–	>70 GeV	>90 GeV	>25, <70 GeV	>80 GeV

The background from non-prompt leptons originating from heavy-quark decays or from photon conversions in the signal regions, or from hadrons misidentified as leptons (collectively referred to as fake leptons in the following), is estimated as in Ref. [18].

Specific control regions, whose event yield is expected to be dominated by each of these production processes, are defined and included in the fit to constrain the normalisation parameters. The control region CRT for $t\bar{t}$ production is defined by changing the following selections with respect to the signal regions: $m_{\mathrm{T2}} > 35$ GeV, $R_1 < 0.3$. Its purity is 92 %. The CR for WW production (CRW) is defined by $m_{\mathrm{T2}} > 35$ GeV, $\Delta X > 0.04$, and has a purity of 72 %. Finally, the CR for Z + jets (CRZ) is defined by $m_{\mathrm{T2}} < 20$ GeV, 30 GeV $< m_{\ell\ell} <$ 80 GeV, with a purity of 86 %. The normalisation factors of the WW, $t\bar{t}$, Z + jets production processes (μ_{WW}, $\mu_{t\bar{t}}$ and μ_Z respectively) are determined by a combined profile likelihood fit. When testing the signal-plus-background hypothesis for rejection, the fit takes automatically into account the signal contamination in the control regions. For signal scenarios considering light ($m_{\tilde{t}_1} < 150$ GeV) stops decaying through $\tilde{t}_1 \to bW^{(*)}\tilde{\chi}_1^0$, the signal contamination becomes so large that μ_{WW} becomes unrealistically low. For such cases the fit is performed excluding CRW and taking the normalisation of the WW background from MC simulation.

Systematic uncertainties, affecting both the modelling of the detector response (detector-related systematic uncertainties) and the theoretical prediction of the cross sections and acceptances of the background processes (theory-related systematic uncertainties) affect the predicted rates in the signal regions. Their classification and estimation follows closely those defined in Ref. [18]. A few differences, discussed in the following, exist on the estimation of the theory-related uncertainties. The total uncertainty on the yield of the WW production process is composed of three terms: the uncertainty on the NLO hard-scattering calculation is taken to be the difference between the prediction of POWHEG and aMC@NLO both using PYTHIA for the parton shower; the uncertainty addressing the choice of the parton-shower model is estimated as the difference of the aMC@NLO predictions showered either with HERWIG or PYTHIA; the uncertainty due to the choice of the renormalisation and factorisation scale is evaluated by changing the scales independently by a factor of two or one-half and taking the maximum difference. The estimated relative uncertainties on the signal region yields are about 6 % in SR1–SR4 and SR6; 11 % in SR7 and 29 % in SR5. Similar comparisons performed on the WZ and ZZ process yield uncertainties ranging from 30 to 45 % depending on the signal region considered. Additional systematic uncertainties are assigned to the small expected yields from Z + jets production (80 %), Wt (50–100 % depending on the SR considered), and non-prompt lepton background.

Table 5 Normalisation factors for the $t\bar{t}$, WW and Z + jets background processes obtained by the combined fit to the control region yields. The uncertainties include systematic and statistical uncertainties

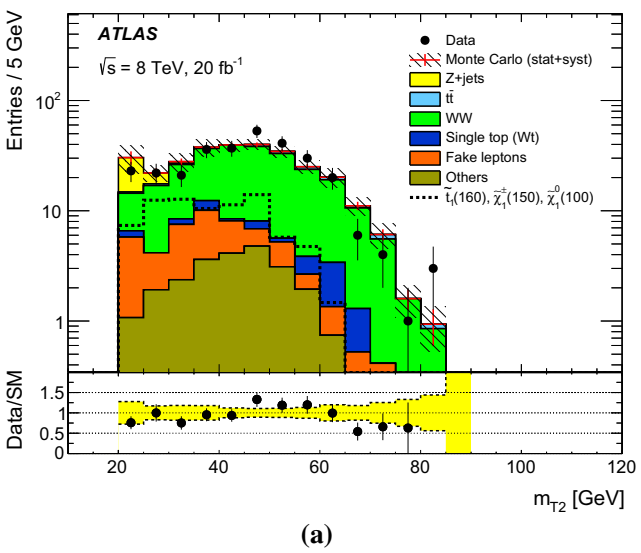
Normalisation factor	Value
$\mu_{t\bar{t}}$	0.94 ± 0.05
μ_{WW}	1.01 ± 0.11
μ_Z	0.95 ± 0.62

The values of the normalisation factors obtained when performing the fit to the control regions only are shown in Table 5.

The overall predictions of the fit are compared to the data in dedicated validation region that are kinematically close to the signal region. They are defined by applying the preselection requirements of Table 4 with the additional selections shown in Table 6. The m_{T2} distribution in WW-VR2 and WW-VRT is shown in Fig. 17.

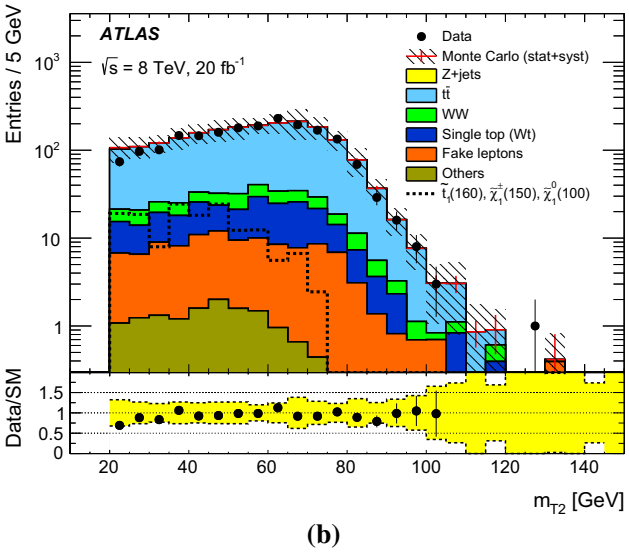
For all signal regions, the expected background yield is dominated by production of WW (35 % in SR1 to 66 % in SR4). Other important background processes are Z + jets in SR1 (20 %), non-prompt leptons in SR2 (12 %), $t\bar{t}$ in all other SR, with contributions of about 10 %. The distributions of $E_{\mathrm{T}}^{\mathrm{miss}}$ and m_{T2} in the signal region WW-SR3 are shown in Fig. 18.

Table 6 Summary of the validation regions used in the WW analysis. The preselection requirements of Table 4 are also applied in all three validation regions



WW-VR1	WW-VR2	WW-VRT
–	–	$0.3 < R_1 < 0.3 + m_{\text{eff}}$ (TeV)
$0.02 < \lvert\Delta X\rvert < 0.04$	$\Delta X < 0.02$	$\Delta X < 0.02$
$R_2 > 0.5$	$R_2 < 0.5$	$R_2 > 0.5$
$\lvert\cos\theta_b\rvert < 0.8$	$\lvert\cos\theta_b\rvert < 0.8$	$\lvert\cos\theta_b\rvert < 0.8$

Table 7 compares the predicted and observed numbers of events in each of the signal regions. No excess above the SM prediction is observed, hence the results are first used to derive model-independent 95 % CL exclusion limits on the minimum number of events beyond the Standard Model in the signal region assuming no signal contamination in the control regions, and then to extract limits on $\sigma_{\text{vis}} = \sigma \times \epsilon \times \mathcal{A}$, where σ is the cross section for non-SM processes, ϵ is the selection efficiency and $\mathcal{A}$ is the selection acceptance. These limits are also reported in Table 7. Finally, 95 % CL exclusion limits are derived in specific supersymmetric models of direct pair production of stops. The first exclusion limit (Fig. 19a) is derived in a model where the stop is assumed to decay as $\tilde{t}_1 \to b\tilde{\chi}_1^{\pm}$ with a branching ratio of 100 %, followed by the decay of the chargino into the neutralino, assumed to be the stable LSP, through $\tilde{\chi}_1^{\pm} \to W^{(*)}\tilde{\chi}_1^0$. The chargino mass is assumed to satisfy the relation $m_{\tilde{\chi}_1^{\pm}} = m_{\tilde{t}_1} - 10$ GeV, and the limit is derived in the $m_{\tilde{t}_1}$–$m_{\tilde{\chi}_1^0}$ plane. Stop masses up to about 250 GeV are excluded, almost independently of the neutralino mass. The second limit is derived in a model where the $\tilde{t}_1$ decays through its three-body or four-body decay (depending on its mass and on that of the neutralino) into $\tilde{t}_1 \to b\ell\nu\tilde{\chi}_1^0$ with a branching ratio of 100 %, under the assumption that the decay happens through an off-shell top quark and an on- or off-shell W boson. The limit is shown in Fig. 19b and fills a gap between the exclusions of the t2L and t1L analyses.



B.2.2 Final states containing two top quarks and a Higgs boson (t2t1h)

If the lightest stop has a mass such that $\Delta m(\tilde{t}_1, \tilde{\chi}_1^0) \sim m_t$, the sensitivity of the searches for the production of a $\tilde{t}_1$ pair is greatly reduced. One of the approaches followed is to search for direct pair production of $\tilde{t}_2$ instead. This is the strategy used, for example, by the t2t1Z analysis, whose signal regions were optimised to detect the decay of a pair-produced $\tilde{t}_2$ followed by the decay $\tilde{t}_2 \to Z\tilde{t}_1$.

Inspired by the search for a SM Higgs boson produced in association with a top quark pair, a search was developed and optimised for the decay $\tilde{t}_2 \to h\tilde{t}_1$, where the Higgs boson is assumed to have SM properties, and the $\tilde{t}_1$ is assumed to decay as $\tilde{t}_1 \to t\tilde{\chi}_1^0$ with a BR of 100 %. The final state is hence characterised by a large jet multiplicity, by the presence of many b-jets from the top quark and Higgs boson decays and by $E_{\text{T}}^{\text{miss}}$ associated with the presence of neutrinos from semileptonic decays of the top quark and of neutralinos.

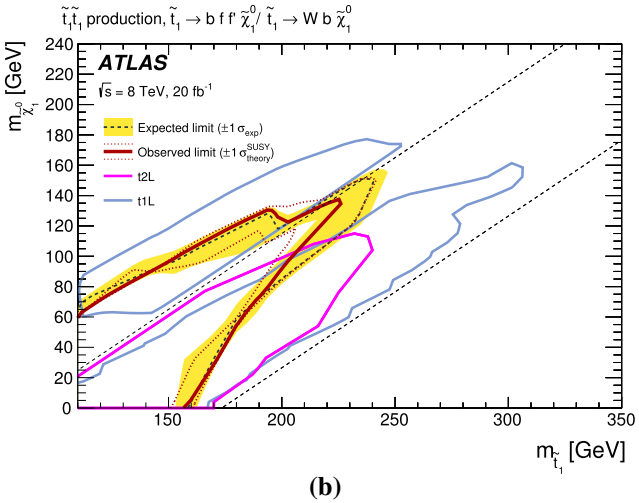
SR5	4	3.4 ± 0.9	6.2	$5.7^{+2.1}_{-1.4}$	0.30
SR6	160	154 ± 19	45.6	$43.8^{+19.3}_{-14.4}$	2.25
SR7	21	23 ± 4	12.4	$13.4^{+4.8}_{-3.4}$	0.61



The selection of electrons, muons, jets and b-jets follows the principles outlined in Appendix A. The specific choices made for the p_{T} and pseudorapidity thresholds and working points of the final-state objects, as well as the trigger selection, are the same as those in Ref. [120]. The selection requires the presence of exactly one electron or muon with $p_{\mathrm{T}} > 25$ GeV, $E_{\mathrm{T}}^{\mathrm{miss}} > 50$ GeV, at least six jets with $p_{\mathrm{T}} > 25$ GeV and $|\eta| < 2.5$, of which at least two are required to be b-tagged. The working point chosen for the b-tagging is such that the efficiency to tag b-jets (evaluated on a MC sample of $t\bar{t}$ production) is about 70 %.

The modelling of the production of $t\bar{t}$ pairs in association with heavy flavour ($t\bar{t}$+HF) is of key relevance in this analysis. A detailed categorisation of $t\bar{t}$+HF is made for the purpose of comparisons with different generators and of the propagation of systematic uncertainties on the different heavy-flavour components. The categorisation is also used to reweight the different flavour components of the $t\bar{t}$+jets background to obtain a better modelling. These categorisation and reweighting procedures are discussed in detail in Ref. [120]. In particular, the $t\bar{t} + b\bar{b}$ component, which is simulated with POWHEG, is reweighted to a full NLO calculation [121] performed in SHERPA 1.4.1+OpenLoops [122,123]. The reweighting is done at generator level using a number of kinematic variables such as the top quark p_{T}, $t\bar{t}$ system p_{T}, ΔR and p_{T} of the dijet system not coming from the top-quark decay. A different reweighting is applied to the $t\bar{t} + c\bar{c}$ and $t\bar{t}$+ light-jets components, which is based on the ratio of the differential cross sections at $\sqrt{s} = 7$ TeV obtained in data and simulation as a function of the top quark p_{T} and $t\bar{t}$ system p_{T} [124].

The selected events are categorised into different channels, depending on the number of b-tagged jets (two,

(a)

(b)

Fig. 19 Exclusion limits at 95 % CL in the scenario where both pair-produced stop decay exclusively via **a** $\tilde{t}_1 \to b\tilde{\chi}_1^{\pm}$ followed by $\tilde{\chi}_1^{\pm} \to W\tilde{\chi}_1^0$, with $\Delta m(\tilde{t}_1, \tilde{\chi}_1^{\pm}) = 10$ GeV, and **b** three-body or four-body decay (depending on the neutralino and stop mass). The *black dashed line* indicates the expected limit, and the *yellow band* indicates the $\pm 1\sigma$ uncertainties, which include all uncertainties except the theoretical uncertainties in the signal. The *red solid line* indicates the observed limit, and the *red dotted lines* indicate the sensitivity to $\pm 1\sigma$ variations of the signal theoretical uncertainties. For **b**, the observed limits achieved by the t1L and t2L analyses are also shown, and the *straight dashed lines* correspond to $\Delta m(\tilde{t}_1, \tilde{\chi}_1^0) = m_W + m_b$ and $\Delta m(\tilde{t}_1, \tilde{\chi}_1^0) = m_t$

three or at least four). The channel with at least four b-jets has the largest signal-to-background ratio. The channels with two and three b-tagged jets are used to calibrate the $t\bar{t}$+jets background prediction and constrain the associated systematic uncertainties, which, in the channel with at least four b-tagged jets, are dominated by the b-tagging, jet energy scale, and $t\bar{t}$+jets heavy-flavour content uncertainties.

For a given b-tag multiplicity, events are further categorised depending on the value of the transverse mass m_{T} of the lepton and the missing transverse momentum. A "low-m_{T}" ("high-m_{T}") region is defined by the requirement $m_{\mathrm{T}} < 120$ GeV ($m_{\mathrm{T}} > 120$ GeV).

The final discriminating variable used is $H_{\mathrm{T}}^{\mathrm{nolep}}$, defined as the scalar sum of $E_{\mathrm{T}}^{\mathrm{miss}}$ and the transverse momenta of all selected jets. The signal is searched for by performing a binned likelihood fit to the $H_{\mathrm{T}}^{\mathrm{nolep}}$ distribution simultaneously in the six channels defined (low/high-m_{T} for three bins in b-tagged jet multiplicity). The binning used for the $H_{\mathrm{T}}^{\mathrm{nolep}}$ distributions is that used in Fig. 20, where the background estimate both before and after the fit is compared to the data in the high-m_{T} region. The dominant post-fit uncertainties are those on the absolute normalisation of the $t\bar{t} + b\bar{b}$ and $t\bar{t} + c\bar{c}$ processes.

The full list of detector systematic uncertainties considered, discussed in detail in Ref. [120], includes, beside a total uncertainty of 2.8 % on the integrated luminosity, systematic uncertainties on the identification efficiency and energy scale uncertainty of the leptons, reconstruction efficiency and energy scale and resolution uncertainties for jets, b-tagging efficiency and mis-tag rate uncertainties. Further modelling uncertainties are considered, which include, beside production cross-section uncertainties for W/Z+jets, single top and $t\bar{t}$, dedicated uncertainties on the NLO calculation of the $t\bar{t}+b\bar{b}$ process and on the modelling of the $t\bar{t}+c\bar{c}$ component.

No significant excess above the expected background is observed, hence 95 % CL limits are derived in a model where $\tilde{t}_2$ production is assumed, followed by the decay $\tilde{t}_2 \to \tilde{t}_1 h$ (with a branching ratio of 100 %) and $\tilde{t}_1 \to t\tilde{\chi}_1^0$ (again with a branching fraction of 100 %).[14] The limit is derived as a function of the $\tilde{t}_2$ and $\tilde{\chi}_1^0$ masses, under the assumption that $\Delta m(\tilde{t}_1, \tilde{\chi}_1^0) = 180$ GeV, and it is presented in Sect. 4.3.

B.2.3 Final states containing two b-jets, a charged lepton, and missing transverse momentum (tb)

Several phenomenological models, where both $\tilde{\chi}_1^{\pm}$and $\tilde{\chi}_1^0$ are lighter than the stop (or the sbottom), allow for the $\tilde{t}_1 \to t\tilde{\chi}_1^0$, $\tilde{t}_1 \to b\tilde{\chi}_1^{\pm}$ and $\tilde{b}_1 \to b\tilde{\chi}_1^0$, $\tilde{b}_1 \to t\tilde{\chi}_1^{\pm}$ decay channels to be open with competing branching ratios. Naturalness arguments require the higgsino mass parameter μ to be smaller than a few hundred GeV, while they impose virtually no constraint on the bino and wino mass parameters M_1 and M_2. If $\mu \ll M_1, M_2$, then the lightest chargino and neutralino masses are both of the order of μ and hence $\Delta m(\tilde{\chi}_1^{\pm}, \tilde{\chi}_1^0)$ is small. Therefore, pair production of stops can lead to

[14] Production of $\tilde{t}_1$ pairs is also included in the simplified models. The acceptance of the selection for such events is very small. Nevertheless, this component is considered as signal in the statistical analysis.

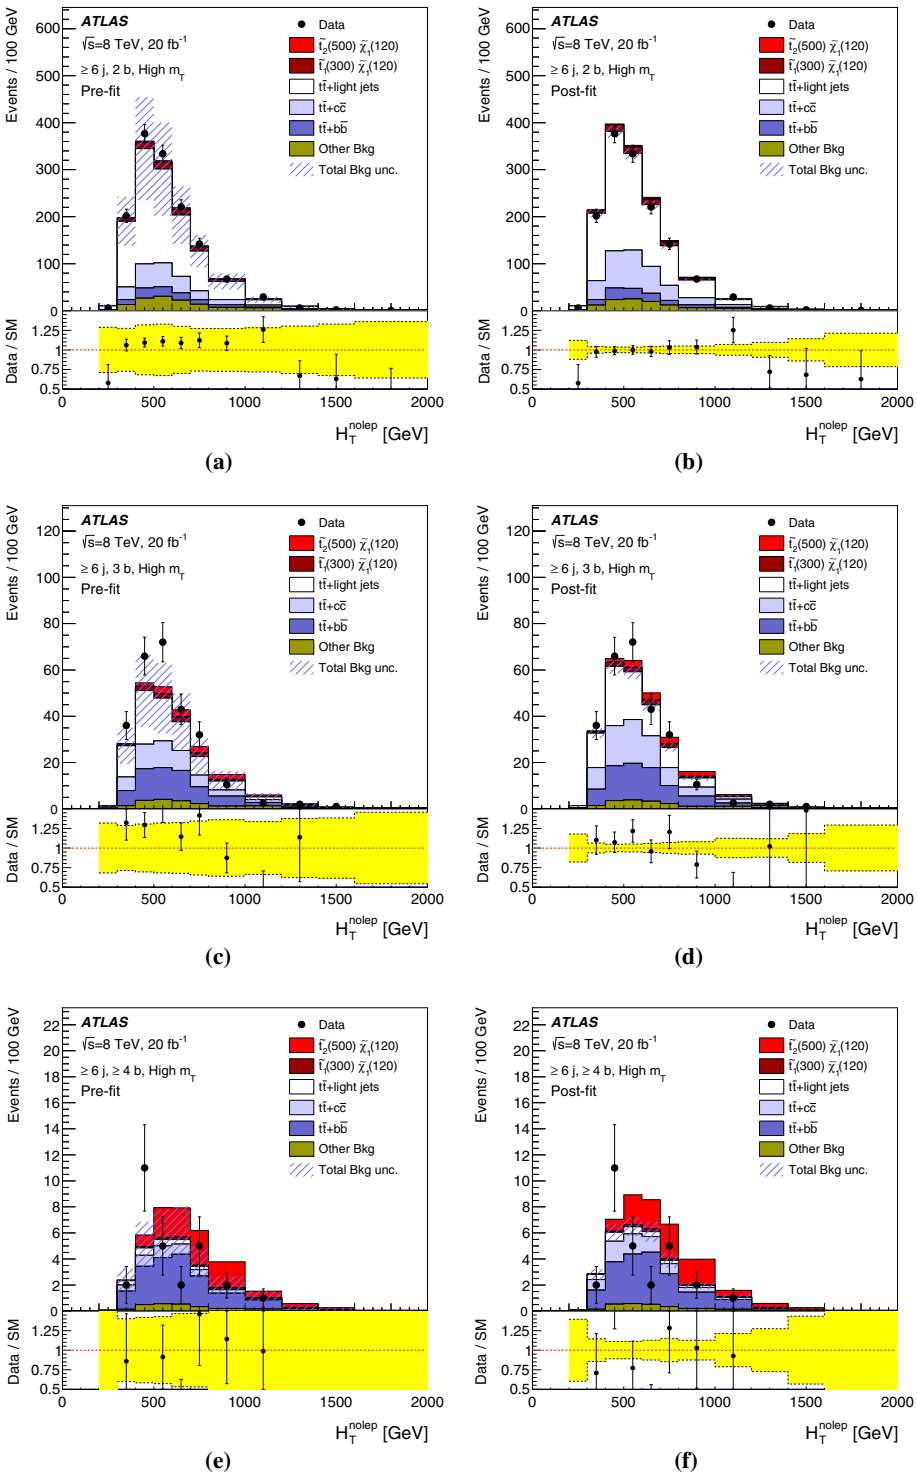


Fig. 20 Comparison between data and prediction for the distribution of $H_{\mathrm{T}}^{\mathrm{nolep}}$, defined as the scalar sum of the missing transverse momentum and the transverse momenta of all selected jets, in the high-m_{T} channels considered: (*top*) two b-tagged jets, (*middle*) three b-tagged jets and (*bottom*) four b-tagged jets, (*left*) before and (*right*) after the combined fit to data under the background-only hypothesis. The expected signal contributions from $\tilde{t}_1$ and $\tilde{t}_2$ pair production, assuming $m_{\tilde{t}_2} = 500$ GeV, $m_{\tilde{t}_1} = 300$ GeV, $m_{\tilde{\chi}_1^0} = 120$ GeV and a branching ratio of 100 % for $\tilde{t}_2 \to h\tilde{t}_1$ are also shown added to the stack (*red histograms*, in *dark* red the contribution from direct $\tilde{t}_1$ pair production). The *bottom panel* displays the ratio of the data to the total background prediction. The *hashed area* represents the statistical and systematics uncertainty on the background

$\tilde{t}_1\tilde{t}_1 \to t\tilde{\chi}_1^0 b\tilde{\chi}_1^\pm \to tb\tilde{\chi}_1^0\tilde{\chi}_1^0 ff'$, where f and f' represents low-p_{T} fermions emitted through $\tilde{\chi}_1^\pm \to ff'\tilde{\chi}_1^0$. Assuming both f and f' are too soft to be detected, the final state is characterised by the presence of a top quark, a bottom quark, and neutralinos escaping the detector. Similarly, $\tilde{b}_1$ pair production can lead to the same final state. Dedicated SRs are defined that target this topology, which is not well covered by the t0L and t1L signal regions aimed at final states containing $t\bar{t}E_{\mathrm{T}}^{\mathrm{miss}}$ and the b0L signal regions targeting $b\bar{b}E_{\mathrm{T}}^{\mathrm{miss}}$ final states.

Both the leptonic and hadronic decays of the top quark have been studied, and the leptonic channel was found to give a better sensitivity to the signal models of interest. The dominant SM background processes in the signal regions are

Table 8 Summary of signal regions used by the tb analysis

SR	tb-SRIn1	tb-SRIn2	tb-SRIn3	tb-SREx1
b-jets	2 b-jets; p_{T} >25 GeV			
1 lepton	p_{T} >25 GeV			
	$\lvert\eta\rvert$ < 2.5 (2.47) for μ (e)			
$E_{\mathrm{T}}^{\mathrm{miss}}$ (GeV)	>200	>120	>220	>160
m_{T} (GeV)	>140	>140	>180	>120
m_{eff} (GeV)	>300	>450	>650	>300
am_{T2} (GeV)	>180	>200	>180	>180
$m_{b\ell}^{\mathrm{min}}$ (GeV)	<170			
$\Delta\phi_{\mathrm{min}}^{b}$	>0.4			
$E_{\mathrm{T}}^{\mathrm{miss}}$ significance (GeV$^{1/2}$)	>8	>12	>5	>10
N_{xjets}	–	–	–	<2

semileptonic $t\bar{t}$ and single top production. The SM background is evaluated using a combination of Monte Carlo and partially data-driven techniques.

Events are selected online by a trigger requiring the presence of one electron or muon. The online selection thresholds are such that the plateau efficiency is reached for lepton transverse momenta of 25 GeV.

The identification criteria for electrons, muons, jets and $E_{\mathrm{T}}^{\mathrm{miss}}$ follow the principles outlined in Appendix A. In particular, electrons and muons are required to be isolated: the scalar p_{T} sum of tracks in a cone $\Delta R = 0.2$ around the electron (muon) is required to be smaller than 10 % of the electron transverse momentum (1.2 GeV). The electron or muon track is excluded from the sum. The b-tagging algorithm is used at an operating point with 70 % efficiency in simulated top-quark pair production events. Signal regions are defined as detailed in Table 8, requiring one and only one electron or muon, two b-tagged jets and a large $E_{\mathrm{T}}^{\mathrm{miss}}$. Three of the SRs, labelled tb–SRin have no additional jet veto applied, while one of them (tb-SREx1) has a veto requirement on the number of jets (N_{xjets}) with p_{T} >50 GeV in addition to the two leading b-tagged jets. The final SR optimisation is performed by using selections on the momenta of the objects, the m_{T} and the m_{eff} variables. In addition, the following kinematic variables are used in the event selection:

- $\Delta\phi_{\mathrm{min}}^{b}$: the minimum azimuthal distance between the closest b-tagged jet and the $E_{\mathrm{T}}^{\mathrm{miss}}$. This variable is used to remove multijet backgrounds with a cut of $\Delta\phi_{\mathrm{min}}^{b} > 0.4$.
- m_{eff}: the scalar sum of the p_{T} of the two b-jets (with $p_{\mathrm{T}} > 25$ GeV and $\lvert\eta\rvert < 2.8$) plus at most one light jet (with $p_{\mathrm{T}} > 25$ GeV and $\lvert\eta\rvert < 2.5$) and the $E_{\mathrm{T}}^{\mathrm{miss}}$. The number of light jets, n, included in this sum depends on the signal region under study, although $n = 1$ was mostly used.
- $E_{\mathrm{T}}^{\mathrm{miss}}$ significance: the ratio of the $E_{\mathrm{T}}^{\mathrm{miss}}$ to the square root of H_{T}, which is the scalar sum of the p_{T} of the two b-jets plus one light jet with $p_{\mathrm{T}} > 25$ GeV and $\lvert\eta\rvert < 2.8$.
- m_{T}: the transverse mass of the lepton and the missing transverse momentum vector.
- m_{bb}: the invariant mass of the two b-tagged jets.
- $m_{b\ell}$: the invariant mass of a b-tagged jet and the charged lepton. This variable is bounded from above at m_t in $t\bar{t}$ production events. Since two jets are b-tagged the variables $m_{b\ell}$ (1) and $m_{b\ell}$ (2) are defined to indicate the invariant mass constructed with the leading and subleading b-jet respectively. The variable $m_{b\ell}^{\mathrm{min}}$ is also defined to indicate the minimum between $m_{b\ell}$ (1) and $m_{b\ell}$ (2).
- am_{T2}: the asymmetric stransverse mass [108] is a kinematic variable which can be used to separate processes in which two decays giving missing transverse momentum occur. It is defined as follows:

$$am_{\mathrm{T2}}^{2}(\chi) = \min_{\not{\mathbf{q}}_{\mathrm{T}}^{(1)}+\not{\mathbf{q}}_{\mathrm{T}}^{(2)}=\not{\mathbf{p}}_{\mathrm{T}}} \times [\max\{m_{\mathrm{T}}^{2}(\mathbf{p}_{\mathrm{T}}(v_1), \not{\mathbf{q}}_{\mathrm{T}}^{(1)}; \chi), m_{\mathrm{T}}^{2}(\mathbf{p}_{\mathrm{T}}(v_2), \not{\mathbf{q}}_{\mathrm{T}}^{(2)}; \chi)\}] \quad (6)$$

where $\mathbf{p}_{\mathrm{T}}(v_i)$ are reconstructed transverse momentum vectors, $\not{\mathbf{q}}_{\mathrm{T}}^{(i)}$ represent the missing transverse momenta from the two decays, with a total missing transverse momentum, $\not{\mathbf{p}}_{\mathrm{T}}$, and χ is a free parameter representing the unknown neutralino mass, which is assumed to be zero in the calculation. The am_{T2} variable is calculated with different choices for $\mathbf{p}_{\mathrm{T}}(v_1)$ and $\mathbf{p}_{\mathrm{T}}(v_2)$, depending on the value of $m_{b\ell}$ (n) ($n = 1, 2$), the invariant mass of the n^{th} b-tagged jet b_n and the lepton:

- if $m_{b\ell}(i) < 170$ GeV and $m_{b\ell}(j) > 170$ GeV, then am_{T2} is calculated with $v_1 = b_i + \ell$ and $v_2 = b_j$;
- if $m_{b\ell}(1) < 170$ GeV and $m_{b\ell}(2) < 170$ GeV, then am_{T2} is evaluated using the two possible combinations for v_1 and v_2, and the minimum is used;

– it both $m_{b\ell}(1) > 170$ GeV and $m_{b\ell}(2) > 170$ GeV the event is rejected.

The case of both $m_{b\ell}$ (1) and $m_{b\ell}$ (2) exceeding 170 GeV is irrelevant: only events with the minimum value of $m_{b\ell}$ smaller than 170 GeV populate the control, validation and signal regions.

The optimisation is carried out using both a pMSSM signal model and simplified models where $\Delta m(\tilde{\chi}_1^{\pm}, \tilde{\chi}_1^0) = 5$ or 10 GeV. In the case of the pMSSM model, additional non-b-tagged jets are expected in the final state via the production of other SUSY particles, hence the optimisation points to SRs with no requirement on the N_{xjets} variable (tb-SRIn). In the case of the simplified models, additional jets come only from initial- or final-state radiation, and as a consequence a strict selection on N_{xjets} is applied as in the selection tb-SREx1.

The main SM backgrounds are top-pair production, W production in association with heavy-flavour jets and single-top production. The MC cross section is used to normalise the single-top background and all the other minor SM backgrounds, such as Z+jets, diboson production, $t\bar{t}$+W and $t\bar{t}$+Z. The normalisation factors of the $t\bar{t}$ and W + jets backgrounds are determined by a combined profile-likelihood fit. Specific control regions, whose event yield is expected to be dominated by each of these production processes, are defined and included in the fit to constrain the normalisation parameters. The $t\bar{t}$ control regions (CRT) are defined by inverting the selection on am_{T2}, requiring am_{T2} <160 (180) GeV for the inclusive (exclusive) SRs. The purity of the $t\bar{t}$ process in the CRTs is in excess of 95 %. The W + jets control regions (CRW) are defined by requiring m_{T} <120 GeV. For the control regions corresponding to the tb-SRIn, events with one b-tagged jet are included in the CRW. Top quark pair production dominates the CRWs, with a W + jets purity of 30 % or better. The normalisation factors μ_W and $\mu_{t\bar{t}}$ are presented in Table 9. The background model is then validated using validation regions, where little signal contamination is expected.

The distributions of the variable am_{T2} in the four SRs are shown in Fig. 21 together with the expected distribution from some of the signal models used to optimise the analysis. Table 10 compares the predicted and observed numbers of events in each of the signal regions. No excess above the SM prediction is observed, hence the results are first used to derive model-independent 95 % CL exclusion limits on the number of events beyond the Standard Model in the signal region, and then to extract limits on $\sigma_{\text{vis}} = \sigma \times \epsilon \times \mathcal{A}$, where σ is the cross section for non-SM processes, ϵ is the selection efficiency and $\mathcal{A}$ is the selection acceptance. All these limits are also reported in Table 10.

Since the number of events observed agrees with the SM predictions, 95 % CL exclusion limits are derived in specific supersymmetric models of direct pair production of stops. Simplified models were simulated with the two decays $\tilde{t}_1 \to t\tilde{\chi}_1^0, \tilde{t}_1 \to b\tilde{\chi}_1^{\pm}$ each having a 50 % BR for values of $\Delta m(\tilde{\chi}_1^{\pm}, \tilde{\chi}_1^0) = 5, 20$ GeV. Furthermore, by using a weighted combination of these simplified models with models corresponding to a 100 % BR in either $\tilde{t}_1 \to t\tilde{\chi}_1^0$ or $\tilde{t}_1 \to b\tilde{\chi}_1^{\pm}$, limits can be obtained for any value of the stop BR. Figure 22 shows the exclusion limits for $\text{BR}(\tilde{t}_1 \to t\tilde{\chi}_1^0) = 25$, 50 and 75 % for the two values of $\Delta m(\tilde{\chi}_1^{\pm}, \tilde{\chi}_1^0)$ considered.

Finally, 95 % CL exclusion limits are also derived for a natural pMSSM model and are presented in Fig. 23

Table 9 Background scale factors for the $t\bar{t}$and W samples, as obtained by the background fit. The errors include both the statistical and systematics uncertainties

Norm. factor	SRinA	SRinB	SRinC	SRexA
$\mu_{t\bar{t}}$	1.06 ± 0.07	1.12 ± 0.09	0.94 ± 0.21	1.06 ± 0.07
μ_W	0.92 ± 0.20	0.61 ± 0.23	0.93 ± 0.27	1.10 ± 0.34

C Further details of the statistical combination of the t0L and t1L signal regions

This section provides additional details on the combination of the t0L and t1L signal regions targeting scenarios in which the stop decays into either $\tilde{t}_1 \to t\tilde{\chi}_1^0$ or the mixed case where $\tilde{t}_1 \to t\tilde{\chi}_1^0$ and $\tilde{t}_1 \to b\tilde{\chi}_1^{\pm}$ are both allowed, as discussed in Sect. 4.1

The statistical combination of the two analyses is performed by running the combined fit simultaneously on the control and signal regions of the two analyses. The detector systematic uncertainties are treated as correlated by using, for each of the uncertainties considered, a single nuisance parameter. The supersymmetric signal parameter strength used is the same for the two analyses, while the normalisation parameters for the background processes are kept independent in each analysis.[15] The nuisance parameters associated with modelling uncertainties of the various processes are also kept independent.

The control regions of the two analyses are not mutually exclusive: the events that belong to both a CR of t0L and one of t1L are, at most about 2 % of the total number of events of the t0L CR. The strategy adopted is to remove them from the corresponding t0L CR for the combination. It has been verified that such removal does not affect the individual results of the t0L analysis.

[15] The choice is motivated by the fact that the phase-space regions in which the two analyses determine the normalisation parameters of the $t\bar{t}$, Z + jets and W + jets (for t0L) and $t\bar{t}$ and W + jets (for t1L) are characterised by different kinematic selections and jet multiplicities.

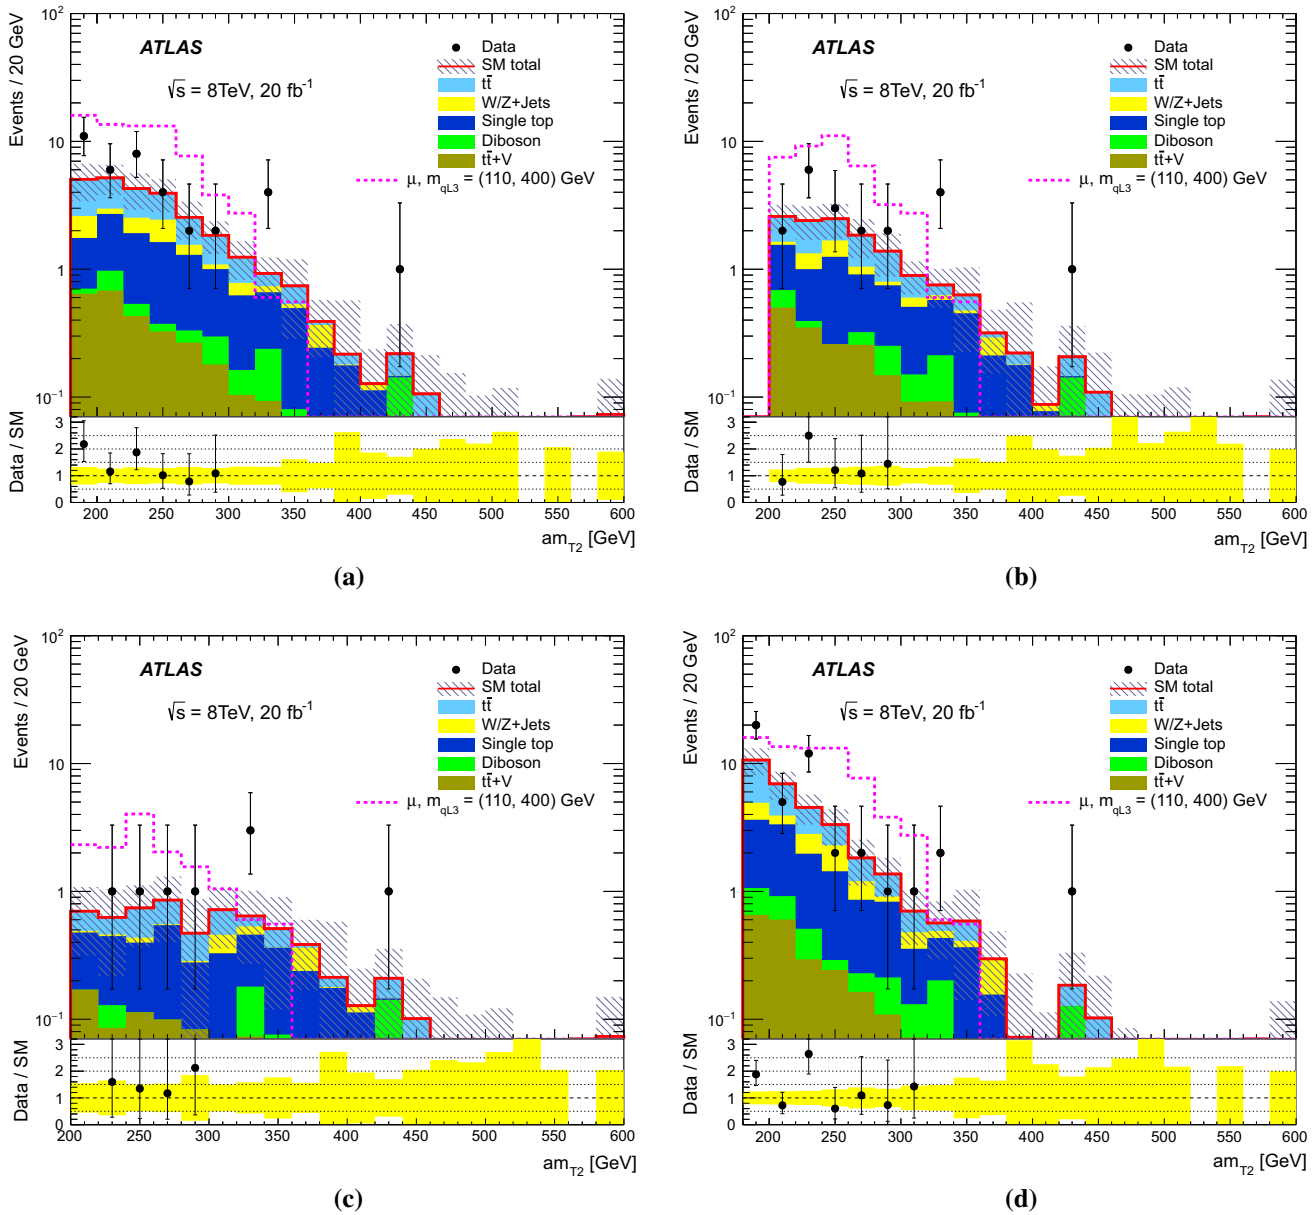

Fig. 21 Distribution of the asymmetric stransverse mass am_{T2} in the **a** SRinA, **b** SRinB (*top right*), **c** SRinC and **d** SRexA defined in the text. The contributions from all SM processes are shown as a *histogram stack*. The contribution from signal points studied by this analysis are also shown. The *lower panels* show the ratio between the data and the SM prediction; the band includes statistical and systematic uncertainties on the SM prediction

Table 10 Observed (Obs) and predicted (Exp) numbers of events in the signal regions of the tb analysis, together with the 95 % CL upper limits on the observed and expected number of signal events (S^{95}_{obs} and S^{95}_{exp} respectively), and on the visible cross section ($\langle\epsilon\sigma\rangle^{95}_{obs}$)

Signal channel	Obs	Exp	S^{95}_{obs}	S^{95}_{exp}	$\langle\epsilon\sigma\rangle^{95}_{obs}$ (fb)
SRinA	38	27 ± 7	28.5	$19.3^{+7.0}_{-6.1}$	1.41
SRinB	20	14.1 ± 2.8	16.3	$10.7^{+4.5}_{-2.6}$	0.81
SRinC	10	7.1 ± 2.9	11.9	$9.8^{+3.3}_{-2.4}$	0.58
SRexA	46	31 ± 7	32.1	$20.3^{+8.0}_{-3.6}$	1.58

For each combination performed, the fit setup is validated by checking that the background normalisation parameters obtained are compatible with those obtained separately by the two analyses, by verifying that no additional constraint on the nuisance parameters is introduced with respect to the individual fits, and by checking that no artificial correlation is introduced between any of the fit parameters.

The 95 % CL limit derived from the combination is shown in Fig. 24, where the combined limit is compared to the individual limits obtained by the t0L and t1L analyses independently.

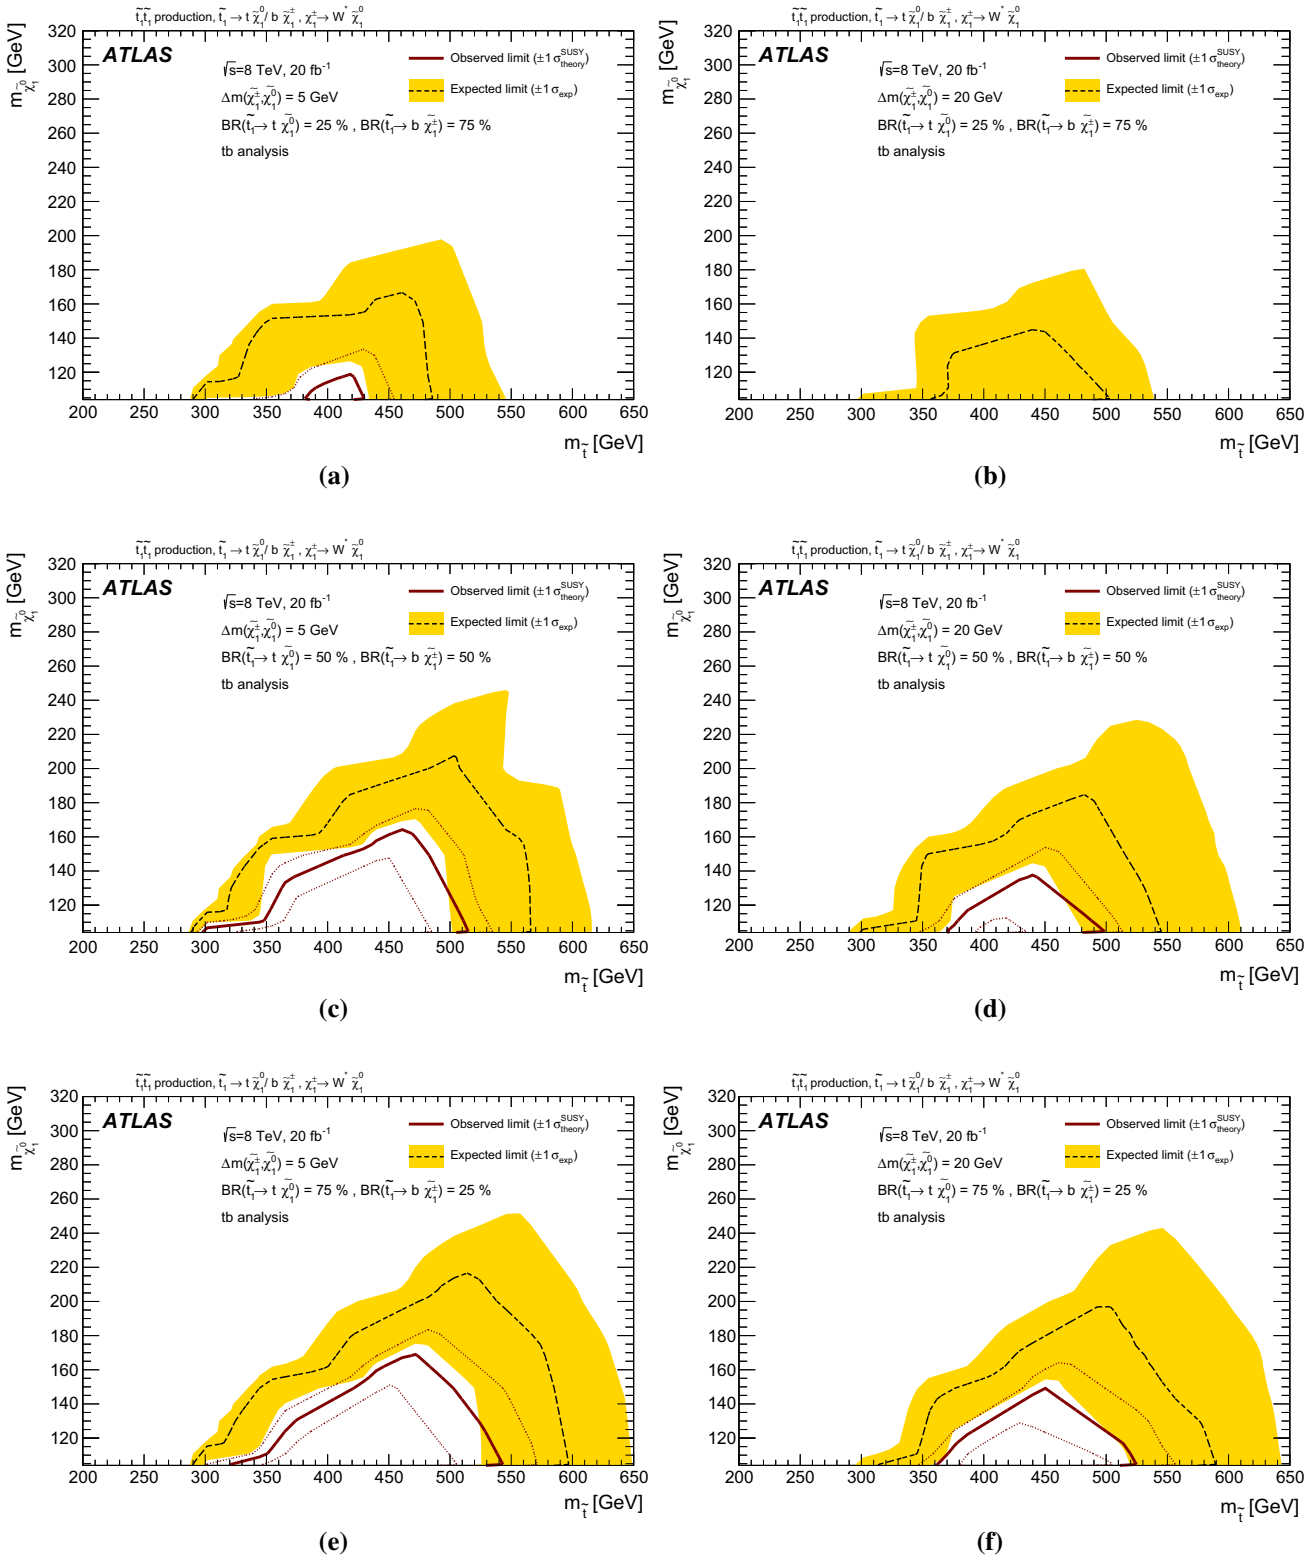

Fig. 22 Exclusion limits at 95 % CL from the tb signal regions for simplified models with stop decays into both $\tilde{t}_1 \to t\tilde{\chi}_1^0$ and $\tilde{t}_1 \to b\tilde{\chi}_1^{\pm}$ and for BR($\tilde{t}_1 \to t\tilde{\chi}_1^0$) = 25, 50, 75 % (in *descending rows*) for the grids $\Delta m(\tilde{\chi}_1^{\pm}, \tilde{\chi}_1^0) = 5, 20$ (*left*, *right columns*). The *black dashed line* indicates the expected limit, and the *yellow band* indicates the $\pm 1\sigma$ uncertainties, which include all uncertainties except the theoretical uncertainties in the signal. The *red solid line* indicates the observed limit, and the *red dotted lines* indicate the sensitivity to $\pm 1\sigma$ variations of the signal theoretical uncertainties. For each point the SR giving the best expected significance is used

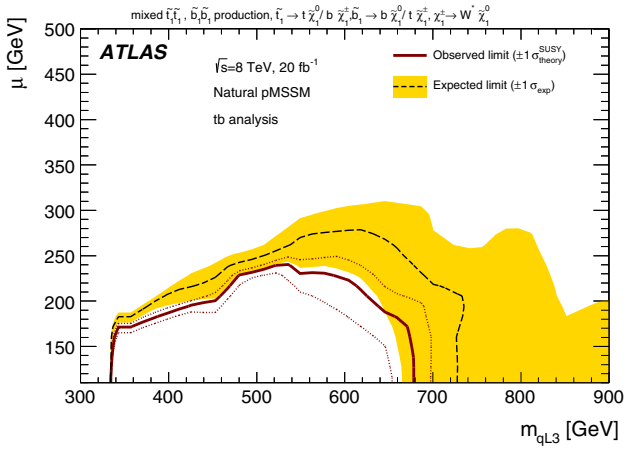

Fig. 23 Exclusion limits at 95 % CL from the tb signal regions for the natural pMSSM model. The *black dashed line* indicates the expected limit, and the *yellow band* indicates the $\pm 1\sigma$ uncertainties, which include all uncertainties except the theoretical uncertainties in the signal. The *red solid line* indicates the observed limit, and the *red dotted lines* indicate the sensitivity to $\pm 1\sigma$ variations of the signal theoretical uncertainties. For each point the SR giving the best expected significance is used

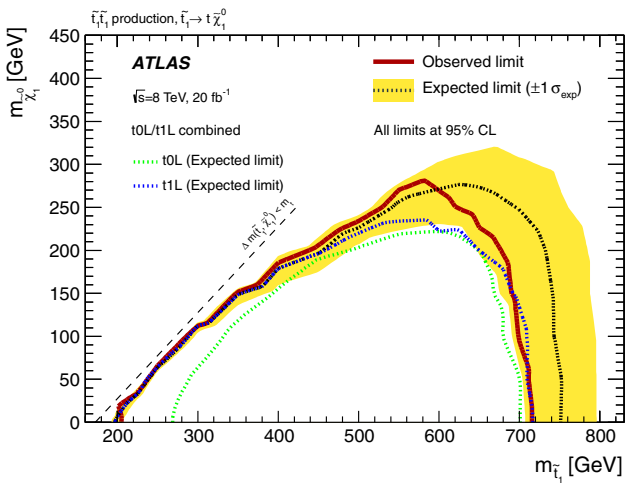

Fig. 24 Combined exclusion limits at 95 % CL in the scenario where both stops decay exclusively via $\tilde{t}_1 \to t\tilde{\chi}_1^0$. The *black dashed line* indicates the expected limit, and the *yellow band* indicates the $\pm 1\sigma$ uncertainties, which include all uncertainties except the theoretical uncertainties in the signal. The *red solid line* indicates the observed limit. For comparison the *dotted green* and *blue lines* show the expected limits from the standalone t0L and t1L analyses

D Signal generation details

Several SUSY models are considered throughout this paper. This section provides the details of how these signal models are generated. For all SUSY models discussed below, the detector response is simulated by passing the generated events through a detector simulation [125] based on GEANT4 [126] or through a fast simulation using a parametric response to the showers in the electromagnetic and hadronic calorimeters [127] and GEANT4-based simulation elsewhere. All samples are produced with a varying number of simulated minimum-bias interactions overlaid on the hard-scattering event to account for multiple pp interactions in the same or nearby bunch crossings (pileup). The simulation is reweighted to match the number of minimum bias interactions in data, which varies between approximately 10 and 30 interactions in each bunch crossing. Corrections are applied to the simulated samples to account for differences between data and simulation for the trigger and reconstruction efficiencies, momentum scale and resolution of the final-state objects, including the efficiency of identifying jets originating from the fragmentation of b-quarks, together with the probability for mis-tagging light-flavour and charm quarks.

Simplified models The signal samples for the scenario where both stops decay to a top quark and a neutralino are generated using Herwig++ 2.5.2 [128] interfaced to PYTHIA 6.426 [129]. The neutralino is fixed to be a pure bino, enhancing the decay of the $\tilde{t}_R$ component of $\tilde{t}_1$ to a right-handed top quark. Signal samples where the two stops decay as $\tilde{t}_1 \to b\tilde{\chi}_1^{\pm}$ are generated with MadGraph 5.1.4.8 [130]. For models where the W boson is on-shell, the $\tilde{t}_1$ decay is treated by MadGraph, while if the W is off-shell, PYTHIA is used to decay the $\tilde{t}_1$. In these samples, the $\tilde{t}_1$ is assumed to be mostly a $\tilde{t}_L$, and the chargino is assumed to decay through $\tilde{\chi}_1^{\pm} \to W^{(*)}b$ with a branching ratio of 100 %. Several assumptions about the chargino masses are considered as described in the body of the paper.

Models in which the stop is assumed to decay either as $\tilde{t}_1 \to t\tilde{\chi}_1^0$ or $\tilde{t}_1 \to b\tilde{\chi}_1^{\pm}$ with different branching ratios are obtained by appropriately weighting three samples: one where both stops decay through $\tilde{t}_1 \to t\tilde{\chi}_1^0$, a second one where both stops decay through $\tilde{t}_1 \to b\tilde{\chi}_1^{\pm}$, and a third one, where one of the two pair-produced stops decays as $\tilde{t}_1 \to t\tilde{\chi}_1^0$ and the other one decays as $\tilde{t}_1 \to b\tilde{\chi}_1^{\pm}$. This last sample is generated with MadGraph, the $\tilde{t}_1$ is assumed to be a maximal mixing of $\tilde{t}_L$ and $\tilde{t}_R$. The mass of the chargino in this sample satisfies the gauge-universality relation $m_{\tilde{\chi}_1^{\pm}} = 2m_{\tilde{\chi}_1^0}$.

The three-body stop decay samples are generated with Herwig++, which performs the matrix element calculation of the three-body decay. The four-body stop decay samples are generated with MadGraph.

For all samples considered, the mass of the bottom quark is fixed to 4.8 GeV and its width is assumed to be zero.

The samples where both stops decay as $\tilde{t}_1 \to c\tilde{\chi}_1^0$ are generated with MadGraph, with one additional parton from the matrix element. Similarly to the case of the limit derived as a function of the stop branching ratio into $\tilde{t}_1 \to t\tilde{\chi}_1^0$,

the samples with both stops decaying as $\tilde{t}_1 \rightarrow c\tilde{\chi}_1^0$ and those where both stops decay through the four-body decay are appropriately weighted and combined with a third sample where one stop decays as $\tilde{t}_1 \rightarrow c\tilde{\chi}_1^0$ and the other decays through the four-body decay to produce a sample of arbitrary branching ratio into $\tilde{t}_1 \rightarrow c\tilde{\chi}_1^0$ (assuming that $\tilde{t}_1 \rightarrow c\tilde{\chi}_1^0$ and the four-body decay are the only possible stop decays). Such mixed samples are also generated with MadGraph.

Sbottom pair production samples are also all produced with MadGraph interfaced to PYTHIA, and no more than one additional parton is added to the matrix element. The PDF set used for all signal samples is CTEQ6L1 [131].

pMSSM models In all cases, the particle spectra are generated with SOFTSUSY 3.3.3 [132], while sparticles decays are calculated with SUSY-HIT [133] (SDECAY 1.3b and HDECAY 3.4). The simulated signal events are generated using Herwig++ 2.6.3 [128] with the CTEQ6L1 PDF set.

Search for the electroweak production of supersymmetric particles in $\sqrt{s} = 8$ TeV *pp* collisions with the ATLAS detector

G. Aad *et al.*[*]
(ATLAS Collaboration)

(Received 23 September 2015; published 4 March 2016)

The ATLAS experiment has performed extensive searches for the electroweak production of charginos, neutralinos, and staus. This article summarizes and extends the search for electroweak supersymmetry with new analyses targeting scenarios not covered by previously published searches. New searches use vector-boson fusion production, initial-state radiation jets, and low-momentum lepton final states, as well as multivariate analysis techniques to improve the sensitivity to scenarios with small mass splittings and low-production cross sections. Results are based on 20 fb^{-1} of proton-proton collision data at $\sqrt{s} = 8$ TeV recorded with the ATLAS experiment at the Large Hadron Collider. No significant excess beyond Standard Model expectations is observed. The new and existing searches are combined and interpreted in terms of 95% confidence-level exclusion limits in simplified models, where a single production process and decay mode is assumed, as well as within phenomenological supersymmetric models.

DOI: 10.1103/PhysRevD.93.052002

I. INTRODUCTION

Supersymmetry (SUSY) [1–9] is a space-time symmetry that postulates for each Standard Model (SM) particle the existence of a partner state whose spin differs by one-half unit. The introduction of these new SUSY particles (sparticles) provides a potential solution to the hierarchy problem [10–13]. If R-parity is conserved [14–18], as assumed in this article, sparticles are always produced in pairs and the lightest supersymmetric particle (LSP) emerges as a stable dark-matter candidate.

The charginos and neutralinos are mixtures of the bino, winos, and higgsinos, collectively referred to as the electroweakinos, that are superpartners of the U(1), SU(2) gauge bosons and the Higgs bosons, respectively. Their mass eigenstates are referred to as $\tilde{\chi}_i^{\pm}$ ($i = 1, 2$) and $\tilde{\chi}_j^0$ ($j = 1, 2, 3, 4$) in order of increasing mass. The direct production of charginos, neutralinos, and sleptons ($\tilde{\ell}$) through electroweak (EW) interactions may dominate the SUSY production at the Large Hadron Collider (LHC) if the masses of the gluinos and squarks are large. Previous searches for electroweak SUSY production at ATLAS targeted the production of $\tilde{\ell}^+\tilde{\ell}^-$, $\tilde{\tau}^+\tilde{\tau}^-$, $\tilde{\chi}_1^+\tilde{\chi}_1^-$ (decaying through $\tilde{\ell}$ or W bosons), $\tilde{\chi}_1^{\pm}\tilde{\chi}_2^0$ (decaying through $\tilde{\ell}$ or W and Z/h bosons), and $\tilde{\chi}_2^0\tilde{\chi}_3^0$ (decaying through $\tilde{\ell}$ or Z bosons) [19–23], and found no significant excess beyond SM expectations. These searches are typically sensitive to scenarios where there is a relatively large $O(m_{W,Z})$ splitting between the produced sparticles and the LSP, leaving uncovered territory for smaller mass splittings.

This article addresses EW SUSY production based on the 20.3 fb^{-1} of $\sqrt{s} = 8$ TeV proton-proton collisions collected by the ATLAS experiment in 2012. A series of new analyses targeting regions in parameter space not covered by previous ATLAS analyses [19–23] are presented. The results from new and published searches are combined and reinterpreted to provide the final 8 TeV ATLAS limits on the production of EW SUSY particles in a variety of models. The dependence of the limits on the mass of the intermediate slepton in models of electroweakino production with $\tilde{\ell}$-mediated decays is also studied, thus generalizing the results of Refs. [19–21].

In cases where the LSP is wino or higgsino dominated, the lighter electroweakino states $\tilde{\chi}_1^{\pm}$, $\tilde{\chi}_2^0$ can have mass differences with the $\tilde{\chi}_1^0$ ranging from a few GeV to a few tens of GeV, depending on the values of the other parameters in the mixing matrix [24]. In particular, in naturalness-inspired models [25,26] the higgsino must be light, so the $\tilde{\chi}_1^0$, $\tilde{\chi}_2^0$, and $\tilde{\chi}_1^{\pm}$ are usually higgsino-dominated and have a small mass splitting. Therefore, a situation with a light $\tilde{\chi}_1^0$ approximately mass degenerate with the $\tilde{\chi}_1^{\pm}$ and $\tilde{\chi}_2^0$ has a strong theoretical motivation. A relatively low mass splitting between the produced sparticles and the LSP (referred to as compressed scenarios) results in low-momentum decay products that are difficult to reconstruct efficiently, and probing these signatures is experimentally challenging. The new analyses introduced in this article improve the sensitivity to the compressed spectra. The two- and three-lepton searches for $\tilde{\chi}_1^+\tilde{\chi}_1^-$ and $\tilde{\chi}_1^{\pm}\tilde{\chi}_2^0$ production in Refs. [19,20] are extended by lowering the transverse momentum threshold on reconstructed leptons, and by boosting the electroweak SUSY system through the

requirement of QCD initial state radiation (ISR). The search for the vector-boson fusion (VBF) production of $\tilde{\chi}_1^{\pm}\tilde{\chi}_1^{\pm}$ uses the signature of a same-sign light lepton (e, μ) pair with two jets to probe compressed spectra.

In many SUSY scenarios with large $\tan\beta$, the stau ($\tilde{\tau}$) is lighter than the selectron and smuon [27], resulting in tau-rich final states. Coannihilation processes [28] favor a light $\tilde{\tau}$ that has a small mass splitting with a bino LSP, as it can set the relic density to the observed value [29]. An additional new search is presented here, which uses a final state with two hadronically decaying τ leptons and multivariate techniques to improve the sensitivity to direct $\tilde{\tau}$ production compared to the search presented in Ref. [22].

Searches for the electroweak production of SUSY particles have been conducted at the Tevatron [30,31] and by the CMS Collaboration [32–34]. At LEP [35–39], searches set lower limits of 103.5 GeV, 99.9 GeV, 94.6 GeV, and 86.6 GeV at 95% confidence level (CL) on the mass of promptly decaying charginos, selectrons, smuons, and staus, respectively. For the interval $0.1 \lesssim \Delta m(\tilde{\chi}_1^{\pm}, \tilde{\chi}_1^0) \lesssim 3$ GeV, the chargino mass limit set by LEP degrades to 91.9 GeV. The slepton mass limits from LEP assume gaugino mass unification, which is not assumed in the results presented here.

The article is organized as follows: Sec. II describes the signal models studied in this article; Sec. III provides a brief description of the ATLAS detector; Secs. IV and V outline the Monte Carlo (MC) simulation and event selection, respectively; Sec. VI discusses the analysis strategy common to all analyses studied in this article; Sec. VII presents the direct stau production search; Sec. VIII presents the compressed spectra searches in direct production; Sec. IX presents the search for same-sign chargino-pair production via VBF; Sec. X provides a global overview of the results of the ATLAS searches for electroweakino production at 8 TeV, integrating the results of the new analyses with published analyses in the framework of several relevant signal models; and finally conclusions are drawn in Sec. XI.

II. SUSY SCENARIOS

The SUSY scenarios considered in this article can be divided into two categories: simplified models and phenomenological models. The simplified models [40] target the production of charginos, neutralinos, and sleptons, where the masses and the decay modes of the relevant particles are the only free parameters. In each of the simplified models, a single production process with a fixed decay chain is considered for optimization of the event selection and interpretation of the results. To illustrate the range of applicability of the searches, several classes of phenomenological models that consider all relevant SUSY production and decay processes are also used to interpret the results. These models include the five-dimensional EW phenomenological minimal supersymmetric standard model (pMSSM) [41], the nonuniversal Higgs masses (NUHM) model [42,43], and a gauge-mediated SUSY breaking (GMSB) model [44–49].

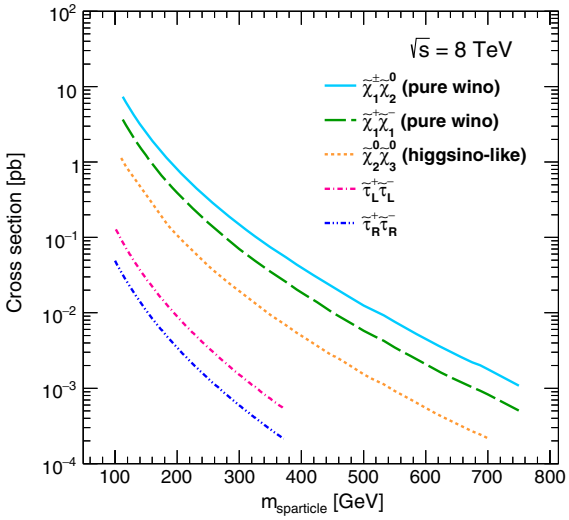

FIG. 1. The production cross sections for the simplified models of the direct production of $\tilde{\chi}_1^{+}\tilde{\chi}_1^{-}$, $\tilde{\chi}_1^{\pm}\tilde{\chi}_2^0$ [where $m(\tilde{\chi}_1^{\pm}) = m(\tilde{\chi}_2^0)$], $\tilde{\chi}_2^0\tilde{\chi}_3^0$ [where $m(\tilde{\chi}_2^0) = m(\tilde{\chi}_3^0)$], and $\tilde{\tau}^{+}\tilde{\tau}^{-}$ studied in this article. The left-handed and right-handed stau-pair production cross sections are shown separately.

R-parity is assumed to be conserved in all SUSY scenarios considered in this article. The LSP is assumed to be the lightest neutralino $\tilde{\chi}_1^0$ except in the GMSB scenarios, where it is the gravitino $\tilde{G}$. The next-to-LSP (NLSP) is usually one or more of the charginos, neutralinos, or sleptons. All SUSY particles are assumed to decay promptly, with the exception of the LSP, which is stable. Finally, SUSY particles that are not considered in a given model are decoupled by setting their masses to values inaccessible at the LHC.

Unless stated otherwise, signal cross sections are calculated to next-to-leading order (NLO) in the strong coupling constant using PROSPINO2 [50] and are shown in Fig. 1 for a number of selected simplified-model production modes. The cross sections for the production of charginos and neutralinos are in agreement with the NLO calculations matched to resummation at next-to-leading logarithmic (NLL) accuracy (NLO + NLL) within about 2% [51–53]. The nominal cross section and the uncertainty are taken from the center and spread, respectively, of the envelope of cross-section predictions using different parton distribution function (PDF) sets and factorization and renormalization scales, as described in Ref. [54].

A. Direct stau-pair production simplified model

Two simplified models describing the direct production of $\tilde{\tau}^{+}\tilde{\tau}^{-}$ are used in this article: one considers stau partners of the left-handed τ lepton ($\tilde{\tau}_L$), and a second considers stau partners of the right-handed τ lepton ($\tilde{\tau}_R$). In both models,

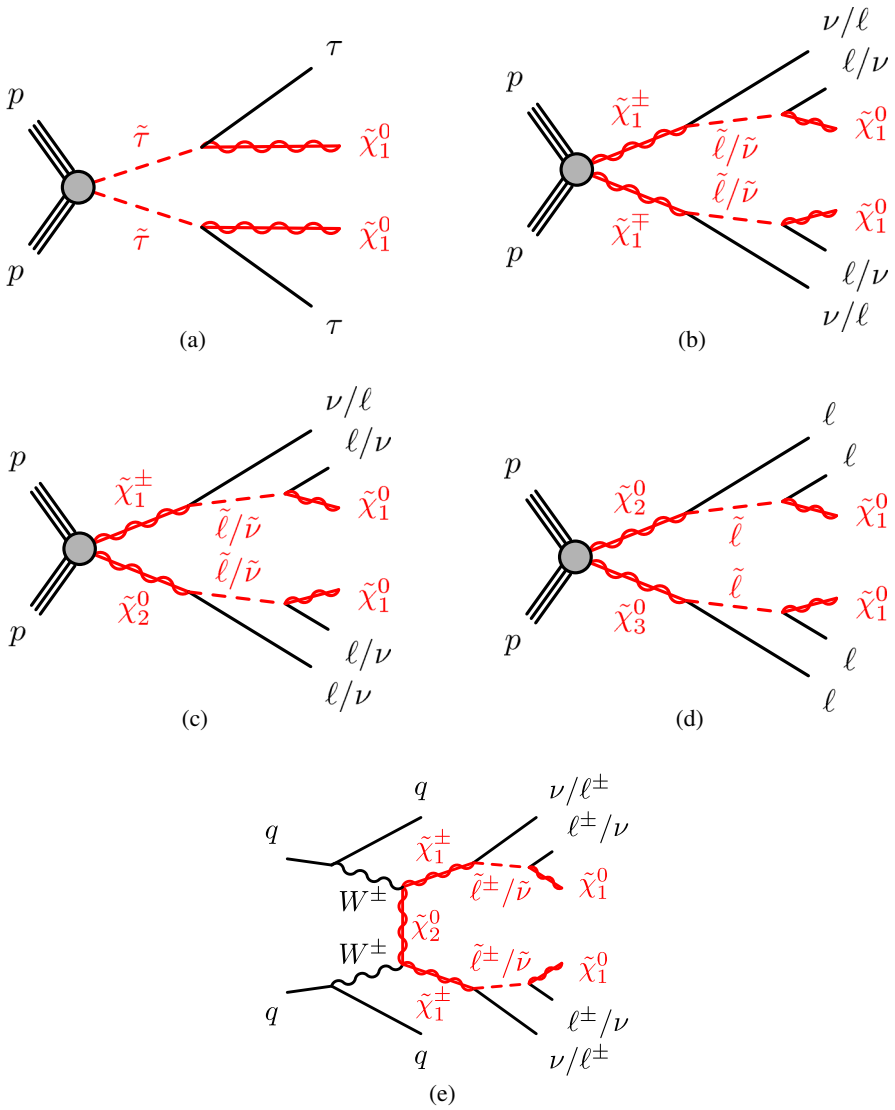

FIG. 2. The diagrams for the simplified models of the direct pair production of staus and the direct production of $\tilde{\chi}_1^+\tilde{\chi}_1^-$, $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$, and $\tilde{\chi}_2^0\tilde{\chi}_3^0$, and the VBF production of $\tilde{\chi}_1^\pm\tilde{\chi}_1^\pm$ studied in this article. All three generations are included in the definition of $\tilde{\ell}/\tilde{\nu}$, except for the direct production of $\tilde{\chi}_2^0\tilde{\chi}_3^0$ where only the first two generations are assumed. The different decay modes are discussed in the text.

the stau decays with a branching fraction of 100% to the SM tau lepton and the LSP. The diagram for this model can be seen in Fig. 2(a).

B. Direct chargino-pair, chargino-neutralino, and neutralino-pair production simplified models

In the simplified models describing the direct production of $\tilde{\chi}_1^+\tilde{\chi}_1^-$ and $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$, both the $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_2^0$ are assumed to be pure wino and mass degenerate, while the $\tilde{\chi}_1^0$ is assumed to be pure bino. However, it is possible to reinterpret the results from these simplified models by assuming different compositions of the $\tilde{\chi}_1^0$, $\tilde{\chi}_2^0$, and $\tilde{\chi}_1^\pm$ for the same masses of the states. Two different scenarios for the decays of the $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_2^0$ are considered, as shown in Figs. 2(b) and 2(c):

(i) $\tilde{\chi}_1^+\tilde{\chi}_1^-/\tilde{\chi}_1^\pm\tilde{\chi}_2^0$ *production with* $\tilde{\ell}_L$*-mediated decays:* The $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_2^0$ decay with a branching fraction of 1/6 via $\tilde{e}_L$, $\tilde{\mu}_L$, $\tilde{\tau}_L$, $\tilde{\nu}_e$, $\tilde{\nu}_\mu$, or $\tilde{\nu}_\tau$ with masses $m_{\tilde{\nu}_\ell} = m_{\tilde{\ell}_L} = x(m_{\tilde{\chi}_1^\pm} - m_{\tilde{\chi}_1^0}) + m_{\tilde{\chi}_1^0}$ with $x = 0.05$, 0.25, 0.5, 0.75, or 0.95,

(ii) $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$ *production with* $\tilde{\tau}_L$*-mediated decay:* The first- and second-generation sleptons and sneutrinos are assumed to be very heavy, so that the $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_2^0$ decay with a branching fraction of 1/2 via $\tilde{\tau}_L$ or $\tilde{\nu}_\tau$ with masses $m_{\tilde{\nu}_\tau} = m_{\tilde{\tau}_L} = 0.5(m_{\tilde{\chi}_1^\pm} + m_{\tilde{\chi}_1^0})$.

In the simplified models considered here, the slepton mass is assumed to lie between the $\tilde{\chi}_1^0$ and $\tilde{\chi}_1^\pm/\tilde{\chi}_2^0$ masses, which increases the branching fraction to leptonic final states compared to scenarios without sleptons.

The compressed spectra searches in this article are less sensitive to scenarios where the $\tilde{\chi}_1^{\pm}/\tilde{\chi}_2^0$ decay through SM W, Z, or Higgs bosons, as the branching fraction to leptonic final states is significantly suppressed. The results of the ATLAS searches for $\tilde{\chi}_1^+\tilde{\chi}_1^-$ production with WW-mediated decays [19], $\tilde{\chi}_1^{\pm}\tilde{\chi}_2^0$ production with WZ-mediated decays [20], and $\tilde{\chi}_1^{\pm}\tilde{\chi}_2^0$ production with Wh-mediated decays [23] are summarized in Sec. X E. In these scenarios with decays mediated by SM bosons, the W, Z, and h bosons are assumed to decay with SM branching fractions.

In the simplified models of the direct production of $\tilde{\chi}_2^0\tilde{\chi}_3^0$, the $\tilde{\chi}_2^0$ and $\tilde{\chi}_3^0$ are assumed to be pure higgsino and mass degenerate, while the $\tilde{\chi}_1^0$ is assumed to be pure bino. The $\tilde{\chi}_2^0$ and $\tilde{\chi}_3^0$ are assumed to decay with a branching fraction of one-half via $\tilde{e}_R$, $\tilde{\mu}_R$ with mass $m_{\tilde{\ell}_R} = x(m_{\tilde{\chi}_2^0} - m_{\tilde{\chi}_1^0}) + m_{\tilde{\chi}_1^0}$ with $x = 0.05$, 0.25, 0.5, 0.75, or 0.95 ($\tilde{\chi}_2^0\tilde{\chi}_3^0$ production with $\tilde{\ell}_R$-mediated decay). The associated diagram is shown in Fig. 2(d). In this $\tilde{\chi}_2^0\tilde{\chi}_3^0$ simplified model, the choice of right-handed sleptons in the decay chain ensures high lepton multiplicities in the final state while suppressing the leptonic branching fraction of any associated chargino, thus enhancing the rate of four-lepton events with respect to events with lower lepton multiplicities.

C. Simplified model of same-sign chargino-pair production via vector-boson fusion

A simplified model for $\tilde{\chi}_1^{\pm}\tilde{\chi}_1^{\pm}$ production via VBF [55,56] is also considered. As in the case of direct production, the $\tilde{\chi}_1^{\pm}$ is assumed to be pure wino, and mass degenerate with the $\tilde{\chi}_2^0$, and the $\tilde{\chi}_1^0$ is assumed to be pure bino. The $\tilde{\chi}_1^{\pm}$ decays with a branching fraction of $1/6$ via $\tilde{e}_L$, $\tilde{\mu}_L$, $\tilde{\tau}_L$, $\tilde{\nu}_e$, $\tilde{\nu}_\mu$, or $\tilde{\nu}_\tau$ with masses $m_{\tilde{\nu}_\ell} = m_{\tilde{\ell}_L} = 0.5(m_{\tilde{\chi}_1^{\pm}} + m_{\tilde{\chi}_1^0})$. The diagram for $\tilde{\chi}_1^{\pm}\tilde{\chi}_1^{\pm}$ production via VBF, where the sparticles are produced along with two jets, is shown in Fig. 2(e). The jets are widely separated in pseudorapidity[1] η and have a relatively high dijet invariant mass m_{jj}. Because of the VBF topology, the charginos are often boosted in the transverse plane, forcing the decay products to be more collinear and energetic, even in highly compressed spectra. This feature of VBF production makes it a good candidate to probe compressed SUSY scenarios that are experimentally difficult to explore via the direct production modes. The signal cross sections are calculated to leading order (LO) in the strong coupling constant using MadGraph 5-1.3.33 [57] (more details on the cross-section calculation are given in the Appendix). The uncertainties on the signal cross sections are calculated by using different PDF sets (2%) and by varying the renormalization and factorization scales between 0.5 and 2 times the nominal values (6%) [58]. For a $\tilde{\chi}_1^{\pm}$ with mass of 120 GeV, the cross section for $\tilde{\chi}_1^{\pm}\tilde{\chi}_1^{\pm}$ production in association with two jets satisfying the criteria $m_{jj} > 350$ GeV and $|\Delta\eta_{jj}| > 1.6$ is 1.1 fb. For the assumed mixings in the chargino-neutralino sector, and the mass values considered in the analysis, the cross section for $\tilde{\chi}_1^{\pm}\tilde{\chi}_1^{\pm}$ VBF production is found to be independent of the $\tilde{\chi}_1^0$ mass.

D. Phenomenological minimal supersymmetric standard model

The analysis results are interpreted in a pMSSM scenario. The masses of the sfermions, the gluino, and the CP-odd Higgs boson are set to high values (2 TeV, 2 TeV, and 500 GeV, respectively), thus decoupling the production of these particles and allowing only the direct production of charginos and neutralinos decaying via SM gauge bosons and the lightest Higgs boson. The remaining four parameters, the ratio of the expectation values of the two Higgs doublets ($\tan\beta$), the gaugino mass parameters M_1 and M_2, and the higgsino mass parameter μ, determine the phenomenology of direct electroweak SUSY production. For the analysis presented here, μ and M_2 are treated as free parameters. The remaining parameters are fixed to $\tan\beta = 10$ and $M_1 = 50$ GeV, so that the relic dark-matter density is below the cosmological bound [29] across most of the μ-M_2 grid. The lightest Higgs boson has a mass close to 125 GeV, which is set by tuning the mixing in the top squark sector, and decays to SUSY as well as SM particles where kinematically allowed.

E. Two-parameter nonuniversal Higgs masses model

Radiatively driven natural SUSY [59] allows the Z and Higgs boson masses to be close to 100 GeV, with gluino and squark masses beyond the TeV scale. In the two-parameter NUHM model (NUHM2) that is considered in this article, the direct production of charginos and neutralinos is dominant in a large area of the parameter space considered. The mass hierarchy, composition, and production cross section of the SUSY particles are governed by the universal soft SUSY-breaking scalar mass m_0, the soft SUSY-breaking gaugino mass $m_{1/2}$, the trilinear SUSY-breaking parameter A_0, the pseudoscalar Higgs boson mass m_A, $\tan\beta$, and μ. Both μ and $m_{1/2}$ are treated as free parameters, and the other parameters are fixed to $m_0 = 5$ TeV, $A_0 = -1.6m_0$, $\tan\beta = 15$, $m_A = 1$ TeV, and $\mathrm{sign}(\mu) > 0$. These conditions ensure a low level of electroweak fine-tuning, while keeping the lightest Higgs boson mass close to 125 GeV and the squark masses to a few TeV. The gluino mass typically satisfies $m_{\tilde{g}} \simeq 2.5m_{1/2}$. For low gluino masses, the production of strongly interacting

[1]ATLAS uses a right-handed coordinate system with its origin at the nominal interaction point (IP) in the center of the detector and the z axis along the beam pipe. The x axis points from the IP to the center of the LHC ring, and the y axis points upward. Cylindrical coordinates (r, ϕ) are used in the transverse plane, ϕ being the azimuthal angle around the z axis. The pseudorapidity is defined in terms of the polar angle θ as $\eta = -\ln\tan(\theta/2)$.

SUSY particles dominates; as the gluino mass increases, the production of electroweakinos becomes more important. The charginos and neutralinos decay via W, Z, and Higgs bosons.

F. Gauge-mediated SUSY breaking model

Minimal GMSB models are described by six parameters: the SUSY-breaking mass scale in the low-energy sector (Λ), the messenger mass (M_{mess}), the number of SU(5) messenger fields (N_5), the scale factor for the gravitino mass (C_{grav}), $\tan\beta$, and μ. In the model presented here, Λ and $\tan\beta$ are treated as free parameters, and the remaining parameters are fixed to $M_{\text{mess}} = 250$ TeV, $N_5 = 3$, $C_{\text{grav}} = 1$, and $\text{sign}(\mu) > 0$. For high Λ values, the EW production of SUSY particles dominates over other SUSY processes. In most of the relevant parameter space, the NLSP is the $\tilde{\tau}$ for large values of $\tan\beta$ ($\tan\beta > 20$), and the final states contain two, three, or four tau leptons. In the region where the mass difference between the stau and selectron/smuon is smaller than the sum of the tau and the electron/muon masses, the stau, selectron, and smuon decay directly into the LSP and a lepton, defining the phenomenology. The charginos and neutralinos decay as $\tilde{\chi}_1^{\pm} \to W^{\pm}\tilde{\chi}_1^0$ and $\tilde{\chi}_2^0 \to Z\tilde{\chi}_1^0$, where the $\tilde{\chi}_1^0$ decays as $\tilde{\chi}_1^0 \to \ell^{\pm}\tilde{\ell}^{\mp} \to \ell^+\ell^-\tilde{G}$ and the LSP is the gravitino $\tilde{G}$.

III. THE ATLAS DETECTOR

The ATLAS detector [60] is a multipurpose particle physics detector with forward-backward symmetric cylindrical geometry. The inner tracking detector (ID) covers $|\eta| < 2.5$ and consists of a silicon pixel detector, a semiconductor microstrip detector, and a transition radiation tracker. The ID is surrounded by a thin superconducting solenoid providing a 2 T axial magnetic field. A high-granularity lead/liquid-argon sampling calorimeter measures the energy and the position of electromagnetic showers within $|\eta| < 3.2$. Sampling calorimeters with liquid argon as the active medium are also used to measure hadronic showers in the end cap ($1.5 < |\eta| < 3.2$) and forward ($3.1 < |\eta| < 4.9$) regions, while a steel/scintillator tile calorimeter measures hadronic showers in the central region ($|\eta| < 1.7$). The muon spectrometer (MS) surrounds the calorimeters and consists of three large superconducting air-core toroid magnets, each with eight coils, a system of precision tracking chambers ($|\eta| < 2.7$), and fast trigger chambers ($|\eta| < 2.4$). A three-level trigger system [61] selects events to be recorded for off-line analysis.

IV. MONTE CARLO SIMULATION

Monte Carlo generators are used to simulate SM processes and new physics signals. The SM processes considered are those that can lead to leptonic signatures. Details of the signal and background MC simulation samples used in this article, as well as the order of cross-section calculations in perturbative QCD used for yield normalization, are shown in Table I.

For all MC simulation samples, the propagation of particles through the ATLAS detector is modeled with GEANT 4 [96] using the full ATLAS detector simulation [97], or a fast simulation using a parametric response of the electromagnetic and hadronic calorimeters [98] and GEANT 4 elsewhere. The effect of multiple proton-proton collisions in the same or nearby beam bunch crossings (in-time and out-of-time pileup) is incorporated into the simulation by overlaying additional minimum-bias events generated with PYTHIA -8 onto hard-scatter events. Simulated events are weighted to match the distribution of the mean number of interactions per bunch crossing in data and are reconstructed in the same manner as data. The simulated MC samples are corrected to account for differences with respect to the data in the heavy-flavor quark jet selection efficiencies and misidentification probabilities, lepton efficiencies, tau misidentification probabilities, as well as the energy and momentum measurements of leptons and jets. The $\tilde{\chi}_1^+\tilde{\chi}_1^-$ ($\tilde{\chi}_1^{\pm}\tilde{\chi}_2^0$) signal samples simulated with HERWIG++ are reweighted to match the $\tilde{\chi}_1^+\tilde{\chi}_1^-$ ($\tilde{\chi}_1^{\pm}\tilde{\chi}_2^0$) system transverse momentum distribution obtained from the MADGRAPH samples that are generated with an additional parton in the matrix element to give a better description of the ISR.

V. EVENT RECONSTRUCTION

Events recorded during stable data-taking conditions are analyzed if the reconstructed primary vertex has five or more tracks with transverse momentum $p_{\text{T}} > 400$ GeV associated with it. The primary vertex of an event is identified as the vertex with the highest $\Sigma {p_{\text{T}}}^2$ of associated tracks. After the application of beam, detector, and data-quality requirements, the total luminosity considered in these analyses corresponds to 20.3 fb^{-1} (20.1 fb^{-1} for the direct stau production analysis due to a different trigger requirement).

Electron candidates are required to have $|\eta| < 2.47$ and $p_{\text{T}} > 7$ GeV, where the p_{T} and η are determined from the calibrated clustered energy deposits in the electromagnetic calorimeter and the matched ID track, respectively. Electrons must satisfy "medium" identification criteria, following Ref. [99]. Muon candidates are reconstructed by combining tracks in the ID and tracks in the MS [100], and are required to have $|\eta| < 2.5$ and $p_{\text{T}} > 5$ GeV. Events containing one or more muons that have transverse impact parameter with respect to the primary vertex $|d_0| > 0.2$ mm or longitudinal impact parameter with respect to the primary vertex $|z_0| > 1$ mm are rejected to suppress cosmic-ray muon background. In the direct stau production analysis, and the two-lepton compressed spectra analyses, electrons and muons are required to have $p_{\text{T}} > 10$ GeV.

Jets are reconstructed with the anti-k_t algorithm [101] with a radius parameter of $R = 0.4$. Three-dimensional

TABLE I. The MC simulation samples used in this article for background and signal estimates. Shown are the generator type, the order of cross-section calculations used for yield normalization, the names of the sets of tunable parameters (tunes) used for the underlying-event generation, and the PDF sets.

calorimeter energy clusters are used as input to the jet reconstruction. The clusters are calibrated using the local hadronic calibration [102], which gives different weights to the energy deposits from the electromagnetic and hadronic components of the showers. The final jet energy calibration corrects the calorimeter response to the particle-level jet energy [102,103], where correction factors are obtained from simulation and then refined and validated using data. Corrections for in-time and out-of-time pileup are also applied based on the jet area method [102]. Central jets must have $|\eta| < 2.4$ and $p_{\mathrm{T}} > 20$ GeV, and a "jet vertex fraction" (JVF) [102] larger than 0.5 if $p_{\mathrm{T}} < 50$ GeV. The JVF is the p_{T}-weighted fraction of the tracks in the jet that are associated with the primary vertex. Requiring large JVF values suppresses jets from pileup. Forward jets are those with $2.4 < |\eta| < 4.5$ and $p_{\mathrm{T}} > 30$ GeV. Events containing jets failing to satisfy the quality criteria described in Ref. [102] are rejected to suppress events with large calorimeter noise and noncollision backgrounds.

Central jets are identified as containing b-hadrons (referred to as b-tagged) using a multivariate technique based on quantities related to reconstructed secondary vertices. The chosen working point of the b-tagging algorithm [104] correctly identifies b-hadrons in simulated $t\bar{t}$ samples with an efficiency of 80%, with a light-flavor jet misidentification probability of about 4% and a c-jet misidentification probability of about 30%.

Hadronically decaying τ leptons (τ_{had}) are reconstructed using jets described above with $|\eta| < 2.47$ and a lower p_{T} threshold of 10 GeV. The τ_{had} reconstruction algorithm uses information about the tracks within $\Delta R \equiv \sqrt{(\Delta\phi)^2 + (\Delta\eta)^2} = 0.2$ of the seed jet, in addition to the electromagnetic and hadronic shower shapes in the calorimeters. The τ_{had} candidates are required to have one or three associated tracks (prongs), as τ leptons predominantly decay to either one or three charged pions together with a neutrino and often additional neutral pions. The τ_{had} candidates are required to have $p_{\mathrm{T}} > 20$ GeV and unit total charge of their constituent tracks. A boosted decision tree algorithm (BDT) uses discriminating track and cluster variables to optimize τ_{had} identification, where "loose," "medium," and "tight" working points are defined [105]. Electrons misidentified as τ_{had} candidates are vetoed using transition radiation and calorimeter information. The τ_{had} candidates are corrected to the τ energy scale [105] using an η- and p_{T}-dependent calibration. Kinematic variables built using taus in this article use only the visible decay products from the hadronically decaying tau.

The missing transverse momentum is the negative vector sum of the transverse momenta of all muons with $p_{\mathrm{T}} > 10$ GeV, electrons with $p_{\mathrm{T}} > 10$ GeV, photons with $p_{\mathrm{T}} > 10$ GeV [99], jets with $p_{\mathrm{T}} > 20$ GeV, and calibrated calorimeter energy clusters with $|\eta| < 4.9$ not associated with these objects. Hadronically decaying τ leptons are included in the $E_{\mathrm{T}}^{\mathrm{miss}}$ calculation as jets. Clusters associated with electrons, photons, and jets are calibrated to the scale of the corresponding objects. Calorimeter energy clusters not associated with these objects are calibrated using both calorimeter and tracker information [106]. For jets, the calibration includes the pileup correction described above, while the JVF requirement is not considered when selecting jet candidates.

To avoid potential ambiguities among objects, "tagged" leptons are candidate leptons separated from each other and from jets in the following order:

(1) If two electron candidates are reconstructed with $\Delta R < 0.1$, the lower energy candidate is discarded.
(2) Jets within $\Delta R = 0.2$ of an electron candidate, and τ_{had} candidates within $\Delta R = 0.2$ of an electron or muon, are discarded.
(3) Electron and muon candidates are discarded if found within $\Delta R = 0.4$ of a remaining jet to suppress leptons from semileptonic decays of c- and b-hadrons.
(4) To reject bremsstrahlung from muons, $e\mu$ ($\mu\mu$) pairs are discarded if the two leptons are within $\Delta R = 0.01$ (0.05) of one another.
(5) Jets found within $\Delta R = 0.2$ of a "signal" τ lepton (see below) are discarded.

Finally, to suppress low-mass decays, if tagged electrons and muons form a same-flavor opposite-sign (SFOS) pair with $m_{\mathrm{SFOS}} < 2$ GeV, both leptons in the pair are discarded.

Tagged leptons satisfying additional identification criteria are called signal leptons. To maximize the search sensitivity, some analyses presented in this article require different additional criteria for signal leptons, and these are highlighted where necessary. Signal τ leptons must satisfy medium identification criteria [105], while for the final signal-region selections, both the medium and tight criteria are used. Unless stated otherwise, signal electrons (muons) are tagged electrons (muons) for which the scalar sum of the transverse momenta of tracks within a cone of $\Delta R = 0.3$ around the lepton candidate is less than 16% (12%) of the lepton p_{T}. Tracks used for the electron (muon) isolation requirement defined above are those that have $p_{\mathrm{T}} > 0.4$ (1.0) GeV and $|z_0| < 2$ mm with respect to the primary vertex of the event. Tracks of the leptons themselves as well as tracks closer in z_0 to another vertex (that is not the primary vertex) are not included. The isolation requirements are imposed to reduce the contributions from semileptonic decays of hadrons and jets misidentified as leptons. Signal electrons must also satisfy tight identification criteria [99], and the sum of the extra transverse energy deposits in the calorimeter (corrected for pileup effects) within a cone of $\Delta R = 0.3$ around the electron candidate must be less than 18% of the electron p_{T}. To further suppress electrons and muons originating from secondary vertices, the d_0 normalized to its uncertainty is required to be small, with $|d_0|/\sigma(d_0) < 5(3)$, and $|z_0 \sin\theta| < 0.4$ mm (1 mm) for electrons (muons).

TABLE II. The triggers used in the analyses and the off-line p_{T} threshold used, ensuring that the lepton(s) or $E_{\mathrm{T}}^{\mathrm{miss}}$ triggering the event are in the plateau region of the trigger efficiency. Where multiple triggers are listed for an analysis, events are used if any of the triggers is passed. Muons are triggered within a restricted range of $|\eta| < 2.4$.

Trigger	p_{T} threshold [GeV]	Analysis
Single τ	150	Direct stau production
Double τ	40,25	
Single isolated e	25	Compressed spectra $\ell^+\ell^-$, 3ℓ
Single isolated μ	25	
Double e	14,14 25,10	Compressed spectra $\ell^+\ell^-$, $\ell^\pm\ell^\pm$, 3ℓ
Double μ	14,14 18,10	Compressed spectra $\ell^+\ell^-$, $\ell^\pm\ell^\pm$, 3ℓ
Triple e	20,9,9	Compressed spectra 3ℓ
Triple μ	7,7,7 19,5,5	Compressed spectra 3ℓ
Combined $e\mu$	$14(e)$,$10(\mu)$ $18(\mu)$,$10(e)$ $9(e)$, $9(e)$, $7(\mu)$ $9(e)$, $7(\mu)$, $7(\mu)$	Compressed spectra 3ℓ
$E_{\mathrm{T}}^{\mathrm{miss}}$	120	Chargino production via VBF

Events must satisfy the relevant trigger for the analysis and satisfy the corresponding p_{T}-threshold requirements shown in Table II.

VI. GENERAL ANALYSIS STRATEGY

The broad range of EW SUSY scenarios considered by the ATLAS experiment is accompanied by a large number of experimental signatures: from the two-tau signature from direct stau production to three-lepton signatures from $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$ production. As much as possible the individual analyses follow a common approach. Signal regions (SR) are defined to target one or more EW SUSY scenarios, using kinematic variables with good signal-background separation, as described in Sec. VI A. The optimization of key selection variables is performed by maximizing the expected sensitivity to the signal model. A common background estimation strategy is used for the analyses in this article: the main SM backgrounds are estimated by normalizing MC simulation samples to data in dedicated control regions (CRs); backgrounds due to nonprompt and fake leptons are derived from data as outlined in Sec. VI B, while small backgrounds are estimated purely using MC simulation samples. The HistFitter [107] software framework is used in all analyses for constraining the background normalizations and the statistical interpretation of the results.

The CRs are defined with kinematic properties similar to the SRs, yet are disjoint from the SR, and have high purity for the background process under consideration. The CRs are designed in a way that minimizes the contamination from the signal model, and cross contamination between multiple CRs is taken into account in the normalization to data. To validate the modeling of the SM backgrounds, the yields and shapes of key kinematic variables are compared to data in validation regions (VR). The VRs are defined to be close to, yet disjoint from the SR and CR, and be dominated by the background process under consideration. The VRs are designed such that the contamination from the signal model is low. Three different fit configurations are used. The "background-only fit" is used for estimating the expected background in the SRs and VRs using observations in the CRs, with no assumptions made on any signal model. In the absence of an observed excess of events in one or more signal regions, the "model-dependent signal fit" is used to set exclusion limits in a particular model, where the signal contribution from the particular model that is being tested is taken into account in all CR and SR. Finally, in the "model-independent signal fit," both the CRs and SRs are used in the same manner as for the model-dependent signal fit, but signal contamination is not accounted for in the CRs. A likelihood function is built as the product of Poisson probability functions, describing the observed and expected number of events in the CRs and SRs. The observed number of events in various CRs and SRs are used in a combined profile likelihood fit to determine the expected SM background yields in each of the SRs. The systematic uncertainties on the expected background yields described in Sec. VI C are included as nuisance parameters, constrained to be Gaussian with a width determined by the size of the uncertainty. Correlations between control and signal regions, and background processes, are taken into account with common nuisance parameters. The free parameters and the nuisance parameters are determined by maximizing the product of the Poisson probability functions and the Gaussian constraints on the nuisance parameters.

After the background modeling is understood and validated, the predicted background in the SR is compared to the observed data. In order to quantify the probability for the background-only hypothesis to fluctuate to the observed number of events or higher, the one-sided p_0-value is calculated. For this calculation, the profile likelihood ratio is used as a test statistic to exclude the signal-plus-background hypothesis if no significant excess is observed. A signal model can be excluded at 95% CL if the CL_s [108] of the signal plus background hypothesis is < 0.05. For each signal region, the expected and observed upper limits at 95% CL on the number of beyond-the-SM

events ($S^{95}_{\rm exp}$ and $S^{95}_{\rm obs}$) are calculated using the model-independent signal fit. The 95% CL upper limits on the signal cross section times efficiency ($\langle\epsilon\sigma\rangle^{95}_{\rm obs}$) and the CL_b value for the background-only hypothesis are also calculated for each analysis in this article.

A. Event variables

A large set of discriminating variables is used in the analysis strategies presented here. The following kinematic variables are defined and their use in the various analyses is detailed in Secs. VII–IX:

$p_{\rm T}^X$ The transverse momentum of a reconstructed object X.

$\Delta\phi(X,Y)$, $\Delta\eta(X,Y)$ The separation in ϕ or η between two reconstructed objects X and Y, e.g. $\Delta\phi(E_{\rm T}^{\rm miss},\ell)$.

$|\Delta\eta_{jj}|$ The separation in η between the leading two jets.

$E_{\rm T}^{\rm miss}$ The magnitude of the missing transverse momentum in the event.

$E_{\rm T}^{\rm miss,rel}$ The quantity $E_{\rm T}^{\rm miss,rel}$ is defined as

$$E_{\rm T}^{\rm miss,rel} = \begin{cases} E_{\rm T}^{\rm miss} & \text{if } \Delta\phi(E_{\rm T}^{\rm miss},\ell/j) \geq \pi/2 \\ E_{\rm T}^{\rm miss} \times \sin\Delta\phi(E_{\rm T}^{\rm miss},\ell/j) & \text{if } \Delta\phi(E_{\rm T}^{\rm miss},\ell/j) < \pi/2 \end{cases}, \tag{1}$$

where $\Delta\phi(E_{\rm T}^{\rm miss},\ell/j)$ is the azimuthal angle between the direction of $E_{\rm T}^{\rm miss}$ and that of the nearest electron, muon, or central jet.

$p_{\rm T}^{\ell\ell}$ The transverse momentum of the two-lepton system.

$H_{\rm T}$ The scalar sum of the transverse momenta of the leptons and jets in the event.

$m_{\rm T}$ The transverse mass formed using the $E_{\rm T}^{\rm miss}$ and the leading lepton or tau in the event

$$m_{\rm T}(\vec{p}_{\rm T}^{\,\ell/\tau}, E_{\rm T}^{\rm miss}) = \sqrt{2p_{\rm T}{}^{\ell/\tau}E_{\rm T}^{\rm miss} - 2\vec{p}_{\rm T}^{\,\ell/\tau}\cdot E_{\rm T}^{\rm miss}}. \tag{2}$$

In the three-lepton analysis, the lepton not forming the SFOS lepton pair with mass closest to the Z boson mass is used. In cases where the second lepton or tau is used, the variable is labeled as $m_{\rm T}^X$, where X is the object used with the $E_{\rm T}^{\rm miss}$ to form the transverse mass.

$m_{\rm SFOS}$ The invariant mass of the SFOS lepton pair in the event. In the three-lepton analysis, the SFOS pair with mass closest to the Z boson mass is used.

$m_{\rm SFOS}^{\rm min}$ The lowest $m_{\rm SFOS}$ value among the possible SFOS combinations.

$m_{\ell\ell\ell}$ The three-lepton invariant mass.

$m_{\tau\tau}$ The two-tau invariant mass.

$m_{\rm T2}$ The "stransverse mass" is calculated as

$$m_{\rm T2} = \min_{\vec{q}_{\rm T}}[\max(m_{\rm T}(\vec{p}_{\rm T}{}^{\ell 1/\tau 1}, \vec{q}_{\rm T}), m_{\rm T}(\vec{p}_{\rm T}{}^{\ell 2/\tau 2}, E_{\rm T}^{\rm miss} - \vec{q}_{\rm T}))], \tag{3}$$

where $\ell 1/\tau 1$ and $\ell 2/\tau 2$ denote the highest- and second-highest-$p_{\rm T}$ leptons or taus in the event, respectively, and $\vec{q}_{\rm T}$ is a test transverse vector that minimizes the larger of the two transverse masses

m_{T}. The m_{T2} distribution has a kinematic end point for events where two massive pair-produced particles each decay to two particles, one of which is detected and the other escapes undetected [109,110].

m_{eff} The scalar sum of the transverse momenta of the signal leptons, taus, jets, and $E_{\mathrm{T}}^{\mathrm{miss}}$ in the event

$$m_{\mathrm{eff}} = E_{\mathrm{T}}^{\mathrm{miss}} + \Sigma p_{\mathrm{T}}{}^{\mathrm{leptons}} + \Sigma p_{\mathrm{T}}{}^{\mathrm{taus}} + \Sigma p_{\mathrm{T}}{}^{\mathrm{jets}}. \tag{4}$$

In the case of the two-tau analysis, only the sum of the $E_{\mathrm{T}}^{\mathrm{miss}}$ and two taus is used.

R_2 The quantity R_2 is defined as

$$R_2 = \frac{E_{\mathrm{T}}^{\mathrm{miss}}}{E_{\mathrm{T}}^{\mathrm{miss}} + p_{\mathrm{T}}{}^{\ell 1} + p_{\mathrm{T}}{}^{\ell 2}}. \tag{5}$$

The R_2 distribution is shifted toward unity for signal events compared to the background, due to the existence of the LSPs that results in a larger $E_{\mathrm{T}}^{\mathrm{miss}}$.

M_{Δ}^{R}, $\Delta\phi_{R}^{\beta}$ The super-razor quantities M_{Δ}^{R} and $\Delta\phi_{R}^{\beta}$ are defined in Ref. [111]. These variables are motivated by the generic process of the pair production of two massive particles, each decaying into a set of visible and invisible particles (i.e. $\tilde{\chi}_1^{\pm} \to \ell\nu_{\ell}\tilde{\chi}_1^0$). Similar to m_{T2}, M_{Δ}^{R} is sensitive to the squared mass difference of the pair-produced massive particle and the invisible particle, via a kinematic end point. These two variables are expected to provide a similar performance for discriminating the signal from the background. For systems where the invisible particle has a mass that is comparable to the pair-produced massive particle (i.e. compressed spectra), the variable $\Delta\phi_{R}^{\beta}$ has a pronounced peak near π. The effect is magnified as the spectrum becomes more and more compressed, making this variable a good discriminator for compressed spectra searches.

B. Common reducible background estimation

Electron and muon candidates can be classified into three main types, depending on their origin: "real" leptons are prompt and isolated leptons from a W or Z boson, a prompt tau, or a SUSY particle decay; "fake" leptons can originate from a misidentified light-flavor quark or gluon jet (referred to as "light flavor"); "nonprompt" leptons can originate from a semileptonic decay of a heavy-flavor quark, from the decay of a meson, or from an electron from a photon conversion. The background due to nonprompt and fake electrons and muons, collectively referred to as "reducible," is commonly estimated using the matrix method described in Ref. [112]. The matrix method extracts the number of events with one or two fake or nonprompt leptons from a system of linear equations relating the number of events with two signal or tagged leptons (before signal lepton identification requirements are applied) to the number of events with two candidates that are either real, fake, or nonprompt. The coefficients of the linear equations are functions of the real-lepton identification efficiencies and of the fake and nonprompt lepton misidentification probabilities, both defined as a fraction of the corresponding tagged leptons satisfying the signal lepton requirements.

The real-lepton identification efficiencies are obtained from MC simulation samples in the region under consideration to account for detailed kinematic dependencies and are multiplied by correction factors to account for residual differences with respect to the data. The correction factors are obtained from a control region rich in $Z \to e^+e^-$ and $Z \to \mu^+\mu^-$ decays. The fake and nonprompt lepton misidentification probabilities are calculated as the weighted averages of the corrected type- and process-dependent misidentification probabilities defined below according to their relative contributions in a given signal or validation region. The type- and process-dependent misidentification probabilities for each relevant fake and nonprompt lepton type (heavy-flavor, light-flavor, or conversion) and for each reducible background process are corrected using the ratio ("correction factor") of the misidentification probability in data to that in simulation obtained from dedicated control samples. The correction factors are assumed to be independent of the selected regions and of any potential composition or kinematic differences. For nonprompt electrons and muons from heavy-flavor quark decays, the correction factor is measured in a $b\bar{b}$-dominated control sample. The correction factor for the conversion candidates is determined in events with a converted photon radiated from a muon in $Z \to \mu\mu$ decays.

C. Common systematic uncertainties

Several sources of systematic uncertainty are considered for the SM background estimates and signal yield predictions. When the MC simulation samples are normalized to data yields in the CR, there is a partial cancellation of both the experimental and theoretical modeling systematic uncertainties.

The experimental systematic uncertainties affecting the simulation-based estimates include the following: the uncertainties due to the jet energy scale and resolution [100,102]; the uncertainties due to the lepton energy scale, energy resolution, and identification efficiency [99,100,105]; the uncertainty due to the hadronic tau misidentification probability [105]; the uncertainty on the $E_{\mathrm{T}}^{\mathrm{miss}}$ from energy deposits not associated with reconstructed objects ($E_{\mathrm{T}}^{\mathrm{miss}}$ soft-term resolution) [106]; and the uncertainties due to b-tagging efficiency and mistag probability [104]. The uncertainty on the integrated luminosity is $\pm 2.8\%$ and is derived following the same methodology as that detailed in Ref. [113]. The uncertainty due to the modeling of the pileup in the MC simulation samples is estimated by varying the distribution of the number of interactions per bunch crossing overlaid in the MC samples by $\pm 10\%$. An uncertainty is applied to MC samples to cover differences in efficiency observed between the trigger in data and the MC trigger simulation.

The systematic uncertainties due to the limitations in theoretical models or calculations affecting the simulation-based background estimates include the cross-section uncertainties that are estimated by varying the renormalization and factorization scales and the PDFs, and the acceptance uncertainties due to PDFs and the choice of MC generator and parton shower. The cross-section uncertainties for the irreducible backgrounds used here are 30% for $t\bar{t}V$ [76,77], 50% for tZ, 5% for ZZ, 7% for WZ, and 100% for the triboson samples. For the Higgs boson samples, a 20% uncertainty is used for VH and VBF production, while a 100% uncertainty is assigned to $t\bar{t}H$ and Higgs boson production via gluon fusion [74]. For the $\tilde{\chi}_1^+\tilde{\chi}_1^-$ and $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$ signal simulations that are sensitive to ISR, the impact of the choice of renormalization scales, factorization scales, the scale for the first emission in the so-called MLM matching scheme [114], and MLM matching scale are evaluated by varying these individually between 0.5 and 2 times the nominal values in MadGraph.

VII. DIRECT STAU PRODUCTION

This section presents a search for direct stau-pair production with subsequent decay into final states with two taus and $E_{\mathrm{T}}^{\mathrm{miss}}$. The search for direct stau production is very challenging, as the final state is difficult to trigger on and to separate from the SM background. In Ref. [22], the best observed upper limit on the direct stau production cross section was found for a stau mass of 80 GeV and a massless $\tilde{\chi}_1^0$, where the theoretical cross section at NLO is 0.07 (0.17) pb for right-handed (left-handed) stau-pair production and the excluded cross section is 0.22 (0.28) pb. This analysis is an update of Ref. [22], using a multivariate analysis technique instead of a simple cut-based method to improve the sensitivity to direct stau-pair production.

A. Event selection

Events are selected using the basic reconstruction, object, and event selection criteria described in Sec. V. In addition, if taus form an SFOS pair with $m_{\mathrm{SFOS}} < 12$ GeV, the event is rejected. Events with exactly two hadronically decaying tau candidates are selected, where the two tau candidates are required to have opposite-sign (OS) charge. At least one tau must satisfy the tight tau identification BDT requirement, and events with additional tagged light leptons are vetoed. Events must satisfy either the single-tau or ditau trigger criteria, as described in Sec. V.

To suppress events from Z boson decays, events are rejected if the invariant mass of the tau pair lies within ± 10 GeV of the peak value of 81 GeV for Z boson candidates.[2] To suppress background from events containing a top quark, events with b-tagged jets are vetoed. To further select SUSY events from direct stau production and suppress WW and $t\bar{t}$ production, m_{T2} is calculated using the two taus and the $E_{\mathrm{T}}^{\mathrm{miss}}$ in the event. The additional requirement of $m_{\mathrm{T2}} > 30$ GeV is applied to select events for the training and optimization of the multivariate analysis (MVA).

After applying the preselection listed above, both the signal and background MC samples are split in two. Half is used for the BDT training and the other half for testing. Twelve variables with good discriminatory power are considered as input for the BDT training procedure: $E_{\mathrm{T}}^{\mathrm{miss}}$, m_{eff}, m_{T2}, $m_{\tau\tau}$, $\Delta\phi(\tau,\tau)$, $\Delta\eta(\tau,\tau)$, $p_{\mathrm{T}}^{\tau 1}$, $p_{\mathrm{T}}^{\tau 2}$, $m_{\mathrm{T}\tau 1}$, $m_{\mathrm{T}\tau 2}$, $\Delta\phi(E_{\mathrm{T}}^{\mathrm{miss}},\tau 1)$, and $\Delta\phi(E_{\mathrm{T}}^{\mathrm{miss}},\tau 2)$. The MC simulation samples are compared to data for these variables and their correlations to ensure that they are modeled well.

A direct stau production scenario with $m(\tilde{\tau}_R,\tilde{\chi}_1^0) = (109, 0)$ GeV is used for the training and optimization of the BDT, and the BDT response requirement (t_{cut}) is chosen based on the best expected sensitivity for discovery. The two-tau MVA SR definition is shown in Table III.

B. Background determination

The main SM backgrounds in the two-tau MVA SR are $W+$jets and diboson production. Contributions from diboson, $t\bar{t}$, and $Z+$jets processes are estimated using MC simulation samples and validated using data in WW-rich, $t\bar{t}$-rich, or Z-rich validation regions, as defined in Ref. [22].

[2]The Z boson mass in ditau decays is reconstructed lower than the Z boson mass value due to the neutrinos from the tau decay.

TABLE III. Two-tau MVA signal region and validation region definitions for the direct stau-pair production analysis, where t_{cut} is the BDT response requirement.

	Common				
	Signal region SR	Multijet VR1	Exactly 2 medium OS taus ≥1 tight tau tagged ℓ veto b-jet veto Z-veto Multijet VR2	W-VR1	W-VR2
m_{T2}	>30 GeV	30–50 GeV	50–80 GeV	>30 GeV	>30 GeV
$E_{\text{T}}^{\text{miss}}$	...	...	...	>100 GeV	>90 GeV
t_{cut}	>0.07	<0.07	<0.07	$-0.2-0.07$	$-0.2-0.07$

The $W+$ jets contribution in the signal region is dominated by events where the W decays to a tau lepton and a jet is misidentified as another tau. The contribution is estimated by normalizing the yields from MC simulation samples to data in a dedicated control region. The $W+$ jets control region selects events with the W boson decaying to a muon and neutrino to suppress the multijet background, which is larger for the electron channel. Events containing exactly one isolated muon and one tau satisfying the tight identification requirement are selected, where the muon and tau must have opposite electrical charge. To reduce the contribution from $Z+$ jets production, $m_{\text{T}}^{\tau}+m_{\text{T}}^{\mu}>80$ GeV is required, and the reconstructed invariant mass of the muon and tau must be outside the Z mass window (12 GeV $< m_{\tau\mu} <$ 40 GeV or $m_{\tau\mu} >$ 100 GeV). To further suppress multijet and $Z+$ jets processes, $E_{\text{T}}^{\text{miss}} > 40$ GeV is required, and the muon and tau must not be back-to-back [$\Delta\phi(\tau,\mu) < 2.7$ and $\Delta\eta(\tau,\mu) < 2.0$]. The contribution from events with top quarks is suppressed by rejecting events containing b-tagged jets. The multijet background in the $W+$ jets control region is estimated using a region with the same requirements, but with a same-sign muon and tau. The contribution from other SM processes is subtracted using MC simulation samples, and the ratio of opposite-sign muon and tau events to same-sign events is assumed to be unity for the multijet background.

The contribution from multijet events in the signal region, where both selected taus are misidentified jets, is small and is estimated using the so-called ABCD method. Four exclusive regions (A, B, C, D) are defined in a two-dimensional plane as a function of the two uncorrelated

TABLE IV. Numbers of events observed in data and expected from SM processes and the SUSY reference point $m(\tilde{\tau}_R,\tilde{\chi}_1^0)=(109,0)$ GeV in the two-tau MVA validation and signal regions. The uncertainties shown include both statistical and systematic components. The "top" contribution includes the single top, $t\bar{t}$, and $t\bar{t}V$ processes. The multijet background estimation is taken from data, as described in the text. In the VR, the multijet scale factor from fitting the background is not applied, while the $W+$ jets scale factor is applied. In the SR, both the multijet and the $W+$ jets scale factors are applied. Also shown are the model-independent limits calculated from the signal region observations: the one-sided p_0-value; the expected and observed upper limits at 95% CL on the number of beyond-the-SM events (S_{exp}^{95} and S_{obs}^{95}) for each signal region, calculated using pseudoexperiments and the CL_s prescription; the observed 95% CL upper limit on the signal cross section times efficiency ($\langle\epsilon\sigma\rangle_{\text{obs}}^{95}$); and the CL_b value for the background-only hypothesis.

SM process	Multijet VR1	Multijet VR2	W-VR1	W-VR2	SR

CL_b	...	...	...	...	0.52

discriminating variables m_{T2} and the tau identification criterion. Regions A and B are required to have two medium taus where at least one meets the tight tau identification criteria, while regions C and D are required to have two loose taus that fail to satisfy the tight tau identification criteria. In regions A and C (B and D) $m_{T2} > 30$ GeV ($m_{T2} < 20$ GeV) is also required. The multijet background in signal region A can be estimated from $N_A = N_C \times N_B/N_D$, where N_A, N_B, N_C, and N_D are the numbers of events in regions A, B, C, and D, respectively. The assumption that the ratios N_A/N_C and N_B/N_D are the same is confirmed using MC simulation samples and in validation regions using data.

A simultaneous likelihood fit to the multijet estimation and $W+$jets CR is performed to normalize the corresponding background estimates and obtain the expected yields in the SR (as described in Sec. VI). After the simultaneous fit, the multijet and $W+$jets normalization factors are found to be $1.4^{+2.5}_{-1.4}$ and 0.98 ± 0.30, respectively. Because of the small number of events in some of the ABCD regions, the uncertainty on the multijet normalization factor is large; however, the multijet contribution to the total background is very small and the effect on the total signal region background uncertainty is small.

Two multijet validation regions are defined with the same selection as for the signal region, but with $t_{cut} < 0.07$ and intermediate m_{T2}. These multijet validation regions are enriched in events with jets misidentified as hadronic tau decays, and good agreement is seen between the data and expectation across the BDT input kinematic variables. A further two validation regions are defined to check the modeling of the $W+$jets background. The intermediate BDT region $-0.2 < t_{cut} < 0.07$ is used, with a high E_T^{miss} selection, where the $W+$jets background is seen to be

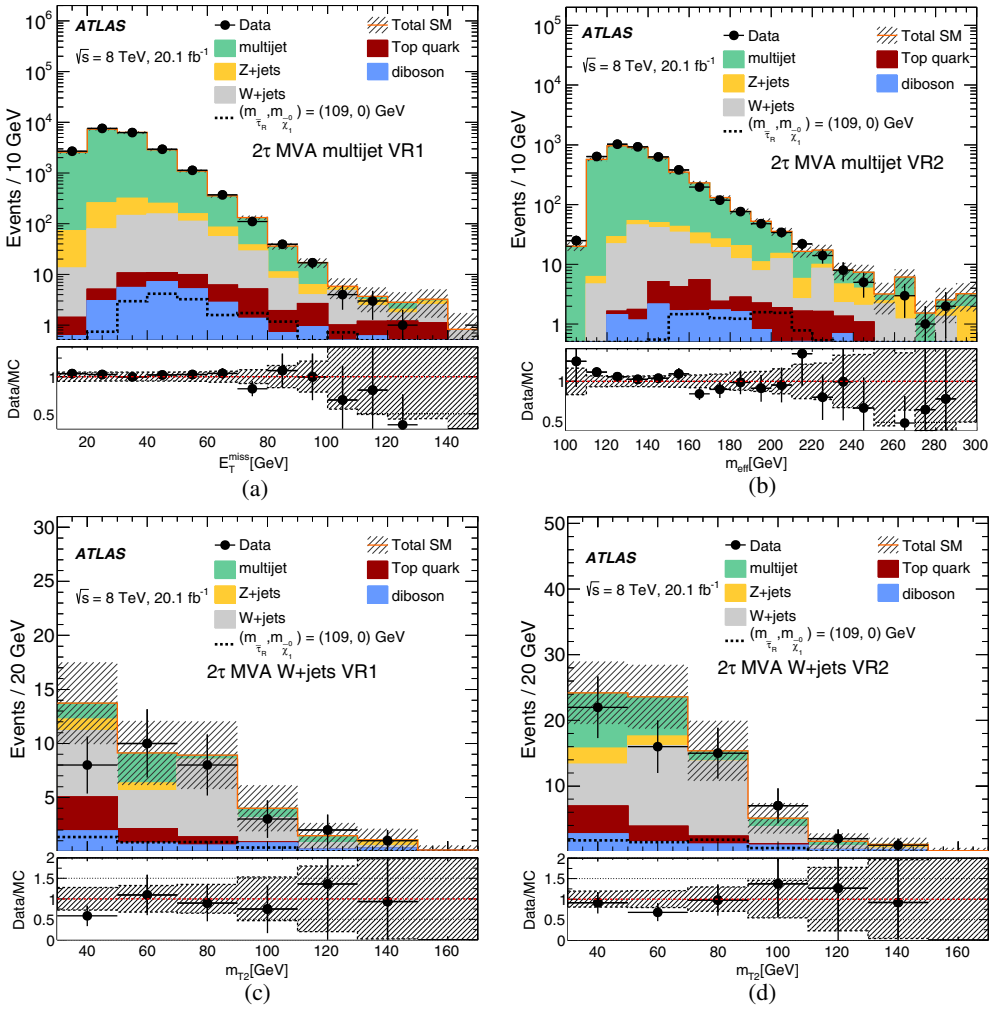

FIG. 3. Distributions in the two-tau MVA validation regions: (a) missing transverse momentum E_T^{miss} in multijet VR1, (b) effective mass m_{eff} in multijet VR2, (c) stransverse mass m_{T2} in W-VR1, and (d) m_{T2} in W-VR2. The lower panel of each plot shows the ratio of data to the SM background prediction. The last bin in each distribution includes the overflow. The uncertainty band includes both the statistical and systematic uncertainties on the SM prediction.

TABLE V. The relative systematic uncertainty (%) on the background estimate in the two-tau MVA SR from the leading sources. Uncertainties from different sources may be correlated and do not necessarily add in quadrature to the total uncertainty.

Systematic source	Uncertainty
Statistical uncertainty on MC samples	20%
$E_{\mathrm{T}}^{\mathrm{miss}}$ soft-term resolution	20%
Statistical uncertainty on the $W+$jets scale factor	15%
Tau misidentification probability	14%
$W+$jets theory and modeling	13%
Jet energy scale	11%
$E_{\mathrm{T}}^{\mathrm{miss}}$ soft-term scale	10%
Total	35%

modeled well. The validation region definitions are shown in Table III. Table IV and Figs. 3(a), 3(b), 3(c), and 3(d) show the agreement between data and expectation in the validation regions. The purity of the multijet and $W+$jets validation regions is ∼90% and ∼50%, respectively, while the signal contamination from the $m(\tilde{\tau}_R,\tilde{\chi}_1^0)=(109,0)$ GeV scenario is $<1\%$ and $<10\%$, respectively.

C. Results

The observed number of events in the signal region is shown in Table IV along with the background expectations, uncertainties, p_0-value, S_{exp}^{95}, S_{obs}^{95}, $\langle\epsilon\sigma\rangle_{\mathrm{obs}}^{95}$, and the CL_b value. The individual sources of uncertainty on the background estimation in the SR are shown in Table V, where the dominant sources are the statistical uncertainty on the MC simulation samples, the uncertainty on the $E_{\mathrm{T}}^{\mathrm{miss}}$ from energy deposits not associated with reconstructed objects, and the statistical uncertainty on the normalization factor applied to the $W+$jets background. Generator modeling uncertainties for the $W+$jets background are estimated by varying the renormalization and factorization scales individually between 0.5 and 2 times the nominal values in Alpgen. Additionally, the impact of the jet p_{T} threshold used for parton-jet matching in Alpgen $W+$jets simulation is assessed by changing the jet p_{T} threshold from 15 GeV to 25 GeV. Figures 4(a), 4(b), 4(c), and 4(d) show the distributions of the BDT response prior to the t_{cut} selection, and the $E_{\mathrm{T}}^{\mathrm{miss}}$, m_{eff}, and m_{T2} quantities in the SR, where good agreement between the expected background and the observed data is seen.

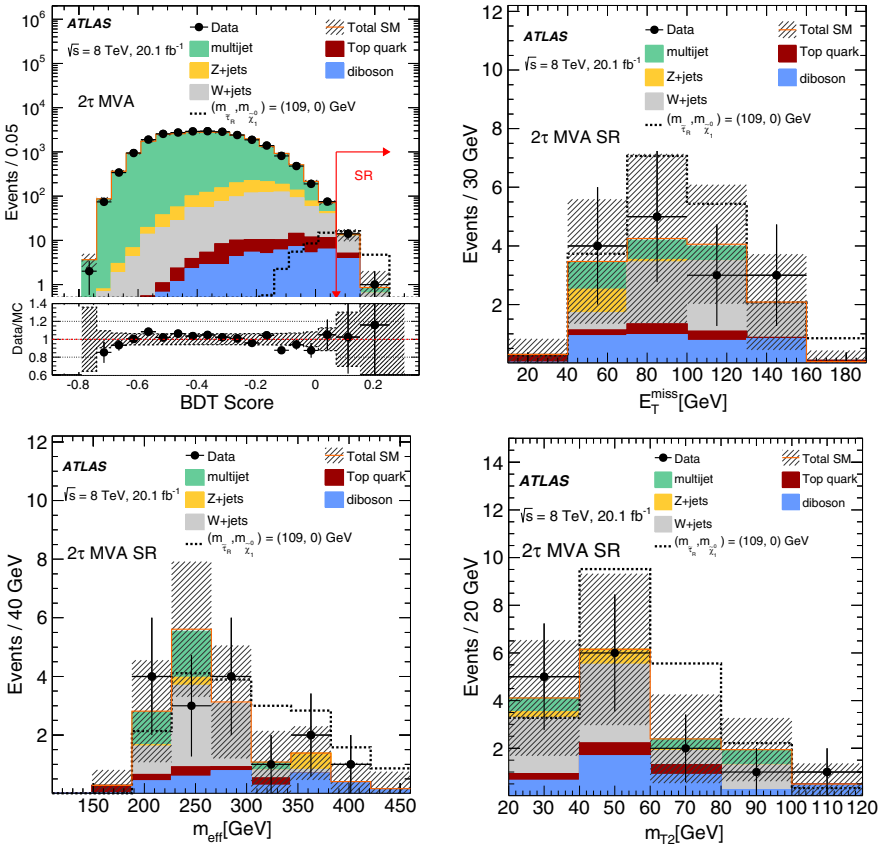

FIG. 4. The BDT response is shown in (a) prior to applying the SR t_{cut} requirement. Also shown are distributions in the two-tau MVA SR: (b) $E_{\mathrm{T}}^{\mathrm{miss}}$, (c) m_{eff}, and (d) m_{T2}. The lower panel in (a) shows the ratio of data to the SM background prediction. The uncertainty band includes both the statistical and systematic uncertainties on the SM prediction. The multijet and $W+$jets normalization factors from the background fits are applied in (b)–(d); only the $W+$jets normalization factor is applied in (a).

VIII. COMPRESSED SPECTRA IN DIRECT PRODUCTION OF $\tilde{\chi}_1^+\tilde{\chi}_1^-$ OR $\tilde{\chi}_1^+\tilde{\chi}_2^0$

In many SUSY scenarios, one or more of the mass differences between the charginos and neutralinos is small, resulting in final states with low-momentum leptons that require dedicated searches. The two-lepton analysis in Ref. [19] excluded $\tilde{\chi}_1^+\tilde{\chi}_1^-$ scenarios with $\tilde{\ell}_L$-mediated decays with $\tilde{\chi}_1^\pm$-$\tilde{\chi}_1^0$ mass splittings down to approximately 100 GeV, while the three-lepton analysis in Ref. [20] excluded $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$ scenarios with $\tilde{\ell}_L$-mediated decays down to $\tilde{\chi}_2^0$-$\tilde{\chi}_1^0$ mass splittings of 20 GeV. The analyses presented in this section focus on event selections based on low-momentum leptons, and also on the production in association with ISR jets to provide improved sensitivity to the compressed spectra scenarios not covered by previous searches. As discussed in Sec. II, simplified models describing $\tilde{\chi}_1^+\tilde{\chi}_1^-$ and $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$ production are considered for these compressed spectra searches, where the $\tilde{\chi}_1^\pm/\tilde{\chi}_2^0$ decay only through sleptons or sneutrinos. The compressed spectra searches are less sensitive to scenarios where the $\tilde{\chi}_1^\pm/\tilde{\chi}_2^0$ decay through SM W, Z, or Higgs bosons, as the branching fraction to leptonic final states is significantly suppressed. The experimental sensitivity to these scenarios is expected to be recovered with a larger data set.

A. Searches with two opposite-sign light leptons

Previous searches for direct $\tilde{\chi}_1^+\tilde{\chi}_1^-$ production using two opposite-sign light-lepton final states are extended here to increase the sensitivity to compressed SUSY scenarios. The opposite-sign, two-lepton analysis presented here probes $\tilde{\chi}_1^\pm$-$\tilde{\chi}_1^0$ mass splittings below 100 GeV using an ISR-jet selection.

1. Event selection

Events are reconstructed as described in Sec. V, with the signal light-lepton p_{T} threshold raised to $p_{\mathrm{T}} = 10$ GeV. In addition, in events where tagged light leptons form an SFOS pair with $m_{\mathrm{SFOS}} < 12$ GeV, both leptons in the pair are rejected. Events must have exactly two signal light leptons with opposite charge and satisfy the symmetric or asymmetric dilepton trigger criteria, as described in Sec. V.

To suppress the top-quark ($t\bar{t}$ and Wt) production contribution to the background, events containing central b-tagged jets or forward jets are rejected. To suppress events from Z boson decays, events with invariant mass of the reconstructed SFOS pair within 10 GeV of the Z boson mass (91.2 GeV) are rejected in the same-flavor channel.

Two SRs, collectively referred to as SR2ℓ-1, are defined. Both are designed to provide sensitivity to $\tilde{\chi}_1^+\tilde{\chi}_1^-$ production with $\tilde{\ell}_L$-mediated decays and low $\tilde{\chi}_1^\pm$-$\tilde{\chi}_1^0$ mass splittings and rely on a high-p_{T} ISR jet to boost the leptons, which would otherwise have too low momentum to be reconstructed. The super-razor variables that are discussed in Sec. VI A are used to discriminate between signal and backgrounds. Both the same-flavor (SF) and different-flavor (DF) channels are used. The first SR, SR2ℓ-1a, requires $R_2 > 0.5(0.7)$ in the SF (DF) channel, whereas the second SR, SR2ℓ-1b, requires $R_2 > 0.65(0.75)$. Both SRs require $M_\Delta^R > 20$ GeV to reduce SM $Z+$jets background, and $\Delta\phi_R^\beta > 2(2.5)$ in the SF (DF) to further increase the signal sensitivity. Table VI summarizes the complete definitions of the SRs. SR2ℓ-1a provides sensitivity for moderate $\tilde{\chi}_1^\pm$-$\tilde{\chi}_1^0$ mass splittings from 50 GeV to 100 GeV, while SR2ℓ-1b provides sensitivity for $\tilde{\chi}_1^\pm$-$\tilde{\chi}_1^0$ mass splittings less than 50 GeV.

2. Background determination

The SM background is dominated by WW diboson and top-quark production. The MC predictions for these SM sources, in addition to contributions from ZV production, where $V = W$ or Z, are normalized in dedicated control regions for each background. The reducible background is estimated using the matrix method as described in Sec. VI B. Finally, contributions from remaining sources of SM background, which include Higgs boson production and $Z+$jets, are small and are estimated from simulation. These are collectively referred to as "Others."

TABLE VI. The selection requirements for the opposite-sign, two-lepton signal and control regions, targeting $\tilde{\chi}_1^+\tilde{\chi}_1^-$ production with small mass splittings between the $\tilde{\chi}_1^\pm$ and LSP.

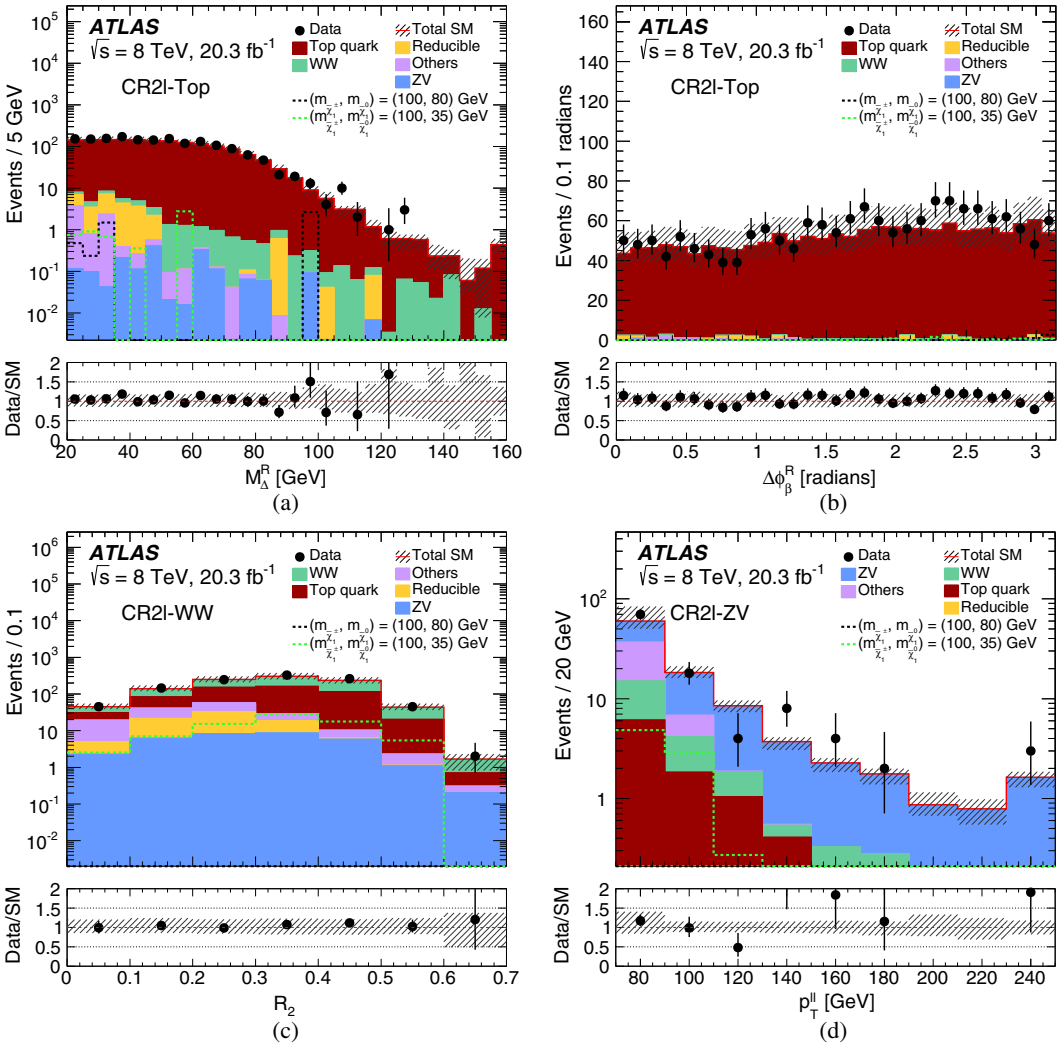

FIG. 5. Distributions in the opposite-sign, two-lepton control regions: (a) super-razor quantity M_{Δ}^{R} and (b) super-razor quantity $\Delta\phi_{R}^{\beta}$ in the top CR, (c) ratio R_2 in the WW CR, and (d) transverse momentum of the two-lepton system $p_{\mathrm{T}}^{\ell\ell}$ in the ZV CR. No data-driven normalization factors are applied to the distributions. The "Others" background category includes $Z+$jets and SM Higgs boson production. The hashed regions represent the total uncertainties on the background estimates. The rightmost bin of each plot includes overflow. The lower panel of each plot shows the ratio of data to the SM background prediction. SM background prediction. Predicted signal distributions in simplified models are also shown.

The top CR is defined using the DF sample in order to suppress events from SM Z boson production. Events are required to have exactly one central light-flavor jet with $p_{\mathrm{T}} > 80$ GeV, no forward jet, and $M_{\Delta}^{R} > 20$ GeV. At least one b-tagged jet is required to enrich the purity in top-quark production and ensure orthogonality to the SRs. Figures 5(a) and 5(b) show the M_{Δ}^{R} and $\Delta\phi_{R}^{\beta}$ distributions in this CR, respectively. The estimated signal contamination in this CR is less than 1% for the signal models considered.

The WW CR is also defined using the DF sample. Events are required to have exactly one central light jet, no forward jet or b-tagged jet, $p_{\mathrm{T}}^{\ell\ell} > 70$ GeV, and $M_{\Delta}^{R} > 20$ GeV. In order to ensure orthogonality to the SRs, $\Delta\phi_{R}^{\beta} < 2$ is required. Figure 5(c) shows the R_2 distribution in this CR. The estimated signal contamination in this CR is less than 20% for the signal models considered.

The ZV CR is defined by using the SF samples and by requiring exactly one central light jet, no forward jet, or b-tagged jet, $p_{\mathrm{T}}^{\ell\ell} > 70$ GeV, $\Delta\phi_{R}^{\beta} > 2$, and $M_{\Delta}^{R} > 20$ GeV. In order to increase the purity in ZV production, events with invariant mass of the reconstructed SFOS pair within 10 GeV of the Z boson mass are used. This requirement also ensures orthogonality to the SRs. Figure 5(d) shows the $p_{\mathrm{T}}^{\ell\ell}$ distribution in this CR. The estimated signal contamination in this CR is less than 10% for the signal models considered.

A simultaneous likelihood fit to the top, WW, and ZV CRs is performed to normalize the corresponding background estimates to obtain yields in the SR (as described

TABLE VII. Numbers of observed and predicted events in the opposite-sign, two-lepton control regions, data/MC normalization factors, and composition of the CRs obtained from the background-only fit. The "Others" background category includes $Z+$ jets and SM Higgs boson production. The $Z+$ jets production is the dominant contribution to this category in the CR2ℓ-ZV.

in Sec. VI). Table VI summarizes the definitions of the CRs, and Table VII summarizes the numbers of observed and predicted events in these CRs, data/MC normalizations, and CR compositions obtained from the simultaneous fit.

Systematic uncertainties affect the estimates of the backgrounds and signal event yields in the control and signal regions. A breakdown of the different sources of systematic uncertainty on the background estimate as described in Sec. VI C is shown in Table VIII. Generator modeling uncertainties are estimated by comparing the results from the POWHEG BOX and MC@NLO event generators for top-quark events, and POWHEG BOX and aMC@NLO for WW events, using HERWIG for parton showering in all cases. Parton showering uncertainties are estimated in top-quark and WW events by comparing POWHEG BOX+HERWIG with POWHEG BOX+PYTHIA. Both generator modeling and parton showering uncertainties are estimated for ZV events by comparing powheg box +pythia to sherpa. Top-quark samples are generated using

TABLE IX. Observed and expected number of events in the opposite-sign two-lepton signal regions. The "Others" background category includes $Z+$ jets and SM Higgs boson production. The numbers of signal events are shown for the $\tilde{\chi}_1^+\tilde{\chi}_1^-$ simplified models with $\tilde{\ell}_L$-mediated decays and different $\tilde{\chi}_1^{\pm}$ and $\tilde{\chi}_1^0$ masses in GeV. The uncertainties shown include both statistical and systematic components. Also shown are the model-independent limits calculated from the opposite-sign two-lepton signal region observations: the one-sided p_0 values; the expected and observed upper limits at 95% CL on the number of beyond-the-SM events ($S_{\rm exp}^{95}$ and $S_{\rm obs}^{95}$) for each signal region, calculated using pseudoexperiments and the CL_s prescription; the observed 95% CL upper limit on the signal cross section times efficiency ($\langle\epsilon\sigma\rangle_{\rm obs}^{95}$); and the CL_b value for the background-only hypothesis.

ACERMC+PYTHIA to evaluate the uncertainties related to the amount of initial- and final-state radiation [115]. The impact of the choice of renormalization and factorization scales is evaluated by varying these individually between 0.5 and 2 times the nominal values in POWHEG BOX for top-quark events and in aMC@NLO for diboson events. The dominant contributions among the "Theory and modeling" uncertainties come from the generator modeling and parton showering uncertainties.

3. Results

The observed number of events in each signal region is shown in Table IX along with the background expectations and uncertainties, p_0-values, $S_{\rm exp}^{95}$, $S_{\rm obs}^{95}$, $\langle\epsilon\sigma\rangle_{\rm obs}^{95}$, and the CL_b values. Figures 6(a)–6(d) show the distributions of the quantities R_2 and M_{Δ}^R in the SR2ℓ-1a and SR2ℓ-1b regions, respectively, prior to the requirements on these variables. For illustration, the distributions are also shown for two $\tilde{\chi}_1^+\tilde{\chi}_1^-$ simplified models with $\tilde{\ell}_L$-mediated decays and different mass splittings.

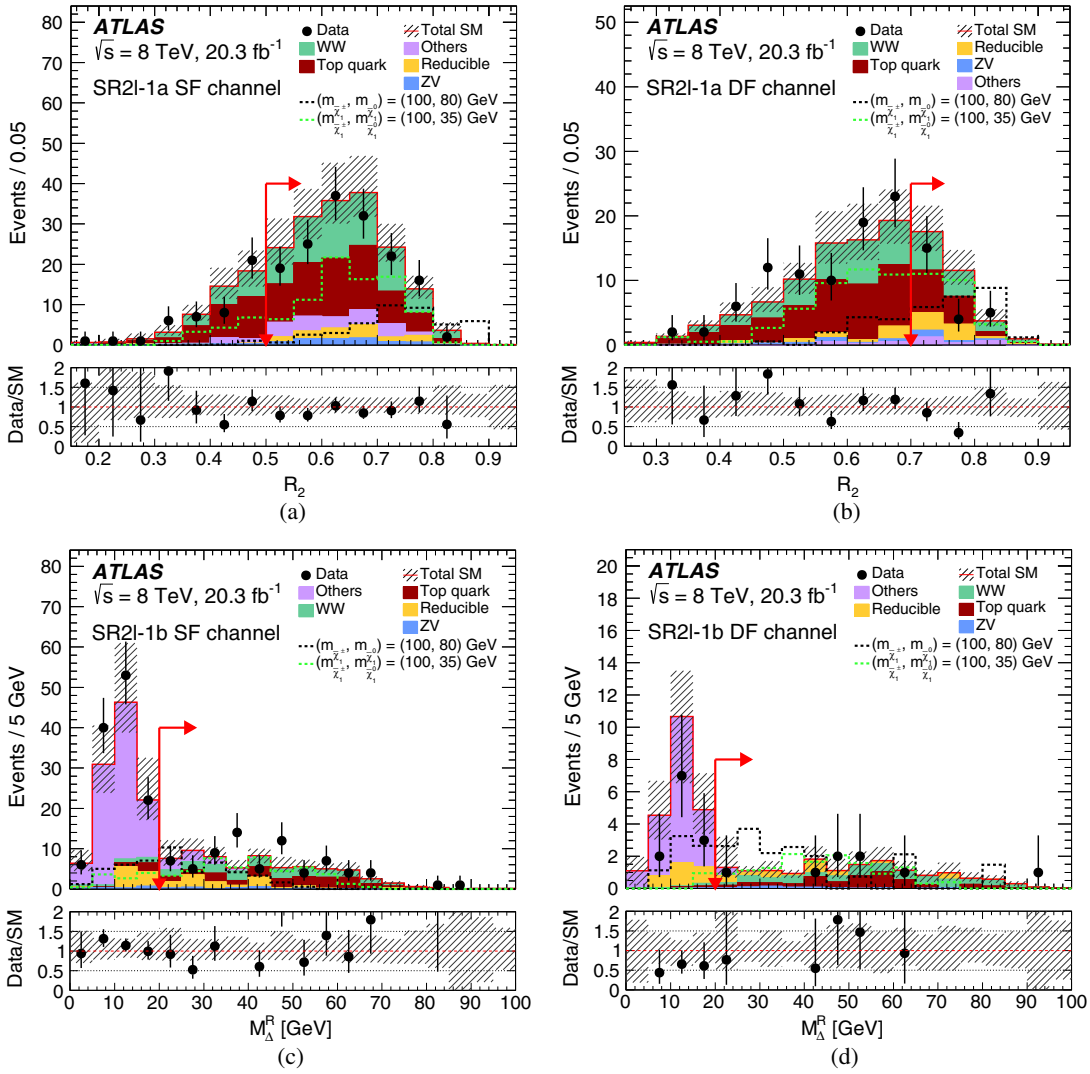

FIG. 6. Distributions of R_2 in the (a) same flavor and (b) different flavor channels in SR2ℓ-1a, and of M_Δ^R in the (c) same flavor and (d) different flavor channels in SR2ℓ-1b, prior to the requirements on these variables. The "Others" background category includes Z + jets and SM Higgs boson production. Arrows indicate the limits on the values of the variables used to define the signal regions. The lower panel of each plot shows the ratio of data to the SM background prediction. The uncertainty band includes both the statistical and systematic uncertainties on the SM prediction. The last bin in each distribution includes the overflow. Predicted signal distributions in simplified models are also shown.

B. Searches with two same-sign light leptons

In compressed mass scenarios, one or more of the three leptons from $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$ production may have momentum too low to be reconstructed. Therefore, the search for $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$ production using two same-sign leptons can complement the three-lepton search documented in Ref. [20] and extend the reach for small mass splittings. The search for same-sign lepton pairs is preferable to opposite-sign pairs, due to the comparatively small SM background. A multivariate analysis technique is used here to discriminate between signal and backgrounds.

1. Event selection

Events are selected using the basic reconstruction, object, and event selection criteria described in Sec. V. In addition, if tagged light leptons form an SFOS pair with $m_{\mathrm{SFOS}} < 12$ GeV, both leptons in the pair are rejected. Signal electrons with $p_{\mathrm{T}} < 60$ GeV have a tightened track (calorimeter) isolation of 7% (13%) of the electron p_{T} applied, whereas for electrons with $p_{\mathrm{T}} > 60$ GeV, a track isolation requirement of 4.2 GeV (7.8 GeV) is used. For signal muons, the track (calorimeter) isolation requirement is tightened to 6% (14%) of the muon p_{T} for $p_{\mathrm{T}} < 60$ GeV, and 4.2 GeV (8.4 GeV) otherwise. The stricter lepton isolation requirements are optimized to suppress the

TABLE X. Same-sign, two-lepton MVA signal region BDT requirements, targeting $\tilde{\chi}_1^{\pm}\tilde{\chi}_2^0$ production with small mass splittings between the $\tilde{\chi}_1^{\pm}/\tilde{\chi}_2^0$ and LSP. The selection on the BDT output, t_{cut}, is independent for each SR.

reducible SM backgrounds with semileptonically decaying b/c-hadrons, which are an important background in this search.

Events must have exactly two light leptons with the same charge, $e^{\pm}e^{\pm}$, $\mu^{\pm}\mu^{\pm}$, or $e^{\pm}\mu^{\pm}$, and satisfy the symmetric or asymmetric dilepton trigger criteria, as described in Sec. V. Eight BDTs are independently trained to define eight signal regions optimized for four mass splitting scenarios, $m(\tilde{\chi}_2^0) - m(\tilde{\chi}_1^0) = 20$, 35, 65, 100 GeV, referred to as ΔM20, ΔM35, ΔM65, and ΔM100, respectively, each with and without the presence of a central light jet with $p_{\mathrm{T}} > 20$ GeV, referred to as ISR and no-ISR. For the BDT training, signal scenarios of $\tilde{\chi}_1^{\pm}\tilde{\chi}_2^0$ production with $\tilde{\ell}_L$-mediated decays are used, where the slepton mass is set at 95% between the $\tilde{\chi}_1^{\pm}$ and the $\tilde{\chi}_1^0$ masses. Seven variables are considered as input for the BDT training procedure: m_{T2}, $p_{\mathrm{T}}{}^{\ell\ell}$, $E_{\mathrm{T}}^{\mathrm{miss,rel}}$, H_{T}, $m_{\mathrm{T}}^{\mathrm{lep1}}$, $m_{\mathrm{T}}^{\mathrm{lep2}}$, and $\Delta\phi(\ell,\ell)$. Three further variables are also considered for the ISR signal regions: $\Delta\phi(,\mathrm{jet1})$ and the ratios $E_{\mathrm{T}}^{\mathrm{miss,rel}}/p_{\mathrm{T}}{}^{\mathrm{jet1}}$ and $p_{\mathrm{T}}{}^{\mathrm{lep1}}/p_{\mathrm{T}}{}^{\mathrm{jet1}}$. These variables exploit the kinematic properties of a compressed mass SUSY system, with and without a high-p_{T} ISR jet. The MC simulation samples are compared to data for these variables and their correlations to ensure that they are modeled well.

For the training and testing of the BDT, the signal and background samples are split into two halves, including those backgrounds estimated from data as described in Sec. VIII B 2. The eight signal region definitions are shown in Table X. Since the selection on the BDT output, t_{cut}, is independent for each SR, the overlap between SRs with looser and tighter selections is small.

2. Background determination

Several SM processes produce events with two same-sign signal leptons. The SM background processes are classified as irreducible background if they lead to events with two real, prompt, same-sign leptons, reducible background if the event has at least one fake or nonprompt lepton, or "charge flip" if the event has one lepton with mismeasured charge.

Irreducible processes include diboson ($W^{\pm}W^{\pm}$, WZ, ZZ), triboson (VVV), $t\bar{t}V$, tZ, and Higgs boson production and are determined using the corresponding MC samples. The reducible $W\gamma$ process is estimated with MC simulation samples; other reducible processes are estimated with the matrix method, similar to that described in Sec. VI B.

In this implementation of the matrix method, the fake and nonprompt lepton misidentification probabilities are measured in control regions that are kinematically close and similar in composition to the signal regions. The regions where the misidentification probabilities are measured are required to have large H_{T} ($H_{\mathrm{T}} > 50$ GeV) and large transverse mass using the leading lepton ($m_{\mathrm{T}} > 50$ GeV). The contamination from signal events in these measurement regions is $< 1\%$. The charge-flip, irreducible, and $W\gamma$ backgrounds are subtracted from the control regions before calculating lepton misidentification probabilities.

Charge-flip processes include sources of opposite-sign prompt leptons for which the charge of one lepton is mismeasured (Z, $t\bar{t}$, W^+W^-). In the relevant momentum range the muon charge-flip background is found to be negligible. Control samples of e^+e^- and $e^{\pm}e^{\pm}$ with invariant mass near the Z boson mass

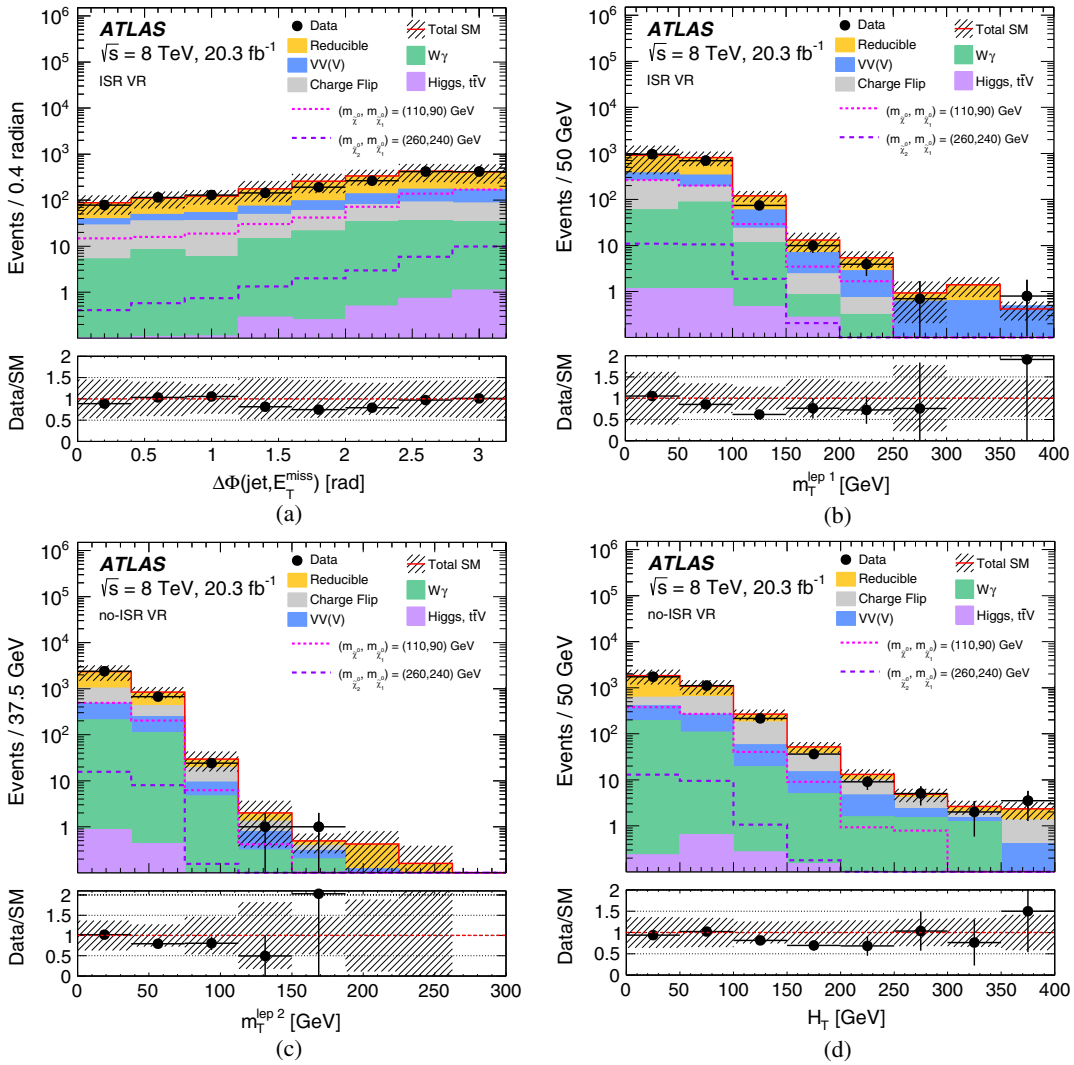

FIG. 7. For events in a selection of the same-sign, two-lepton MVA validation regions: (a) separation in ϕ between the leading jet and the $E_{\mathrm{T}}^{\mathrm{miss}}$, $\Delta\phi(\mathrm{jet}, E_{\mathrm{T}}^{\mathrm{miss}})$ and (b) transverse mass using the leading lepton $m_{\mathrm{T}}^{\mathrm{lep1}}$ in the ISR VR, (c) transverse mass using the second leading lepton $m_{\mathrm{T}}^{\mathrm{lep2}}$ and (d) scalar sum H_{T} of the p_{T} of the leptons and jets in the non-ISR VR. The lower panel of each plot shows the ratio of data to the SM background prediction. The uncertainty band includes both the statistical and systematic uncertainties on the SM prediction.

($75 < m_{\ell\ell} < 100$ GeV) are used to extract the electron charge-flip rate. A small background due to misidentified jets is subtracted by interpolating the mass sidebands and subtracting them from the observed data events. A likelihood fit is used that takes the numbers of e^+e^- and $e^\pm e^\pm$ pairs observed in the charge-flip control regions as input. The charge-flip probability is a free parameter of the fit and is extracted as a function of the electron p_{T} and η. The charge-flip background event yield is found by applying the charge-flip probability to control regions in data with the same kinematic requirements as the signal and validation regions, but with opposite-sign light lepton pairs. The contamination from fake and nonprompt leptons, and from signal events, is negligible in the e^+e^- and $e^\pm e^\pm$ control regions.

Generator modeling uncertainties for the diboson processes are estimated by comparing the results from the POWHEG BOX and MC@NLO event generators, while parton showering uncertainties are estimated by comparing MC@NLO+HERWIG with MC@NLO+PYTHIA. The impact of the choice of renormalization and factorization scales is evaluated by varying these individually between 0.5 and 2 times the nominal values in aMC@NLO for diboson events.

To test the background prediction methods, two validation regions with looser selection on the BDT output than the SRs are defined; the definitions are shown in Table X. The light-lepton flavor content (ee, $\mu\mu$, or $e\mu$) is checked separately in each validation region. Table XI and Figures 7(a)–7(d) show the agreement between data and expectation in the validation regions.

TABLE XII. The model-independent limits calculated from the same-sign two-lepton MVA signal region observations: the observed 95% CL upper limit on the signal cross section times efficiency ($\langle\epsilon\sigma\rangle^{95}_{\rm obs}$); the expected and observed upper limits at 95% CL on the number of beyond-the-SM events ($S^{95}_{\rm exp}$ and $S^{95}_{\rm obs}$) for each signal region, calculated using pseudoexperiments and the CL_s prescription; the CL_b value for the background-only hypothesis; and the one-sided p_0 values.

3. Results

The observed number of events in each signal region is shown in Table XII along with the background expectation and uncertainties, p_0-values, $S^{95}_{\rm exp}$, $S^{95}_{\rm obs}$, $\langle\epsilon\sigma\rangle^{95}_{\rm obs}$, and the CL_b values. No significant excess with respect to the SM expectation is observed. The sizes and sources of uncertainty on the background estimation in the signal regions are shown in Table XIII, where the dominant sources of uncertainty are the statistical uncertainty on the reducible background estimation,

C. Searches with three light leptons

Previous searches for $\tilde{\chi}_1^{\pm}\tilde{\chi}_2^0$ production using the three-lepton final state are extended here to increase the sensitivity to compressed SUSY scenarios. The three-lepton analysis presented here probes $\tilde{\chi}_2^0$-$\tilde{\chi}_1^0$ mass splittings below 25 GeV using low-p_{T} leptons and ISR jets.

1. Event selection

Events are selected as described in Sec. V. In addition, signal muons with $p_{\mathrm{T}} < 15$ GeV have tightened track and calorimeter isolation requirements of 7% of the muon p_{T}. The stricter muon isolation requirements suppress SM backgrounds with semileptonically decaying b/c-hadrons, which are larger for muons rather than electrons due to the lower muon-p_{T} threshold. Events must satisfy a single-lepton, dilepton, or trilepton trigger.

Four signal regions are defined with exactly three light leptons, all with $p_{\mathrm{T}} < 30$ GeV, and at least one SFOS pair present among the leptons. All signal regions veto events with b-tagged jets to reduce the $t\bar{t}$ SM background and events with $8.4 < m_{\mathrm{SFOS}} < 10.4$ GeV to suppress backgrounds with leptonic Υ decays. The three-lepton signal region selections are summarized in Table XIV.

The first two signal regions, SR3ℓ-0a and SR3ℓ-0b, closely follow the selection in Ref. [20], using $E_{\mathrm{T}}^{\mathrm{miss}}$, m_{T}, and m_{SFOS} selections. SR3ℓ-0a and SR3ℓ-0b are defined with $E_{\mathrm{T}}^{\mathrm{miss}} > 50$ GeV and $30 < m_{\ell\ell\ell} < 60$ GeV to reject diboson processes. Events with a jet with $p_{\mathrm{T}} > 50$ GeV are vetoed to be disjoint from the ISR signal region. The first signal region, SR3ℓ-0a, targets the smallest $\tilde{\chi}_2^0$-$\tilde{\chi}_1^0$ mass splittings by selecting events with $m_{\mathrm{SFOS}}^{\mathrm{min}}$ between 4 and 15 GeV. In addition, SR3ℓ-0a requires small m_{T} to reduce the WZ SM background. The second signal region, SR3ℓ-0b, targets the slightly larger $\tilde{\chi}_2^0$-$\tilde{\chi}_1^0$ mass splittings by selecting events with $m_{\mathrm{SFOS}}^{\mathrm{min}}$ between 15 and 25 GeV.

The third and fourth signal regions, SR3ℓ-1a and SR3ℓ-1b, both require the presence of a $p_{\mathrm{T}} > 50$ GeV jet to target signal production with ISR. The leptons from a

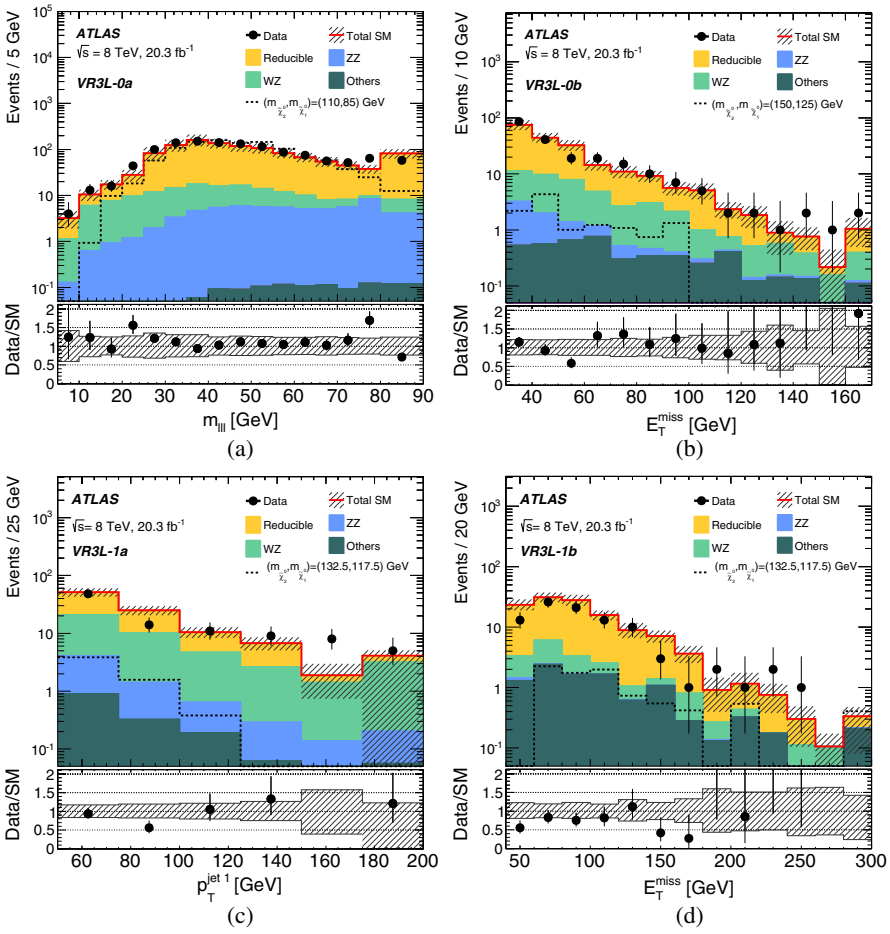

FIG. 8. Distributions in the three-lepton validation regions: (a) three-lepton invariant mass $m_{\ell\ell\ell}$ in VR3ℓ-0a, (b) $E_{\mathrm{T}}^{\mathrm{miss}}$ in VR3ℓ-0a, (c) transverse momentum of the leading jet $p_{\mathrm{T}}^{\mathrm{jet1}}$ in VR3ℓ-1a, and (d) $E_{\mathrm{T}}^{\mathrm{miss}}$ in VR3ℓ-1a. The "Others" background category includes $t\bar{t}V + tZ$, VVV, and SM Higgs boson production. The lower panel of each plot shows the ratio of data to the SM background prediction. The uncertainty band includes both the statistical and systematic uncertainties on the SM prediction. The last bin in each distribution includes the overflow.

compressed SUSY decay chain would have too low p_{T} to be reconstructed; however, because of the recoil against the high-p_{T} ISR jet, all three leptons can be boosted enough to meet the selection requirements. The third signal region, SR3ℓ-1a, targets the smallest $\tilde{\chi}_2^0$-$\tilde{\chi}_1^0$ mass splittings and selects events with $5 < m_{\mathrm{SFOS}}^{\mathrm{min}} < 15$ GeV. Here the leading jet is required to be back-to-back in the transverse plane with the $E_{\mathrm{T}}^{\mathrm{miss}}$, $\Delta\phi(E_{\mathrm{T}}^{\mathrm{miss}}, \mathrm{jet1}) > 2.7$ rad, and the ratio of leading lepton p_{T} to the jet p_{T} is required to be small, $p_{\mathrm{T}}^{\mathrm{lep1}}/p_{\mathrm{T}}^{\mathrm{jet1}} < 0.2$, to suppress the diboson and $t\bar{t}$ backgrounds. The fourth signal region, SR3ℓ-1b, targets the slightly larger $\tilde{\chi}_2^0$-$\tilde{\chi}_1^0$ mass splittings by selecting events with $15 < m_{\mathrm{SFOS}}^{\mathrm{min}} < 25$ GeV. To suppress the WZ and $t\bar{t}$ backgrounds in SR3ℓ-1b, the angle between the $E_{\mathrm{T}}^{\mathrm{miss}}$ and the three-lepton system is required to be large, $\Delta\phi(E_{\mathrm{T}}^{\mathrm{miss}}, 3\ell) > 0.7\pi$ rad.

2. Background determination

Several SM processes produce events with three signal leptons. The SM background processes are classified as irreducible background if they lead to events with three or more real leptons, or as reducible background if the event has at least one fake or nonprompt lepton. The predictions for irreducible and reducible backgrounds are tested in validation regions. For this search, irreducible processes include diboson (WZ and ZZ), VVV, $t\bar{t}V$, tZ, and Higgs boson production and are determined from MC simulation samples.

Reducible processes include single and pair production of top quarks, WW production, and a single W or Z boson produced in association with jets or photons. The dominant reducible background component is $t\bar{t}$, followed by Z + jets. The reducible background is estimated using the matrix method, similar to that described in Sec. VI B. In this implementation of the matrix method, the highest-p_{T} signal electron or muon is taken to be real, and only the second and third leptons are used in the matrix method. Simulation studies show that neglecting the case that the leading lepton is nonprompt or fake is valid in more than 95% of the events.

TABLE XVII. Expected and observed yields in the three-lepton signal regions. The uncertainties shown include both statistical and systematic components. The "Others" background category includes $t\bar{t}V$, VVV, and SM Higgs boson production. Also shown are the model-independent limits calculated from the three-lepton signal region observations: the one-sided p_0-values; the expected and observed upper limits at 95% CL on the number of beyond-the-SM events (S^{95}_{exp} and S^{95}_{obs}) for each signal region, calculated using pseudoexperiments and the CL_s prescription; the observed 95% CL upper limit on the signal cross section times efficiency ($\langle\epsilon\sigma\rangle^{95}_{\mathrm{obs}}$); and the CL_b value for the background-only hypothesis.

CL_b	0.59	0.50	0.69	0.54

The uncertainty on the reducible background includes the MC statistical uncertainty on the weights for the process-dependent misidentification probabilities, the uncertainty on the correction factors for the misidentification probability, the statistical uncertainty on the data events to which the matrix equation is applied, and the statistical uncertainty from the misidentification probability measured in simulation.

The systematic uncertainty related to the theoretical modeling of the WZ and ZZ backgrounds is assessed by comparing MC estimates with data in dedicated regions. The WZ region requires three light leptons with $p_{\mathrm{T}} > 30$ GeV, an SFOS pair among the three leptons, $30 < E^{\mathrm{miss}}_{\mathrm{T}} < 50$ GeV, and one jet with $p_{\mathrm{T}} > 50$ GeV. Events with an SFOS pair or three-lepton invariant mass within 10 GeV of the Z boson mass are vetoed. The ZZ region is defined with four light leptons with $p_{\mathrm{T}} > 10$ GeV, two SFOS pairs with invariant mass within 10 GeV of the Z boson mass, and $E^{\mathrm{miss}}_{\mathrm{T}} < 50$ GeV. This approach for estimating the systematic uncertainties is used here instead of the MC-based approach discussed in Sec. VI C. The WZ and ZZ MC simulation samples are both found to agree with observations in the dedicated regions within 15%, which is applied as a systematic uncertainty in the three-lepton validation and signal regions.

The background predictions are tested in validation regions that are defined to be adjacent to, yet disjoint from, the signal regions. Low-$E^{\mathrm{miss}}_{\mathrm{T}}$ validation regions ("a" regions) and high-$E^{\mathrm{miss}}_{\mathrm{T}}$ + b-jet validation regions ("b" regions) are defined to target different background processes. The definition of the regions and the targeted processes are shown in Table XV. In the three-lepton validation regions, the observed data counts and SM expectations are in good agreement within statistical and systematic uncertainties, as shown in Table XVI and Figs. 8(a)–8(d).

TABLE XVIII. Breakdown of the dominant systematic uncertainties on background estimates in the three-lepton signal regions. The percentages show the size of the uncertainty relative to the total expected background.

Source of uncertainty	SR3ℓ-0a	SR3ℓ-0b	SR3ℓ-1a	SR3ℓ-1b

3. Results

The observed number of events in each signal region is shown in Table XVII along with the background expectations and uncertainties, p_0-values, S_{exp}^{95}, S_{obs}^{95}, $\langle\epsilon\sigma\rangle_{\mathrm{obs}}^{95}$, and the CL_b values. The sizes and sources of uncertainty on the background estimation in the three-lepton signal regions are shown in Table XVIII, where the dominant sources of uncertainty are the statistical uncertainty on the data for the reducible background estimate, and the uncertainty on the electron and muon misidentification probabilities. Figures 9(a), 9(b), 9(c), and 9(d) show the distributions of the quantities $E_{\mathrm{T}}^{\mathrm{miss}}$, $m_{\ell\ell\ell}$, $\Delta\phi(E_{\mathrm{T}}^{\mathrm{miss}},\mathrm{jet1})$, and $p_{\mathrm{T}}^{\mathrm{jet1}}$ in SR3ℓ-0a, SR3ℓ-0b, SR3ℓ-1a, and SR3ℓ-1b regions, respectively, prior to the requirements on these variables. For illustration, the distributions are also shown for a $\tilde{\chi}_1^{\pm}\tilde{\chi}_2^0$ scenario with $\tilde{\ell}_L$-mediated decays, where the slepton mass is set halfway between the $\tilde{\chi}_1^{\pm}$ and the $\tilde{\chi}_1^0$ masses.

IX. SAME-SIGN CHARGINO-PAIR PRODUCTION VIA VECTOR-BOSON FUSION

This section presents a search for the same-sign chargino-pair production via VBF with subsequent $\tilde{\ell}_L$-mediated chargino decays into final states with two same-sign light leptons, at least two jets, and $E_{\mathrm{T}}^{\mathrm{miss}}$. Although the cross section for VBF production is significantly lower than that for direct production, the two additional jets in the event provide a means to separate the signal from the background for compressed spectra scenarios and complement the direct production searches that use low-momentum leptons and ISR jets.

A. Event selection

Events are selected using the basic reconstruction, object, and event selection criteria described in Sec. V. In addition, signal muons with $p_{\mathrm{T}} < 15$ GeV have tightened isolation requirements as in the three-lepton analysis described in Sec. VIII C. A tighter isolation is needed for muons rather than electrons due to the lower p_{T} threshold for muons. The stringent lepton isolation suppresses the dominant reducible background processes. Events are required to satisfy an $E_{\mathrm{T}}^{\mathrm{miss}}$ trigger.

One signal region, SR2ℓ-2, is defined with exactly two same-sign light leptons, at least two jets (central light or forward) and large missing transverse momentum $E_{\mathrm{T}}^{\mathrm{miss}} > 120$ GeV. In order to select events that originate from VBF production, the highest-p_{T} jet (jet 1) and the second highest-p_{T} jet (jet 2) are required to have large invariant mass, $m_{jj} > 350$ GeV, to be well separated in pseudorapidity, $|\Delta\eta_{jj}| > 1.6$, and to be in opposite sides of the detector, $\eta^{\mathrm{jet1}} \cdot \eta^{\mathrm{jet2}} < 0$. The last requirement greatly reduces the SM background originating from non-VBF diboson and Higgs boson production. The residual SM background originating from diboson and top-quark production is minimized by requiring the events to have no b-tagged jets, moderate invariant mass of the two leptons ($m_{\ell\ell} < 100$ GeV), small stransverse mass ($m_{\mathrm{T2}} < 40$ GeV), and a high-p_{T} jet ($p_{\mathrm{T}}^{\mathrm{jet1}} > 95$ GeV). In addition, requirements are made on the ratios of the jet p_{T}, $E_{\mathrm{T}}^{\mathrm{miss}}$, p_{T}^{jj}, and $p_{\mathrm{T}}^{\ell\ell}$. The SR definition is summarized in Table XIX.

B. Background determination

Several SM processes lead to events with two same-sign signal leptons. The irreducible background is dominated by diboson production, which is estimated using MC simulation samples. The dominant reducible background component is from $W+$jets production, followed by $t\bar{t}$ production, and these are estimated using a data-driven technique called the "fake factor method," similar to that described in Ref. [116]. The production of $W\gamma$ is also an important background component and is modeled using MC simulation samples. The charge-flip background is estimated by applying data-driven corrections to the MC simulation samples, following the procedure outlined in Sec. VIII B 2.

The fake factor method estimates the contributions from processes that produce one or two fake or nonprompt

The uncertainty band includes both the statistical and the systematic uncertainties on the SM prediction. The last bin in each distribution includes the overflow.

leptons using data events that contain one signal lepton and one lepton failing to satisfy the signal lepton requirements. These events are scaled by a "fake factor" to predict the reducible background in the signal region. The fake factor is defined as the ratio of events with two signal leptons to events with one signal lepton and one lepton failing the signal lepton requirements. It is measured in data using a control sample of jets faking leptons in $Z \to \ell\ell$ events. The SM background process dependence of the fake factor is studied using simulation, and no strong dependence is observed. Residual differences are covered by assigning a 30% uncertainty, independent of the lepton p_{T}, to the fake factor. The uncertainty on the reducible background estimate ranges from 37% to 42%, depending on the channel (ee, $\mu\mu$, or $e\mu$), and is dominated by the prompt lepton contamination in the control sample and the uncertainty on the extrapolation of fake factors into the signal region.

The contributions from diboson processes are estimated using MC simulation samples. SHERPA is used to produce all diboson samples, taking into account both the strong and the electroweak production of associated jets. The $W^{\pm}W^{\pm} + 2$jets and $WZ + 2$jets processes are normalized to NLO cross sections using corrections evaluated in dedicated VBF fiducial regions at the parton level. The corrections are calculated separately for strong and electroweak jet production. For the $W^{\pm}W^{\pm} + 2$jets production, the fiducial cross section is calculated using POWHEG BOX +PYTHIA [62,63,117], and the fiducial region is defined to be identical to the signal region at the parton level, except for the lepton isolation requirement. For the $WZ + 2$jets production, the fiducial cross sections are calculated using VBFNLO-2.7.0 [118]. Since it is not possible to define a fiducial region that is identical to the signal region using VBFNLO-2.7.0, a looser set of requirements is imposed.

TABLE XXII. The dominant systematic uncertainties on the background estimates for the same-sign, two-lepton VBF signal region. The percentages show the size of the uncertainty relative to the total expected background. Because of correlations between the systematic uncertainties, the total uncertainty is different from the sum in quadrature of the individual uncertainties.

Source of uncertainty	SR2ℓ-2
Fake factor closure test	13%
Statistical uncertainty on the reducible background	11%
$WZ + 2$jets scale and PDF	5%
Statistical uncertainty on $WZ + 2$jets	4%
Statistical uncertainty on the electron fake factor	3%
Jet energy resolution	3%
Statistical uncertainty on $W^{\pm}W^{\pm} + 2$jets	3%
$W^{\pm}W^{\pm} + 2$jets scale and PDF	1%
Total	21%

The generator modeling uncertainty is estimated by comparing POWHEG BOX+PYTHIA with VBFNLO-2.7.0 for $W^{\pm}W^{\pm}$+2jets production, and parton showering uncertainties are estimated by comparing POWHEG BOX+HERWIG with POWHEG BOX+PYTHIA. The impact of the choice of renormalization and factorization scales is evaluated by varying each between 0.5 and 2 times the nominal values. The uncertainties due to the PDFs are evaluated using 90% CL CT10 PDF eigenvectors. Finally, the interference between the strong and electroweak jet production is studied at LO accuracy using SHERPA and is found to have a negligible effect on the combined fiducial cross section in the signal region.

The background predictions are tested in VRs that are defined to be as kinematically close to the SR as possible. The first VR, VR-Fakes, is defined with two signal light

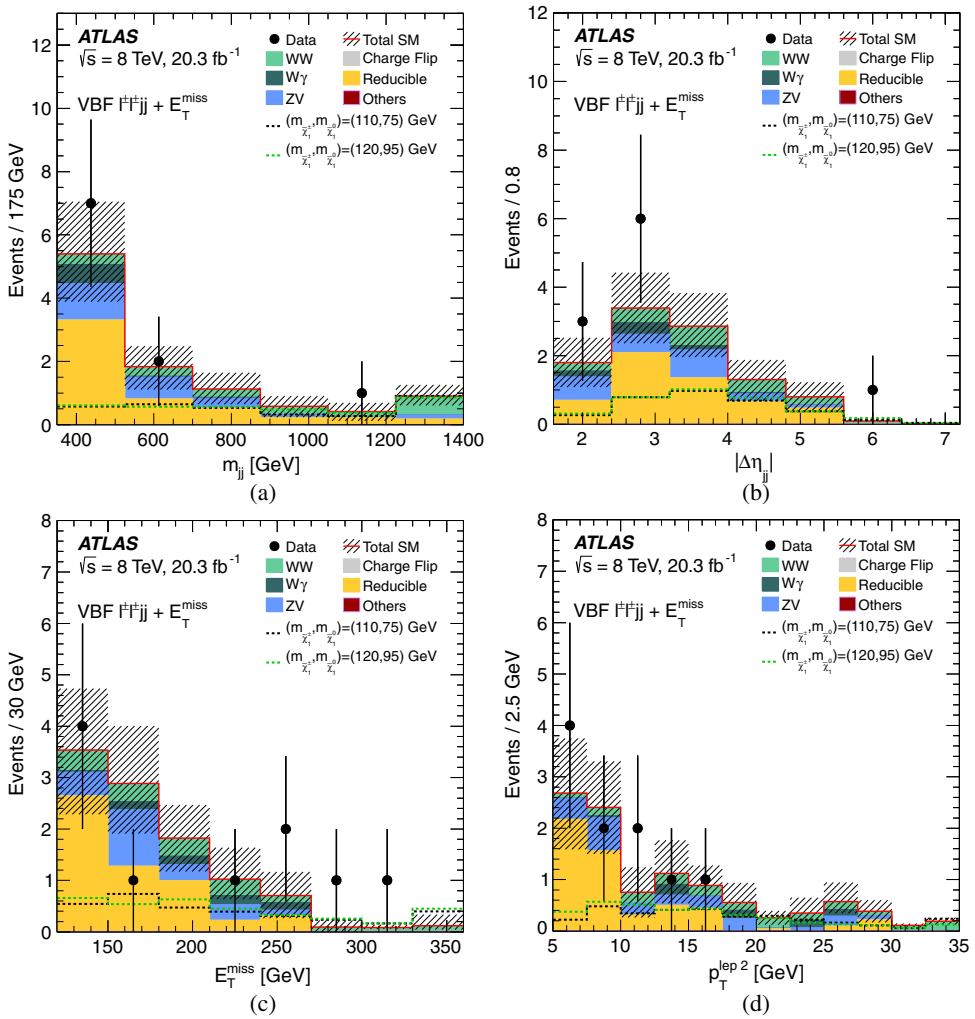

FIG. 11. For events in the same-sign VBF signal region, the (a) m_{jj}, (b) separation in η between the two leading jets $|\Delta\eta_{jj}|$, (c) $E_{\mathrm{T}}^{\mathrm{miss}}$, and (d) $p_{\mathrm{T}}{}^{\ell 2}$ in SR2ℓ-2. The "Others" background category includes $t\bar{t}V + tZ$, VVV, and SM Higgs boson production. The uncertainty band includes both the statistical and systematic uncertainties on the SM prediction. The last bin in each distribution includes the overflow.

leptons, large $E_{\mathrm{T}}^{\mathrm{miss}}$, and at least two jets to test backgrounds with fake and nonprompt leptons modeled by the fake factor method. The second VR, VR-VV, adopts the same requirements as the VR-Fakes, in addition to higher lepton-p_{T} thresholds and a b-jet veto that allow it to test the MC modeling of the diboson background. By definition, the VRs are not disjoint from the SR, but have negligible overlaps. The overlap between the VR-Fakes (VR-VV) and the SR is 2.4% (0.2%), and the largest signal contamination is 1.9% (0.9%) of the total expected background in the VR-Fakes (VR-VV). The definitions of the validation regions are shown in Table XX, along with the targeted processes. The yields in the VRs are shown in Table XXI, where the background expectation is in good agreement with the observed data, within the total uncertainties. Figures 10(a), 10(b), 10(c), and 10(d) show the distributions of $p_{\mathrm{T}}^{\mathrm{lep2}}$ and m_{jj} in VR-VV, along with $p_{\mathrm{T}}^{\mathrm{lep2}}$ and $E_{\mathrm{T}}^{\mathrm{miss}}$ in VR-Fakes, with good agreement observed.

C. Results

The observed number of events in the signal region is shown in Table XXI along with the background expectation and uncertainties, p_0-value, S_{exp}^{95}, S_{obs}^{95}, $\langle\epsilon\sigma\rangle_{\mathrm{obs}}^{95}$, and the CL_b value. No significant excess with respect to the SM expectation is observed. A breakdown of the different sources of systematic uncertainty in the signal region, including those described in Sec. VI C, is shown in Table XXII. Figures 11(a)–11(d) show the distributions of the quantities m_{jj}, $|\Delta\eta_{jj}|$, $E_{\mathrm{T}}^{\mathrm{miss}}$, and $p_{\mathrm{T}}^{\mathrm{lep2}}$ in the signal region.

X. INTERPRETATION OF RESULTS

Previous ATLAS searches for EW SUSY production [19–23] are combined with the new analyses presented in Secs. VII–IX. The combined results are interpreted in the SUSY models discussed in Sec. II. The analyses combined for each SUSY model are shown in Table XXIII. Limits in the simplified models targeted by the analysis presented in the previous sections are presented in Secs. X A–X D. A summary is provided in Sec. X E, including the limits previously obtained from the ATLAS searches for $\tilde{\chi}_1^+\tilde{\chi}_1^-$ production with WW-mediated decays [19], $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$ production with WZ-mediated decays [20], and $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$ production with Wh-mediated decays [23]. Finally, limits on phenomenological models are presented in Secs. X F–X H. For these models, the new searches presented in this article are not included, since they target very specific areas of parameter space and their sensitivity is small.

Exclusion limits are calculated by statistically combining results from a number of disjoint signal regions. In general, the analyses in Table XXIII are mutually exclusive by design (the exceptions are indicated in the table), using the lepton multiplicity and charge, and are statistically combined. Where overlapping signal regions exist within an analysis, the signal region with the best-expected exclusion is used. During the combinations, all experimental uncertainties are treated as correlated between regions and processes, with the exception of the experimental uncertainties on data-driven backgrounds, which are correlated between regions only. Theoretical uncertainties on the irreducible background and signal are treated as correlated between regions, while statistical uncertainties are treated as

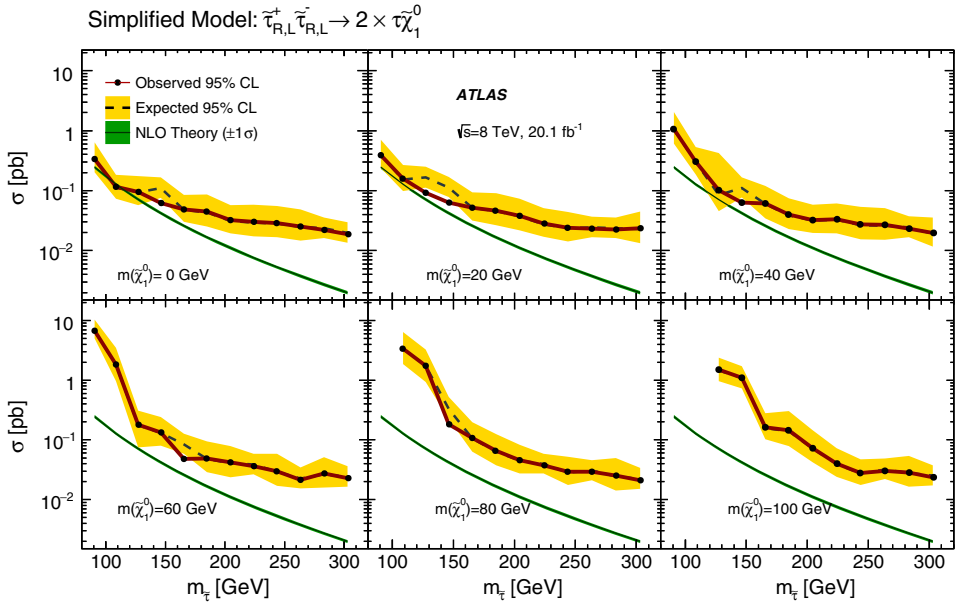

FIG. 12. The 95% CL exclusion limits on the cross section for production of left- and right-handed stau pairs for various $\tilde{\chi}^{0}_{1}$ masses. The NLO theoretical cross section for left- and right-handed stau pair production is also shown.

uncorrelated between regions and processes. For the exclusion limits, the observed and expected 95% CL limits are calculated using asymptotic formulas for each SUSY model point, taking into account the theoretical and experimental uncertainties on the SM background and the experimental uncertainties on the signal. Where the three-lepton [20] analysis is used in the combination, 95% CL limits are calculated using pseudoexperiments as the asymptotic approximation becomes inappropriate where the expected and observed yields are close to zero. The impact of the theoretical uncertainties on the signal cross section is shown for the observed mass limit; where quoted in the text, mass limits refer to the -1σ variation on the observed limit.

A. Direct stau production

The combination of the two-tau MVA results in Sec. VII with the simple cut-based analysis from Ref. [22] is used to set limits on the direct production of stau pairs. For each

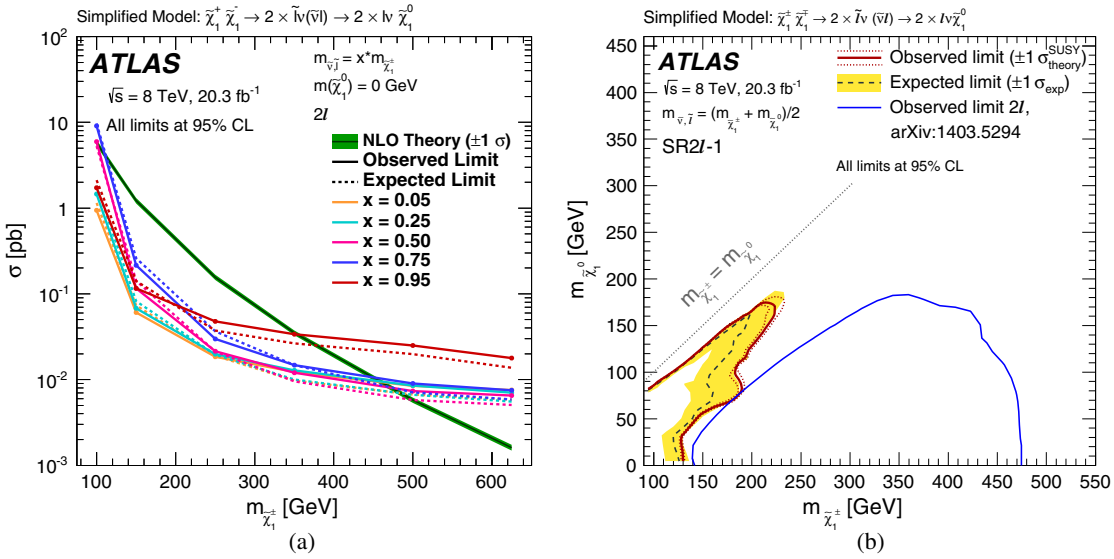

FIG. 13. The 95% CL exclusion limits on $\tilde{\chi}^{+}_{1}\tilde{\chi}^{-}_{1}$ production with $\tilde{\ell}_{L}$-mediated decays, (a) where the $\tilde{\chi}^{0}_{1}$ is massless and the intermediate slepton mass is set to 5%, 25%, 50%, 75%, and 95% of the $\tilde{\chi}^{\pm}_{1}$ mass, and (b) as a function of the $\tilde{\chi}^{\pm}_{1}$ and $\tilde{\chi}^{0}_{1}$ masses, where the slepton mass is halfway between the $\tilde{\chi}^{0}_{2}$ and $\tilde{\chi}^{0}_{1}$ masses. The limits in (a) are set using the 2ℓ analysis from Ref. [19], while the limits in (b) use the opposite-sign, two-lepton analysis from this article. The limit from Ref. [19] is also shown in (b).

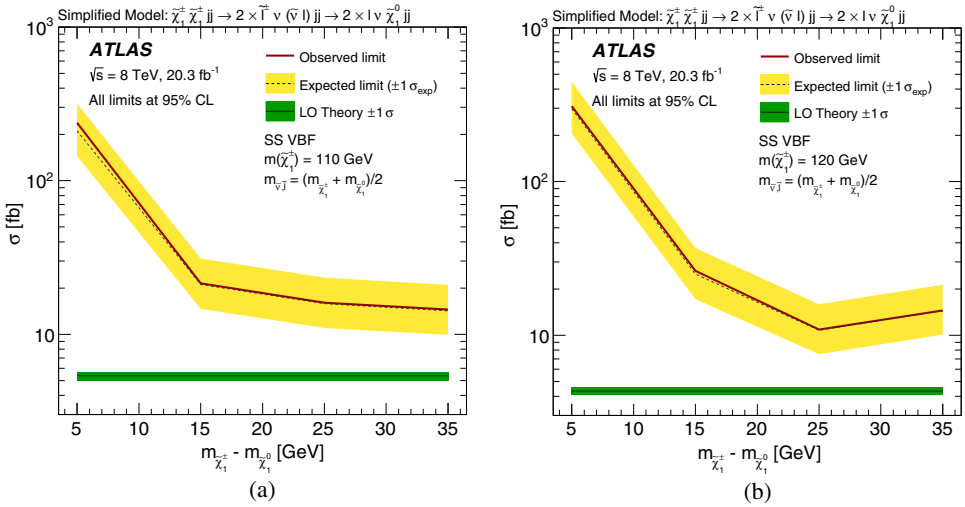

FIG. 14. The 95% CL upper limit on the signal cross section for VBF $\tilde{\chi}_1^\pm\tilde{\chi}_1^\pm$ production for (a) $m(\tilde{\chi}_1^\pm) = 110$ GeV and (b) $m(\tilde{\chi}_1^\pm) = 120$ GeV. The limits are set with respect to the mass difference between the $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_1^0$, and use the results from the same-sign, two-lepton VBF analysis.

signal point, the signal region with the best expected limit is used. The upper limits on the cross section for direct stau production are shown in Fig. 12 for combined $\tilde{\tau}_L\tilde{\tau}_L$ and $\tilde{\tau}_R\tilde{\tau}_R$ production, where the observed limit is nearly always above the theoretical prediction. One scenario of combined $\tilde{\tau}_L\tilde{\tau}_L$ and $\tilde{\tau}_R\tilde{\tau}_R$ production is excluded, where the $\tilde{\tau}_R$ mass is 109 GeV and the $\tilde{\chi}_1^0$ is massless. For this scenario, cross sections above 0.115 pb are excluded, where the theoretical cross section at NLO is 0.128 pb. No scenarios can be excluded where only $\tilde{\tau}_R\tilde{\tau}_R$ production or $\tilde{\tau}_L\tilde{\tau}_L$ production is considered. Cross sections above 0.06 (0.21) pb are excluded for $\tilde{\tau}_R\tilde{\tau}_R$ ($\tilde{\tau}_L\tilde{\tau}_L$) production with a $\tilde{\tau}_R$ ($\tilde{\tau}_L$) mass of 109 GeV and a massless $\tilde{\chi}_1^0$, where the theoretical cross section at NLO is 0.04 (0.09) pb. For this scenario [$m(\tilde{\tau}_R) = 109$ GeV, $m(\tilde{\chi}_1^0) = 0$ GeV], the expected yields from $\tilde{\tau}_R\tilde{\tau}_R$ production are larger than from $\tilde{\tau}_L\tilde{\tau}_L$ in the signal region, making the experimental limits stronger for $\tilde{\tau}_R\tilde{\tau}_R$ production. However, for other mass points the experimental limit is generally weaker for $\tilde{\tau}_R\tilde{\tau}_R$ production due to

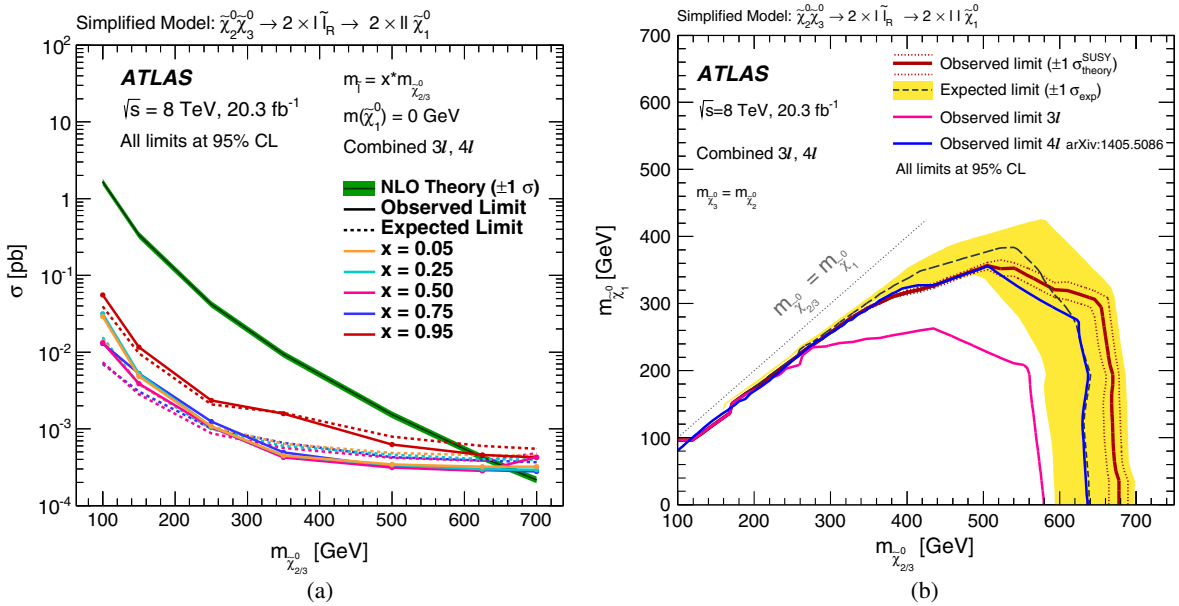

FIG. 15. The 95% CL exclusion limits on $\tilde{\chi}_2^0\tilde{\chi}_3^0$ production with $\tilde{\ell}_R$-mediated decays, (a) where the $\tilde{\chi}_1^0$ is massless and the intermediate slepton mass is set to 5%, 25%, 50%, 75%, and 95% of the $\tilde{\chi}_2^0$ mass, and (b) as a function of the $\tilde{\chi}_2^0$ and $\tilde{\chi}_1^0$ masses, where the slepton mass is halfway between the $\tilde{\chi}_2^0$ and $\tilde{\chi}_1^0$ masses. The limits in (a) and (b) are set using a combination of the 3ℓ analysis from Ref. [20] and the 4ℓ analysis from Ref. [21].

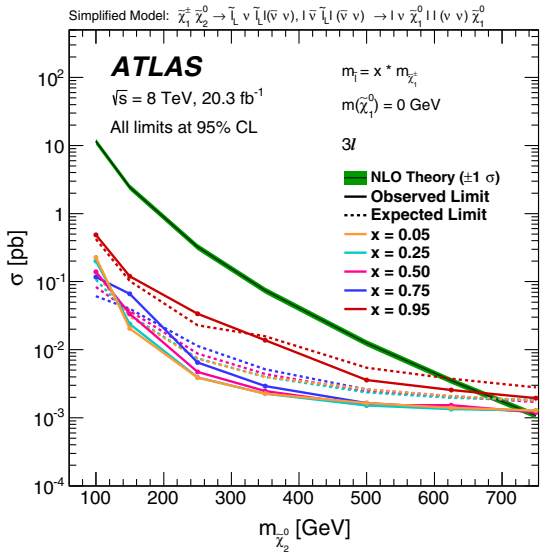

FIG. 16. The 95% CL upper cross-section limits on $\tilde{\chi}_1^{\pm}\tilde{\chi}_2^0$ production with $\tilde{\ell}_L$-mediated decays, where the $\tilde{\chi}_1^0$ is massless and the intermediate slepton mass is set to 5%, 25%, 50%, 75%, and 95% of the $\tilde{\chi}_1^{\pm}$ mass. The limits are set using the 3ℓ analysis from Ref. [20].

the lower production cross section. These limits on direct production of stau pairs improve upon the previous limits in Ref. [22], particularly for stau masses below ∼150 GeV.

B. Direct chargino production

The opposite-sign, two-lepton analysis in Ref. [19] is used to reinterpret the limits on $\tilde{\chi}_1^+$ production decaying through sleptons, where the slepton mass is varied between the $\tilde{\chi}_1^{\pm}$ and $\tilde{\chi}_1^0$ masses. Scenarios where the slepton mass is 5%, 25%, 50%, 75%, and 95% of the $\tilde{\chi}_1^{\pm}$ mass are studied for a massless $\tilde{\chi}_1^0$, and the limits are shown in Fig. 13(a). For the majority of the $\tilde{\chi}_1^{\pm}$ masses considered, the slepton mass does not have a significant effect on the sensitivity, and $\tilde{\chi}_1^{\pm}$ masses are excluded up to ∼500 GeV. The sensitivity is reduced for a very small mass splitting between the chargino and the slepton ($x = 0.95$), as in this case leptons from the $\tilde{\chi}_1^{\pm} \to \tilde{\nu}\ell$ decays have low momentum, making these events difficult to reconstruct in the two lepton final state.

Limits are also set in the $\tilde{\chi}_1^+\tilde{\chi}_1^-$ scenario with $\tilde{\ell}_L$-mediated decays, with slepton masses set halfway between the $\tilde{\chi}_1^{\pm}$ and the $\tilde{\chi}_1^0$ masses, where both the $\tilde{\chi}_1^{\pm}$ and the $\tilde{\chi}_1^0$ masses are varied. Figure 13(b) shows the opposite-sign, two-lepton analysis presented in Sec. VIII A, which provides new sensitivity to compressed scenarios for $\tilde{\chi}_1^{\pm}$ masses below ∼220 GeV. The 2ℓ analysis in Ref. [19] continues to dominate the sensitivity to scenarios with large mass splittings, excluding $\tilde{\chi}_1^{\pm}$ masses up to ∼465 GeV.

The same-sign, two-lepton VBF analysis described in Sec. IX is used to set limits on VBF $\tilde{\chi}_1^{\pm}\tilde{\chi}_1^{\pm}$ production, where the $\tilde{\chi}_1^{\pm}$ decays through sleptons. Figures 14(a) and 14(b) show the 95% CL upper limits on the cross section for $m(\tilde{\chi}_1^{\pm}) = 110$ GeV and $m(\tilde{\chi}_1^{\pm}) = 120$ GeV, as a function of the mass splitting between the chargino and the neutralino. The best observed upper limit on the VBF $\tilde{\chi}_1^{\pm}\tilde{\chi}_1^{\pm}$ production cross section is found for a $\tilde{\chi}_1^{\pm}$ mass of 120 GeV and $m(\tilde{\chi}_1^{\pm}) - m(\tilde{\chi}_1^0) = 25$ GeV, where the theoretical cross section at LO is 4.33 fb and the excluded cross section is 10.9 fb. The sensitivity is slightly stronger for higher $\tilde{\chi}_1^{\pm}$ masses, since these scenarios were used for optimizing the signal selection.

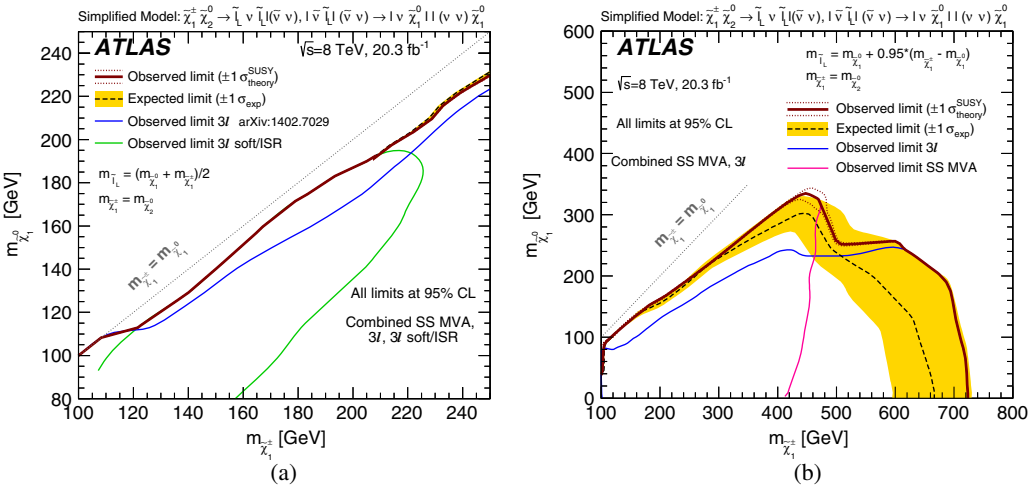

FIG. 17. The 95% CL exclusion limits on $\tilde{\chi}_1^{\pm}\tilde{\chi}_2^0$ production with $\tilde{\ell}_L$-mediated decays, as a function of the $\tilde{\chi}_1^{\pm}$ and $\tilde{\chi}_1^0$ masses, where the intermediate slepton mass is set to the $\tilde{\chi}_1^0$ mass plus (a) 50% or (b) 95% of the difference between the $\tilde{\chi}_1^{\pm}$ and the $\tilde{\chi}_1^0$ masses. The limits in (a) are set using a combination of the 3ℓ analysis from Ref. [20] and the same-sign, two-lepton analysis from this article, while the limits in (b) use the combination of the three-lepton and same-sign, two-lepton analyses from this article.

C. Direct neutralino production

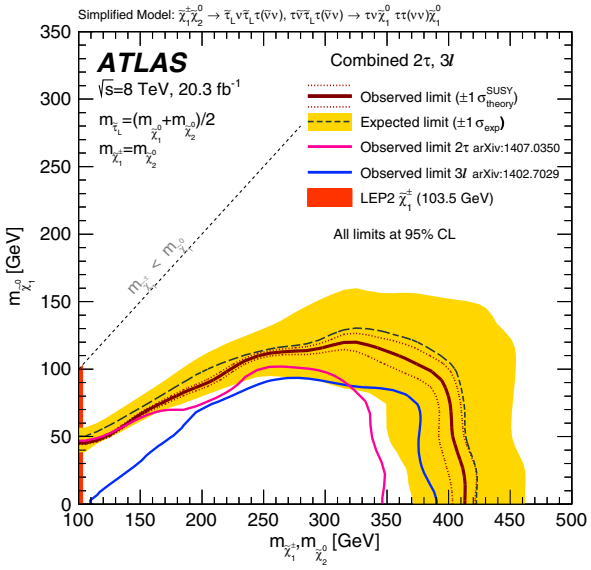
The combination of the three-lepton analysis in Ref. [20] and four-lepton analysis in Ref. [21] is used to set limits on $\tilde{\chi}_2^0\tilde{\chi}_3^0$ production with $\tilde{\ell}_R$-mediated decays, where the slepton mass is varied between the $\tilde{\chi}_2^0$ and $\tilde{\chi}_1^0$ masses. Scenarios where the slepton mass is 5%, 25%, 50%, 75%, and 95% of the $\tilde{\chi}_2^0$ mass are studied for a massless $\tilde{\chi}_1^0$, and the limits are shown in Fig. 15(a). For the majority of $\tilde{\chi}_2^0$ masses considered, the slepton mass does not have a significant effect on the sensitivity, and $\tilde{\chi}_2^0$ masses are excluded up to ~600 GeV. The sensitivity is reduced for a very small mass splitting between the $\tilde{\chi}_2^0$ and slepton ($x = 0.95$) as the lepton produced in the $\tilde{\chi}_2^0 \to \ell\tilde{\ell}_R$ decay has low momentum. The reduced sensitivity is not seen for a very small mass splitting between the slepton and the LSP ($x = 0.05$) as the lepton produced in the $\tilde{\ell}_R \to \ell\tilde{\chi}_1^0$ decay can carry some of the momentum of the slepton.

Limits are also set in the $\tilde{\chi}_2^0\tilde{\chi}_3^0$ scenario with $\tilde{\ell}_R$-mediated decays, with slepton masses set halfway between the $\tilde{\chi}_2^0$ and the $\tilde{\chi}_1^0$ masses, where both the $\tilde{\chi}_2^0$ and the $\tilde{\chi}_1^0$ masses are varied. The combination of the three- and four-lepton analysis is again used here and limits are shown in Fig. 15(b), where $\tilde{\chi}_2^0$, $\tilde{\chi}_3^0$ masses up to 670 GeV are excluded, improving the previous limits by 30 GeV for $\tilde{\chi}_1^0$ masses below 200 GeV.

D. Direct neutralino-chargino production

The three-lepton analysis in Ref. [20] is used to reinterpret the limits on $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$ production decaying through sleptons. Scenarios where the slepton mass is 5%, 25%, 50%, 75%, and 95% of the $\tilde{\chi}_1^\pm$ mass are studied for a massless $\tilde{\chi}_1^0$. The limits on these variable slepton mass scenarios are shown in Fig. 16. For the majority of $\tilde{\chi}_1^\pm$ masses considered, the slepton mass does not have a significant effect on the sensitivity, and $\tilde{\chi}_1^\pm$ masses are excluded up to ~700 GeV. The same reduction in sensitivity is seen for a small mass splitting between the $\tilde{\chi}_2^0$ and slepton ($x = 0.95$) as in the $\tilde{\chi}_2^0\tilde{\chi}_3^0$ interpretation in Sec. X C. For $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$ production scenarios decaying through SM W, Z, or Higgs bosons [20], the results in Fig. 16 would be degraded due to lower branching fractions into leptonic final states. The pMSSM scenario in Sec. X F shows the sensitivity to SUSY scenarios without sleptons in the $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$ decay chain.

Limits are also set in the $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$ scenarios with $\tilde{\ell}_L$-mediated decays, with slepton masses set halfway and at 95% between the $\tilde{\chi}_1^\pm$ and the $\tilde{\chi}_1^0$ masses, where both the $\tilde{\chi}_1^\pm$ and the $\tilde{\chi}_1^0$ masses are varied. Figures 17(a) and 17(b) show that the combination of the published and new analyses gives an improved sensitivity to compressed scenarios up to $\tilde{\chi}_1^\pm$ masses of ~250 GeV. In scenarios with large mass splittings, $\tilde{\chi}_1^\pm$ masses are excluded up to ~700 GeV for slepton masses set to the $\tilde{\chi}_1^0$ mass plus 50% or 95% of the difference between the $\tilde{\chi}_1^\pm$ and the $\tilde{\chi}_1^0$ masses. In the compressed areas of the $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$ scenario with $\tilde{\ell}_L$-mediated decays, and slepton masses set halfway (95%) between the $\tilde{\chi}_1^\pm$ and the $\tilde{\chi}_1^0$ masses, the three-lepton (same-sign, two-lepton) analysis has the strongest sensitivity.



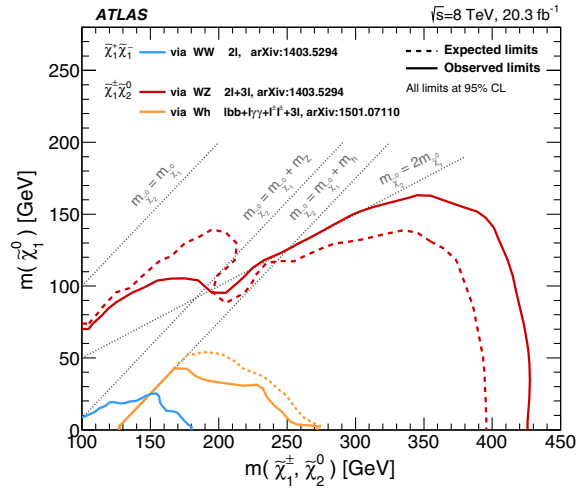


FIG. 18. The 95% CL exclusion limits on $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$ production with $\tilde{\tau}$-mediated decays, as a function of the $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_1^0$ masses. The limits are set using a combination of the 3ℓ analysis from Ref. [20] and the 2τ analysis from Ref. [22].

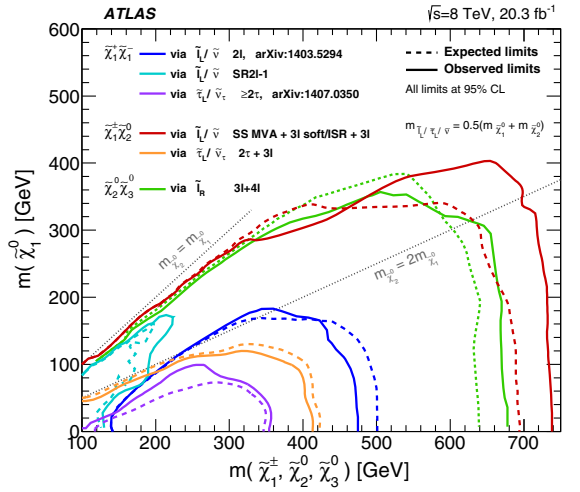

Finally, limits are set in the $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$ scenario with $\tilde{\tau}$-mediated decays, using combined results from the two-tau analysis in Ref. [22] and the three-lepton analysis in Ref. [20]. Figure 18 shows that the sensitivity to large $\tilde{\chi}_1^\pm$ masses is improved by 20 GeV with the new combination, where $\tilde{\chi}_1^\pm$ masses are excluded up to ~400 GeV for massless $\tilde{\chi}_1^0$.

E. Summary of simplified electroweakino production

The ATLAS results for electroweakino searches at 8 TeV in the framework of simplified models are summarized in Figs. 19(a) and 19(b) in the $m(\tilde{\chi}_1^\pm,\tilde{\chi}_2^0)$-$m(\tilde{\chi}_1^0)$ plane. As explained in Sec. II, each of the $\tilde{\chi}_1^\pm/\tilde{\chi}_2^0/\tilde{\chi}_3^0$ decays considered in the plot is assumed to have a 100% branching fraction, and the production cross section is for pure wino $\tilde{\chi}_1^+\tilde{\chi}_1^-$ and $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$, and pure higgsino $\tilde{\chi}_2^0\tilde{\chi}_3^0$. The limits for $\tilde{\chi}_1^+\tilde{\chi}_1^-$ and $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$ production with decays mediated by SM bosons are summarized in Fig. 19(a). All of the limits are from the two-lepton, three-lepton, and Wh analyses from Refs. [19,20,23]. The new analyses targeting compressed spectra presented in this article have only a small sensitivity to these scenarios and did not significantly improve upon published limits. The limits for $\tilde{\chi}_1^+\tilde{\chi}_1^-$, $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$, and $\tilde{\chi}_2^0\tilde{\chi}_3^0$ production with $\tilde{\ell}$-mediated decays are

(a)

(b)

FIG. 19. The 95% CL exclusion limits on $\tilde{\chi}_1^+\tilde{\chi}_1^-$, $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$, and $\tilde{\chi}_2^0\tilde{\chi}_3^0$ production with (a) SM-boson-mediated decays and (b) $\tilde{\ell}$-mediated decays, as a function of the $\tilde{\chi}_1^\pm$, $\tilde{\chi}_2^0$, and $\tilde{\chi}_1^0$ masses. The production cross section is for pure wino $\tilde{\chi}_1^+\tilde{\chi}_1^-$ and $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$, and pure higgsino $\tilde{\chi}_2^0\tilde{\chi}_3^0$.

summarized in Fig. 19(b). The limits are from the new analyses in Secs. X B–X D and the previously published analyses.

F. pMSSM

The two-lepton, three-lepton, and Wh analyses from Refs. [19,20,23] are combined to improve the sensitivity in the considered pMSSM scenario where the EW SUSY production and the decays through W, Z, or h bosons are dominant. The 95% CL exclusion in the pMSSM $\mu - M_2$ plane for the scenario of heavy sleptons, $\tan\beta = 10$, and $M_1 = 50$ GeV is shown in Fig. 20. Including the Wh analysis in the new combination results in a stronger limit at high values of M_2, in particular in the intermediate μ region.

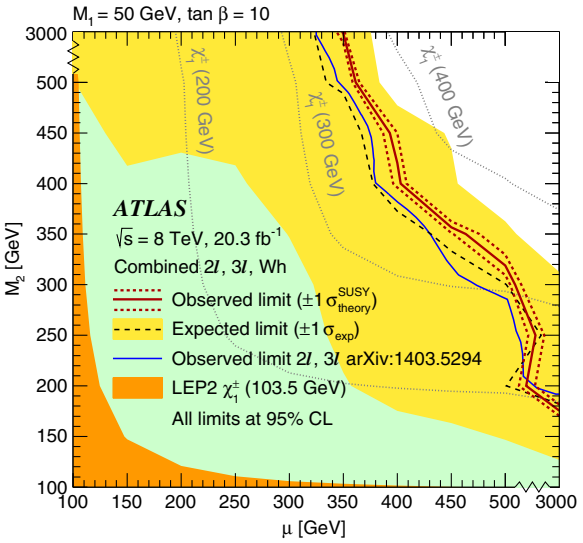

FIG. 20. The 95% CL exclusion limit in the pMSSM scenario, using a combination of the 2ℓ and 3ℓ analyses from Ref. [19] and the Wh analysis from Ref. [23]. The areas excluded by the -1σ expected limit are shown in green. The blue contour corresponds to the limits from the combination of the 2ℓ and 3ℓ analyses from Ref. [19]. The grey dotted contours show the chargino mass isolines.

G. NUHM2

The two-, three-, and four-lepton analyses from Refs. [19–21] are combined to set limits in a new interpretation for the NUHM2 model. The 95% CL exclusion in the NUHM2 $m_{1/2} - \mu$ plane is shown in Fig. 21, where the three-lepton analysis offers the best sensitivity

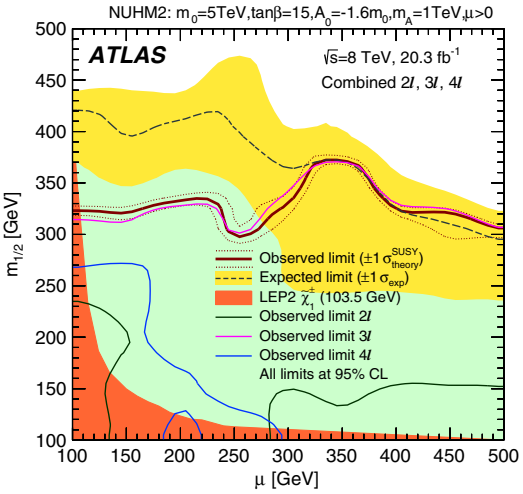

FIG. 21. The 95% CL exclusion limit in the NUHM2 scenario, using a combination of the 2ℓ, 3ℓ, and 4ℓ analyses from Refs. [19–21]. The areas excluded by the -1σ expected limit are shown in green. The black, pink, and blue contours correspond to the limits from the 2ℓ, 3ℓ, and 4ℓ analyses, respectively.

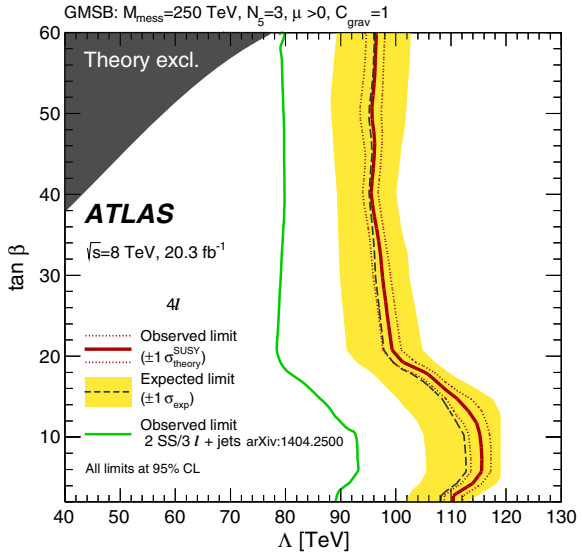

FIG. 22. The 95% CL exclusion limit in the GMSB scenario, using the 4ℓ analysis from Ref. [21]. The green contour corresponds to the limit from the $2\mathrm{SS}/3\ell+\mathrm{jets}$ analysis from Ref. [119].

and drives the combined limit. The results in the three-lepton signal regions lead to a weaker observed exclusion than expected for the compressed scenarios in the high-$m_{1/2}$, low-μ region. In general, $m_{1/2}$ values up to 300 GeV are excluded in the NUHM2 model.

H. GMSB

The four-lepton analysis from Ref. [21] is reinterpreted in the GMSB model described in Sec. II. The 95% CL exclusion in the GMSB Λ-$\tan\beta$ plane is shown in Fig. 22, where Λ values up to 94 TeV are excluded for all values of $\tan\beta$. For $\tan\beta=10$, Λ values below 113 TeV are excluded. These results improve upon the previous limit in Ref. [119] by 20 TeV (15 TeV) in the low (high) $\tan\beta$ region.

XI. CONCLUSION

This article summarizes and extends the search for the production of electroweak SUSY particles using 20 fb^{-1} of $\sqrt{s}=8$ TeV pp collision data collected with the ATLAS detector at the LHC. New analyses targeting scenarios with compressed mass spectra, VBF production of charginos and neutralinos, and the direct production of stau pairs provide sensitivity to EW SUSY scenarios not optimally covered in previous publications. The new and previous results are combined to set exclusion limits in a wide range of simplified and phenomenological SUSY models. For $\tilde{\chi}_1^+\tilde{\chi}_1^-$ production with $\tilde{\ell}_L$-mediated decays, $\tilde{\chi}_1^\pm$ with masses up to ~500 GeV are excluded. In the $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$ and $\tilde{\chi}_2^0\tilde{\chi}_3^0$ scenarios with $\tilde{\ell}_L$-mediated decays, $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_2^0$ masses are excluded up to 700 GeV and 670 GeV, respectively. For all three $\tilde{\ell}_L$-mediated decay scenarios, the value of the slepton mass is not seen to have a significant effect on the sensitivity. Exclusions are also set in pMSSM, NUHM2, and GMSB models, improving upon previous limits.

ACKNOWLEDGMENTS

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently. We thank Sabine Kraml for her advice while preparing the model files of the NUHM2 grid. We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWFW and FWF, Austria; ANAS, Azerbaijan; SSTC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC, and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST, and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR, and VSC CR, Czech Republic; DNRF, DNSRC, and Lundbeck Foundation, Denmark; EPLANET, ERC, and NSRF, European Union; IN2P3-CNRS, CEA-DSM/IRFU, France; GNSF, Georgia; BMBF, DFG, HGF, MPG, and AvH Foundation, Germany; GSRT and NSRF, Greece; RGC, Hong Kong SAR, China; ISF, MINERVA, GIF, I-CORE, and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; BRF and RCN, Norway; MNiSW and NCN, Poland; GRICES and FCT, Portugal; MNE/IFA, Romania; MES of Russia and NRC KI, Russian Federation; JINR; MSTD, Serbia; MSSR, Slovakia; ARRS and MIZŠ, Slovenia; DST/NRF, South Africa; MINECO, Spain; SRC and Wallenberg Foundation, Sweden; SER, SNSF, and Cantons of Bern and Geneva, Switzerland; NSC, Taiwan; TAEK, Turkey; STFC, the Royal Society and Leverhulme Trust, United Kingdom; DOE and NSF, United States of America. The crucial computing support from all WLCG partners is acknowledged gratefully, in particular from CERN and the ATLAS Tier-1 facilities at TRIUMF (Canada), NDGF (Denmark, Norway, Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy), NL-T1 (Netherlands), PIC (Spain), ASGC (Taiwan), RAL (UK), and BNL (USA) and in the Tier-2 facilities worldwide.

APPENDIX: CROSS-SECTION CALCULATION FOR THE SAME-SIGN CHARGINO-PAIR PRODUCTION VIA VECTOR-BOSON FUSION

The cross sections for same-sign chargino-pair production via vector-boson fusion (including radiative processes) are calculated to LO in the strong coupling constant using MadGraph 5-1.3.33 [57]. The default

value of 99 is used for the maximum number of QCD and QED couplings. Same-sign chargino pairs are generated in association with two additional partons with $|\eta| < 5$ and no p_{T} requirement. No jet-parton matching is performed. All SUSY particles, except for the $\tilde{\chi}_1^{\pm}$, $\tilde{\chi}_1^0$, $\tilde{\chi}_2^0$, $\tilde{\ell}$, and $\tilde{\nu}$, are decoupled by setting their physical masses to ~100 TeV. The $\tilde{\chi}_1^{\pm}$ and $\tilde{\chi}_2^0$ are assumed to be mass degenerate. The sleptons are assumed to be mass degenerate with sneutrinos and have masses set halfway between $\tilde{\chi}_1^{\pm}$ and $\tilde{\chi}_1^0$ masses. Cross sections are also calculated using MadGraph 5-2.2.3 and are in agreement with those calculated using MadGraph 5-1.3.33. Details from the "`proc_card.dat`" are provided below.

```
import model mssm
define p=g u c d s u~ c~ d~ s~
define j=g u c d s u~ c~ d~ s~
define l+=e+ mu+
define l-=e- mu-
define vl=ve vm vt
define vl~ = ve~ vm~ vt~
generate    pp>x1+x1+jj@1
add process pp>x1-x1-jj@2
output -f
```

Search for massive, long-lived particles using multitrack displaced vertices or displaced lepton pairs in *pp* collisions at $\sqrt{s} = 8$ TeV with the ATLAS detector

G. Aad *et al.*[*]
(ATLAS Collaboration)

(Received 21 April 2015; revised manuscript received 19 August 2015; published 13 October 2015)

Many extensions of the Standard Model posit the existence of heavy particles with long lifetimes. This article presents the results of a search for events containing at least one long-lived particle that decays at a significant distance from its production point into two leptons or into five or more charged particles. This analysis uses a data sample of proton-proton collisions at $\sqrt{s} = 8$ TeV corresponding to an integrated luminosity of 20.3 fb^{-1} collected in 2012 by the ATLAS detector operating at the Large Hadron Collider. No events are observed in any of the signal regions, and limits are set on model parameters within supersymmetric scenarios involving R-parity violation, split supersymmetry, and gauge mediation. In some of the search channels, the trigger and search strategy are based only on the decay products of individual long-lived particles, irrespective of the rest of the event. In these cases, the provided limits can easily be reinterpreted in different scenarios.

I. INTRODUCTION

Several extensions to the Standard Model (SM) predict the production at the Large Hadron Collider (LHC) of heavy particles with lifetimes of order picoseconds to nanoseconds (e.g., see Ref. [1] and references therein). At the LHC experiments, the decay of a long-lived particle (LLP) with lifetime in this range could be observed as a displaced vertex (DV), with daughter particles produced at a significant distance from the interaction point (IP) of the incoming proton beams. Particle decays may be suppressed by small couplings or high mass scales, thus resulting in long lifetimes. An example of a small-coupling scenario is supersymmetry with R-parity violation (RPV) [2,3]. The present (largely indirect) constraints on RPV couplings allow the decay of the lightest supersymmetric particle (LSP) as it traverses a particle detector at the LHC. In general gauge-mediated supersymmetry breaking (GGM) scenarios [4], the next-to-lightest supersymmetric particle (NLSP) decays into an SM particle and the LSP, which is a very light gravitino. The NLSP width is suppressed by the large supersymmetry-breaking scale, and may be such that its decay leads to the formation of a DV. Within split supersymmetry [5,6], gluino ($\tilde{g}$) decay is suppressed by the high mass of the squarks. Long-lived gluinos then hadronize into heavy "R-hadrons" that may decay at a detectable distance from their production point. Additional scenarios with LLPs include hidden-valley [7], dark-sector gauge bosons [8], and stealth supersymmetry [9]. Some of the models are disfavored [10] by the recent observation of a Higgs boson at $m_H \approx 125$ GeV [11,12].

This article presents the results of a search for DVs that arise from decays of long-lived, heavy particles, at radial distances of millimeters to tens of centimeters from the proton-proton IP in the ATLAS detector at the LHC. Two types of signatures are considered. In the dilepton signature, the vertex is formed from at least two lepton candidates (with "lepton" referring to an electron or a muon), with opposite electric charges. In the multitrack signature, the DV must contain at least five charged-particle tracks. This signature is divided into four different final states, in which the DV must be accompanied by a high-transverse-momentum (high-p_{T}) muon or electron candidate that originates from the DV, jets, or missing transverse momentum ($E_{\mathrm{T}}^{\mathrm{miss}}$). These signatures are labeled DV + muon, DV + electron, DV + jets, and DV + $E_{\mathrm{T}}^{\mathrm{miss}}$, respectively. In all signatures, at least one DV is required per event. In all cases, the expected background is much less than one event.

The multitrack results improve on the previous ATLAS searches for this signature [13,14] in several ways. The LHC center-of-mass energy is increased to 8 TeV, and the integrated luminosity is more than 4 times larger. While the previous search required only a high-p_{T} muon trigger, the current search also uses high-p_{T} electron, jets, or $E_{\mathrm{T}}^{\mathrm{miss}}$ triggers. Furthermore, the detector volume used for the search has been enlarged by more than a factor of 3.

This is the first search for high-mass, displaced lepton pairs at ATLAS. A previous ATLAS search [15] considered pairs of muons that were highly collimated due to the low

mass of the decaying particle. ATLAS has also searched for long-lived particles that decay inside the hadronic calorimeter [16,17], the inner detector, or the muon spectrometer [18], or that traverse the entire detector [19].

Related searches have been performed at other experiments. The CMS Collaboration has searched for decays of a long-lived particle into a final state containing two electrons, two muons [20,21], an electron and a muon [22], or a quark-antiquark pair [23]. The LHCb Collaboration has searched for long-lived particles that decay into jet pairs [24]. The Belle Collaboration has searched for long-lived heavy neutrinos [25], and the *BABAR* Collaboration has searched for displaced vertices formed of two charged particles [26]. The D0 Collaboration has searched for displaced lepton pairs [27] and $b\bar{b}$ pairs [28], and the CDF Collaboration has searched for long-lived particles decaying to Z bosons [29]. LLPs have also been searched for by the ALEPH Collaboration at LEP [30].

This article is organized as follows. First, the ATLAS detector and event samples used are described in Secs. II and III, respectively. The event reconstruction and vertex selection criteria are given in Sec. IV, while the signal efficiency is detailed in Sec. V. The background estimation is given in Sec. VI, with the systematic uncertainties on background and signal in Sec. VII. Finally, the search results are given in Sec. VIII, along with their interpretations in various supersymmetric scenarios.

II. THE ATLAS DETECTOR

The ATLAS experiment[1] [31] is a multipurpose detector at the LHC. The detector consists of several layers of subdetectors. From the IP outwards, there is an inner tracking detector (ID), electromagnetic and hadronic calorimeters, and a muon spectrometer (MS).

The ID is immersed in a 2 T axial magnetic field and extends from a radius of about 45 mm to 1100 mm and to $|z|$ of about 3100 mm. It provides tracking and vertex information for charged particles within the pseudorapidity region $|\eta| < 2.5$. At small radii, silicon pixel layers and stereo pairs of silicon microstrip detectors provide high-resolution position measurements. The pixel system consists of three barrel layers, and three forward disks on either side of the IP. The barrel pixel layers, which are positioned at radii of 50.5 mm, 88.5 mm, and 122.5 mm, are of particular relevance to this work. The silicon microstrip tracker (SCT) comprises four double layers in the barrel and nine forward disks on either side. The radial position of the innermost (outermost) SCT barrel layer is 30.3 cm (52.0 cm). A further tracking system, a transition-radiation tracker (TRT), is positioned at larger radii, with coverage up to $|\eta| = 2.0$. This device has two hit thresholds, the higher of which is used to assist in the identification of electrons through the production of transition radiation within the TRT.

The calorimeter provides coverage over the range $|\eta| < 4.9$. It consists of a lead/liquid-argon electromagnetic calorimeter, a hadronic calorimeter comprising a steel and scintillator-tile system in the barrel region, and a liquid-argon system with copper and tungsten absorbers in the end caps.

The MS provides muon identification and contributes to the muon momentum measurement. This device has a coverage in pseudorapidity of $|\eta| < 2.7$ and is a three-layer system of gas-filled tracking chambers. The pseudorapidity region $|\eta| < 2.4$ is additionally covered by separate trigger chambers, used by the hardware trigger for the first level of triggering (level-1). The MS is immersed in a magnetic field that is produced by a set of toroid magnets, one for the barrel and one each for the two end caps.

Online event selection is performed with a three-level trigger system. It is composed of a hardware-based level-1 trigger that uses information from the MS trigger chambers and the calorimeters, followed by two software-based trigger levels.

III. DATA AND SIMULATED EVENTS

The data used in this analysis were collected in 2012 at a pp center-of-mass energy of $\sqrt{s} = 8$ TeV. After the application of detector and data-quality requirements, the integrated luminosity of the data sample is 20.3 fb^{-1}. The uncertainty on the integrated luminosity is $\pm 2.8\%$. It is derived following the same methodology as that detailed in Ref. [32]. With respect to the origin of the ATLAS coordinate system at the center of the detector, the mean position of the pp collision, averaged throughout the collected data sample, is $\langle x \rangle = -0.3$ mm, $\langle y \rangle = 0.7$ mm, $\langle z \rangle = -7.7$ mm. The root-mean-square spread of the z distribution of the collisions is $\sigma_z = 47.7$ mm, and the spreads in the x and y directions are less than 0.1 mm.

Samples of simulated Monte Carlo (MC) events are used to study the reconstruction and trigger efficiency for signal events within RPV, split supersymmetry, and GGM scenarios. In each simulated event, two gluinos or two squarks are created in the pp collision. Both of these primary particles undergo decay chains described by the same set of effective operators. In the simulated GGM and RPV scenarios, the LLP is the lightest neutralino $\tilde{\chi}_1^0$. In the split-supersymmetry scenario, the LLP is the gluino. Diagrams representing the simulated processes are shown in Fig. 1.

[1]ATLAS uses a right-handed coordinate system with its origin at the nominal IP in the center of the detector and the z axis along the beam pipe. The x axis points from the IP to the center of the LHC ring, and the y axis points upward. Cylindrical coordinates (r, ϕ) are used in the transverse plane, ϕ being the azimuthal angle around the beam pipe. The pseudorapidity is defined in terms of the polar angle θ as $\eta = -\ln\tan(\theta/2)$.

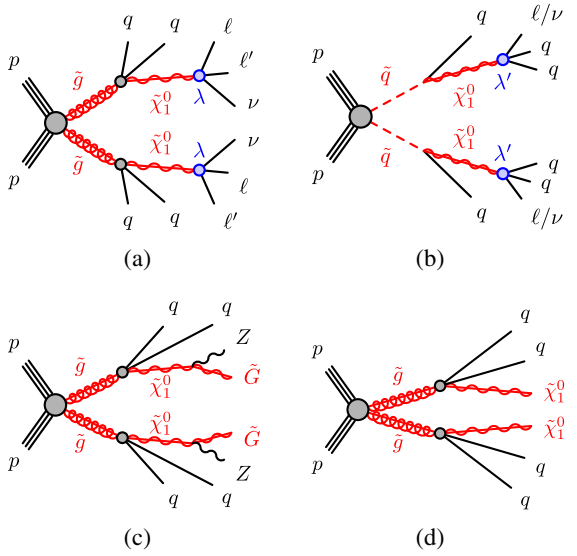

FIG. 1 (color online). Diagrams representing some of the processes under study, corresponding to the simulated event samples. In RPV scenarios, the long-lived neutralino may decay via the (a) λ_{ijk} or (b) λ'_{ijk} couplings. (c) Long-lived neutralino decay in a GGM scenario. (d) Long-lived R-hadron decay in a split-supersymmetry scenario. The quarks and leptons shown may have different flavors. Filled circles indicate effective interactions.

All samples are generated with the AUET2B ATLAS underlying-event tune [33] and the CTEQ6L1 parton distribution function (PDF) set [34]. Events are generated consistently with the position of the pp luminous region and weighted so as to yield the correct z distribution of the collisions. Each generated event is processed with the GEANT4-based [35] ATLAS detector simulation [36] and treated in the same way as the collision data. The samples include a realistic modeling of the effects of multiple pp collisions per bunch crossing observed in the data, obtained by overlaying additional simulated pp events generated using PYTHIA8 [37], on top of the hard scattering events, and reweighting events such that the distribution of the number of interactions per bunch crossing matches that in the data.

In what follows, the notation $P \to A[L \to F]$ denotes an MC sample in which a primary particle P produced in the pp collision decays into a long-lived particle L and additional particles denoted A. The decay of the LLP into final state F is enclosed in square brackets. Samples where the primary particle is long-lived are denoted with $[L \to F]$. In both cases, masses may be indicated with parentheses, as in $[L(100\ \text{GeV}) \to F]$. The symbol q indicates a u- or d-quark unless otherwise specified, and ℓ indicates an electron or a muon. Charge conjugation of fermions is to be understood where appropriate.

RPV samples of the type $\tilde{g} \to qq[\tilde{\chi}_1^0 \to \ell\ell'\nu]$ are produced with HERWIG++ 2.6.3 [38]. Decays of the neutralino into a neutrino and light leptons, which may be e^+e^-, $\mu^+\mu^-$, or $e^\pm\mu^\mp$, take place due to the nonzero values of the RPV couplings λ_{121} and λ_{122} [2].

RPV samples of $\tilde{q} \to q[\tilde{\chi}_1^0 \to \ell qq/\nu qq]$ are generated with PYTHIA6.426.2 [39]. The $\tilde{\chi}_1^0$ decay into two light quarks and an electron, muon, or neutrino is governed by the nonzero RPV coupling λ'_{i11}. Samples containing heavy-flavor quarks, $\tilde{q} \to q[\tilde{\chi}_1^0 \to \ell qb]$ (produced with $\lambda'_{i13} \neq 0$) and $\tilde{q} \to q[\tilde{\chi}_1^0 \to \ell cb]$ (corresponding to $\lambda'_{i23} \neq 0$) are also generated, in order to study the impact of long-lived charm and bottom hadrons on the efficiency of DV reconstruction. A $\tilde{g} \to qq[\tilde{\chi}_1^0 \to \ell qq]$ sample is used to quantify the effect of prompt NLSP decays on the reconstruction efficiency, by comparing with the corresponding model with squark production.

PYTHIA6.426.2 is used to produce GGM samples denoted $\tilde{g} \to qq[\tilde{\chi}_1^0 \to \tilde{G}Z]$, in which the NLSP $\tilde{\chi}_1^0$ is a Higgsino-like neutralino. Both the leptonic and hadronic decays of the Z boson are considered.

Within a split-supersymmetry scenario, PYTHIA6.427 is used to simulate production and hadronization of a primary, long-lived gluino. GEANT4 simulates the propagation of the R-hadron through the detector [40], and PYTHIA decays the R-hadron into a stable neutralino plus two quarks (u, d, s, c, or b), a gluon, or two top quarks. The resulting samples are denoted $[\tilde{g} \to qq\tilde{\chi}_1^0]$, $[\tilde{g} \to g\tilde{\chi}_1^0]$, or $[\tilde{g} \to tt\tilde{\chi}_1^0]$, respectively.

Signal cross sections are calculated to next-to-leading order in the strong coupling constant, adding the resummation of soft gluon emission at next-to-leading-logarithmic accuracy (NLO + NLL) [41–45]. The nominal cross section and its uncertainty are taken from an envelope of cross-section predictions using different PDF sets and factorization and renormalization scales, as described in Ref. [46].

In addition to these signal samples, MC samples of QCD dijet events, Drell-Yan events, and cosmic-ray muons are used for estimating some systematic uncertainties and some of the smaller background rates, as well as for validation of aspects of the background-estimation methods.

IV. EVENT RECONSTRUCTION AND SELECTION

The event-reconstruction and selection procedures are designed, based on MC and experience from previous analyses [13,14], to strongly suppress background and accommodate robust background-estimation methods (described in Sec. VI), while efficiently accepting signal events over a broad range of LLP masses, lifetimes, and velocities.

The initial event selection is performed with a combination of triggers that require the presence of lepton candidates, jets, or $E_{\mathrm{T}}^{\mathrm{miss}}$. This selection is described in Sec. IV A.

Off-line selection criteria for leptons, jets, and $E_{\mathrm{T}}^{\mathrm{miss}}$ (see Sec. IV B) are used to further filter events for off-line processing, as described in Sec. IV C.

Events satisfying the filter requirements undergo a CPU-intensive process termed "retracking," aimed at efficient reconstruction of tracks with large impact parameter (d_0) with respect to the transverse position of any primary vertex (PV) of particles formed from the pp collision. Retracking is described in Sec. IV D.

At the final event-selection stage, the presence of a pp collision is ensured by first requiring the event to have a PV formed from at least five tracks and situated in the longitudinal range $|z| < 200$ mm, consistent with the IP.

The final selection is based on the reconstruction of a multitrack DV or dilepton DV, described in Secs. IV E and IV F, respectively.

A. Trigger requirements

Events must satisfy trigger requirements based on muon, electron, jets, or $E_{\mathrm{T}}^{\mathrm{miss}}$ criteria.

Where muon triggers are used, a muon candidate is required by the trigger algorithm to be identified in the MS with transverse momentum $p_{\mathrm{T}} > 50$ GeV. Its pseudorapidity must be in the MS-barrel region $|\eta| < 1.07$, to reduce the trigger rate from fake muons due to beam background in the end cap region.

Photon triggers are used for channels requiring electron candidates, since the ID track of a high-d_0 electron may not be reconstructed. These require only a high-energy deposit in the electromagnetic calorimeter and have no veto or selection based on ID tracks. Photon triggers provide significantly less background rejection than muon triggers. Therefore, the trigger used for final states involving electrons requires either a single photon candidate with $p_{\mathrm{T}} > 120$ GeV or two photon candidates with $p_{\mathrm{T}} > 40$ GeV each.

The trigger requirement for the DV + $E_{\mathrm{T}}^{\mathrm{miss}}$ search is $E_{\mathrm{T}}^{\mathrm{miss}} > 80$ GeV. The DV + jets trigger requires four jets with $p_{\mathrm{T}} > 80$ GeV, five jets with $p_{\mathrm{T}} > 55$ GeV, or six jets with $p_{\mathrm{T}} > 45$ GeV.

B. Off-line object definition

The reconstruction and selection criteria for $E_{\mathrm{T}}^{\mathrm{miss}}$, muon, electron, and jet candidates are described in what follows. These object definitions are used by the off-line filter (Sec. IV C) and the final analysis (Secs. IV E and IV F).

1. Muon selection

Muon candidates are required to be reconstructed in both the MS and the ID. The ID track associated with the muon candidate is required to have at least four SCT hits, but the number of required hits is reduced if the track crosses nonoperational sensors. Furthermore, the track must satisfy an $|\eta|$-dependent requirement on the number of TRT hits. No pixel hit requirement is applied to the muon-candidate track, which is different from the standard ATLAS muon-reconstruction algorithm [47].

2. Photon and electron selection

Photon and electron candidates are identified with criteria based on the fraction of the candidate energy deposited in the hadronic calorimeter and on the shape of the electromagnetic shower. In addition, electron candidates must be in the pseudorapidity region $|\eta| < 2.47$ and must satisfy requirements on the number of TRT hits associated with the ID track, the fraction of high-threshold TRT hits, and the pseudorapidity difference between the electron-candidate track and the associated calorimeter cluster. In contrast to the standard ATLAS electron-selection requirements [48], no requirement on the number of silicon hits is applied.

3. Jet and $E_{\mathrm{T}}^{\mathrm{miss}}$ selection

Jet candidates are reconstructed using the anti-k_t jet clustering algorithm [49,50] with a radius parameter $R = 0.6$. The inputs to this algorithm are the energies of clusters [51,52] of calorimeter cells seeded by those with energy significantly above the measured noise. Jet momenta are constructed by performing a four-vector sum over these cell clusters, treating each cell as a four-momentum with zero mass. Jets are initially calibrated to the electromagnetic energy scale, which correctly measures the energy deposited in the calorimeter by electromagnetic showers [51]. Further jet-energy scale corrections are derived from MC simulation and data, and used to calibrate the energies of jets to the scale of their constituent particles [51]. Jets are required to satisfy $|\eta| < 4.5$ after all corrections are applied.

A special category of jets is termed "trackless" jets. These are reconstructed as above, except that the anti-k_t radius parameter is $R = 0.4$, the jet pseudorapidity is in the range $|\eta| < 2.5$, and the scalar sum of the transverse momenta of the tracks in the jet is required to satisfy $\sum_{\mathrm{tr}} p_{\mathrm{T}} < 5$ GeV. Trackless jets may arise from decays of LLPs that take place far from the PV, where track-reconstruction efficiency is low.

The measurement of the missing transverse momentum $E_{\mathrm{T}}^{\mathrm{miss}}$ is based on the calibrated transverse momenta of all jet and lepton candidates, as well as all calorimeter energy clusters not associated with such objects [53,54].

C. Off-line–filter requirements

Events are selected for retracking and subsequent off-line analysis based on off-line filters that require one of the following:

(i) A muon candidate with $p_{\mathrm{T}} > 50$ GeV, an electron candidate with $p_{\mathrm{T}} > 110$ GeV, or a photon candidate with $p_{\mathrm{T}} > 130$ GeV. Electron candidates, and muon candidates that are associated with an ID track at this stage, are required to have $d_0 > 1.5$ mm. The sample selected by this criterion contains 8.5×10^6 events.

(ii) A pair of candidate electrons, photons, or an electron-photon pair, with p_{T} thresholds between 38 and 48 GeV per object, and electron impact parameter satisfying $d_0 > 2.0$ mm or $d_0 > 2.5$ mm depending on the channel. This criterion selects 2.4×10^6 events.

(iii) Either two 50 GeV trackless jets and $E_{\mathrm{T}}^{\mathrm{miss}} > 100$ GeV (selecting 1.9×10^4 events) or one 45 GeV trackless jet and between four and six jets passing the same p_{T} thresholds as those applied in the trigger, listed in Sec. IV A (selecting 4.6×10^5 events).

D. Retracking

In standard ATLAS tracking [31], several algorithms are used to reconstruct charged-particle tracks. In the silicon-seeded approach, combinations of hits in the pixel and SCT detectors are used to form initial track candidates (seeds) that are then extended into the TRT. Another algorithm starts from track segments formed of TRT hits, and extrapolates back into the SCT, adding any silicon hits that are compatible with the reconstructed trajectory. Both of these methods place constraints on the transverse and longitudinal impact parameters of track candidates that result in a low efficiency for tracks originating from a DV, many of which have large d_0.

To recover some of these lost tracks, the silicon-seeded tracking algorithm is rerun off-line, using only hits that are not associated with existing tracks, for the events that satisfy the trigger and filter requirements (Secs. IV A and IV C). This retracking procedure is performed with the looser requirement $d_0 < 300$ mm and $|z_0| < 1500$ mm. Furthermore, retracking requires a track to have at least five detector hits that are not shared with other tracks, while the corresponding requirement in standard silicon-seeded tracking is at least six hits. To reduce the rate of false seed tracks, it is required that these additional tracks have $p_{\mathrm{T}} > 1$ GeV, while the standard-tracking requirement is $p_{\mathrm{T}} > 400$ MeV.

The remainder of the analysis proceeds with both the standard-tracking tracks and retracking tracks. To realize the benefits of retracking for lepton candidates, the lepton-identification algorithms are rerun with the retracking tracks.

E. Multitrack vertex reconstruction and final selection

1. Multitrack vertex reconstruction

Tracks used for DV reconstruction are required to satisfy $p_{\mathrm{T}} > 1$ GeV and to have at least two SCT hits, to ensure high track quality. The requirement $d_0 > 2$ mm is also applied, rejecting at least 97% of tracks originating from a PV. The tracks are rejected if they have no TRT hits and fewer than two pixel hits, in order to remove fake tracks.

The selected tracks are used to construct a multitrack DV by means of an algorithm based on the incompatibility-graph approach [55].

The algorithm starts by finding two-track seed vertices from all pairs of tracks. Seed vertices that have a vertex fit χ^2 of less than 5.0 (for 1 degree of freedom) are retained. If the seed vertex is inside the innermost pixel layer, both tracks must have a hit in this layer. If the vertex is between the first and second (second and third) pixel layers, both tracks must have a hit in either the second or third pixel layer (third pixel layer or the SCT). A seed vertex is rejected if any of its tracks have hits at radial positions smaller than that of the vertex. The interesting case of a charged LLP is not precluded by this selection, as the track formed by the LLP itself fails the $d_0 > 2$ mm requirement, and is therefore not included in the seed vertex. To ensure consistency between the position of the seed vertex and the direction $\hat{p}$ of the three-momentum vector of the seed-vertex tracks, the requirement $\vec{d} \cdot \hat{p} > -20$ mm is applied, where $\vec{d} = \vec{r}_{\mathrm{DV}} - \vec{r}_{\mathrm{PV}}$ is referred to as the "distance vector" between the position of the DV and that of the first PV. The first PV is defined as the PV with the largest $\sum p_{\mathrm{T}}^2$, where the sum is over tracks associated with the PV.

Multitrack vertices are formed from combinations of seed vertices in an iterative process, as follows. If a track is assigned to several vertices, the vertex DV_1 with respect to which it has the largest χ^2 is identified. If this χ^2 is larger than 6, the track is removed from DV_1. Otherwise, the algorithm finds the vertex DV_2 that has the smallest value of D/σ_D, where D is the distance between DV_1 and DV_2, and σ_D is the estimated uncertainty on D. If $D/\sigma_D < 3$, a single vertex is formed from all the tracks of both vertices. If this is not the case, the track is removed from DV_1. This process continues until no track is associated with more than one vertex. Finally, vertices are combined and refitted if they are separated by less than 1 mm. No requirement is made on the total charge of the tracks forming a vertex.

2. Vertex selection

The reduced χ^2 of the DV fit is required to be smaller than 5.0. The DV position must be within the fiducial region $r_{\mathrm{DV}} < 300$ mm, $|z_{\mathrm{DV}}| < 300$ mm, where r_{DV} and z_{DV} are the radial and longitudinal DV positions with respect to the origin. To minimize background due to tracks originating from the PVs, the transverse distance $\Delta_{xy} = \sqrt{(x_{\mathrm{DV}} - x_{\mathrm{PV}})^2 + (y_{\mathrm{DV}} - y_{\mathrm{PV}})^2}$ between the DV and any of the PVs is required to be at least 4 mm. Here x and y are the transverse coordinates of a given vertex, with the subscripts PV and DV denoting the type of vertex.

DVs that are situated within regions of dense detector material are vetoed using a three-dimensional map of the detector within the fiducial region. The map is constructed in an iterative process, beginning with geometrically simple detector elements that are fully accounted for in the MC

simulation. Subsequently, detailed structures, as well as the positioning and thickness of the simple elements, are obtained from the spatial distribution of vertices obtained from the data, taking advantage of the known ϕ periodicity of the detector to reduce statistical uncertainties. The vertices used to construct the map are required to be formed from fewer than five tracks, in order to avoid the signal region defined below. The invariant mass of these vertices, assuming massless tracks, must be greater than 50 MeV, to suppress vertices from photon conversions, which have low spatial resolution due to the small opening angle between the electrons, as well as electron scattering. Vertices arising from decays of K_S^0 mesons are removed with an invariant-mass criterion. The transverse-plane projection of the positions of vertices that occur inside the material regions is shown in Fig. 2.

As the final step in multitrack DV selection, the number of tracks forming the DV is required to satisfy $N_{\mathrm{tr}} \geq 5$, and the invariant mass m_{DV} of all the tracks in the vertex must be greater than 10 GeV. In calculating m_{DV}, each track is taken to have the mass of the charged pion. Candidate vertices that pass (fail) the $m_{\mathrm{DV}} > 10$ GeV requirement are hereafter referred to as being high-m_{DV} (low-m_{DV}) vertices.

The typical position resolution of the DV in the multitrack signal MC samples is tens of microns for r_{DV} and about 200 μm for z_{DV} near the IP. For vertices beyond the outermost pixel layer, which is located at a radius of 122.5 mm, the typical resolution is several hundred microns for both coordinates.

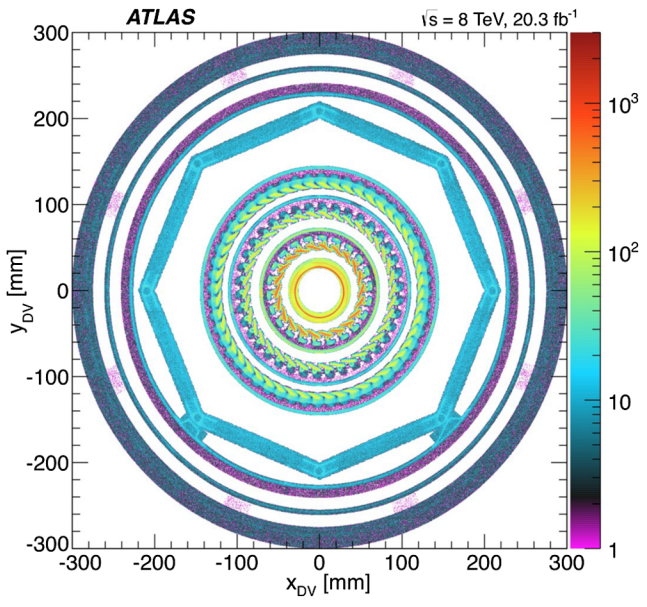

FIG. 2 (color online). Transverse-plane density (in arbitrary units) of vertices with fewer than five tracks in material regions that are excluded by the material veto in the region $|z| < 300$ mm. The innermost circle corresponds to the beam pipe. This is surrounded by the three pixel layers. The octagonal shape and outermost circles are due to support structures separating the pixel and SCT detectors.

3. DV + lepton selection

In the DV + muon search, the muon candidate is required to have triggered the event and have transverse momentum $p_{\mathrm{T}} > 55$ GeV, which is well into the region where the trigger efficiency is approximately independent of the muon momentum. The muon candidate is further required to be in the range $|\eta| < 1.07$ and have transverse impact parameter $d_0 > 1.5$ mm. A cosmic-ray muon traversing the entire ATLAS detector is reconstructed as two back-to-back muon candidates. To reject cosmic-ray background, events are discarded if they contain two muon candidates with $\Delta R_{\mathrm{cosmic}} = \sqrt{(\pi - \Delta\phi)^2 - (\eta_1 + \eta_2)^2} < 0.04$, where η_1 and η_2 are the pseudorapidities of the two reconstructed muon candidates and $\Delta\phi$ is their angular separation in the azimuthal plane. This has a negligible impact on the signal efficiency.

In the DV + electron search, the electron candidate is required to have triggered the event and to satisfy $p_{\mathrm{T}} > 125$ GeV and $d_0 > 1.5$ mm.

To ensure that the lepton candidate is associated with the reconstructed DV, the distance of closest approach of the selected muon or electron candidate to the DV is required to be less than 0.5 mm. This requirement ensures that the reconstructed DV gave rise to the muon or electron candidate that triggered the event, and so the selection efficiency for each LLP decay is independent of the rest of the event. This facilitates a straightforward calculation of the event-selection efficiency for scenarios with different numbers of LLPs. The aforementioned selections are collectively referred to as the vertex-selection criteria. Events containing one or more vertices satisfying these criteria are accepted.

4. DV + jets and DV + $E_{\mathrm{T}}^{\mathrm{miss}}$ selection

The DV + jets selection requires one of the following: four jets with $p_{\mathrm{T}} > 90$ GeV; five jets with $p_{\mathrm{T}} > 65$ GeV; or six jets with $p_{\mathrm{T}} > 55$ GeV. All jets considered in these selection criteria are required to have $|\eta| < 2.8$. DV + jet candidate events are discarded if they contain any candidate jet failing to satisfy quality criteria designed to suppress detector noise and noncollision backgrounds [56,57]. This has a negligible effect on the signal efficiency. In the DV + $E_{\mathrm{T}}^{\mathrm{miss}}$ search, the requirement $E_{\mathrm{T}}^{\mathrm{miss}} > 180$ GeV is applied. For these selection criteria, the trigger efficiency is approximately independent of the $E_{\mathrm{T}}^{\mathrm{miss}}$ and the jet transverse momenta.

F. Dilepton selection

In the dilepton search, muon candidates are required to satisfy $p_{\mathrm{T}} > 10$ GeV, $|\eta| < 2.5$, and $d_0 > 2$ mm. For electron candidates, the requirements are $p_{\mathrm{T}} > 10$ GeV

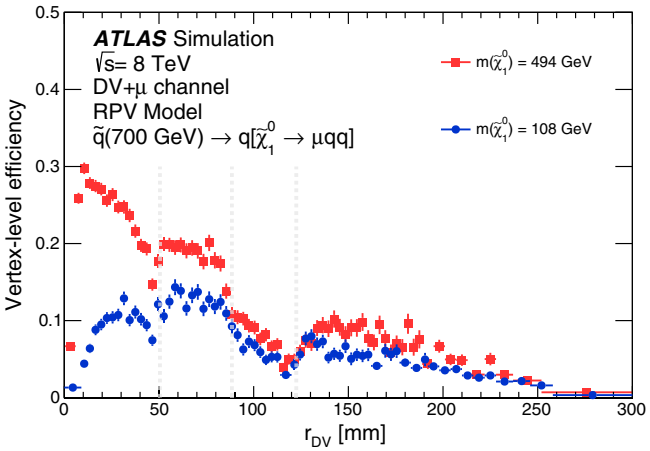
and $d_0 > 2.5$ mm. A lepton candidate is discarded if its ID track is in the pseudorapidity region $|\eta| < 0.02$, where the background-estimation procedure is observed to be unreliable (see Sec. VI).

To avoid double counting of vertices, lepton candidates used to form a dilepton DV must not have the same ID track as another lepton candidate. If two muon candidates or two electron candidates do share an ID track, the candidate that has the lower transverse momentum is discarded. If muon and electron candidates share an ID track, the electron candidate is discarded. Cosmic-ray muons, even those that interact while traversing the detector, are rejected by requiring that all lepton-candidate pairs satisfy $\Delta R_{\text{cosmic}} > 0.04$.

A dilepton DV is formed from at least two opposite-charge tracks identified as two electrons, two muons, or an electron and a muon. Any number of additional tracks may be included in the vertex. At this stage, it is verified that the dilepton selection criteria applied at the trigger and filter level (see Secs. IV A and IV C) are satisfied by the two lepton candidates forming the DV. Finally, the dilepton DV is required to satisfy the DV selection criteria specified in Sec. IV E 2, except for the requirement on the number of tracks, which is $N_{\text{tr}} \geq 2$. As in the DV + lepton case, the dilepton-DV selection relies only on the leptons in the DV and is independent of the rest of the event.

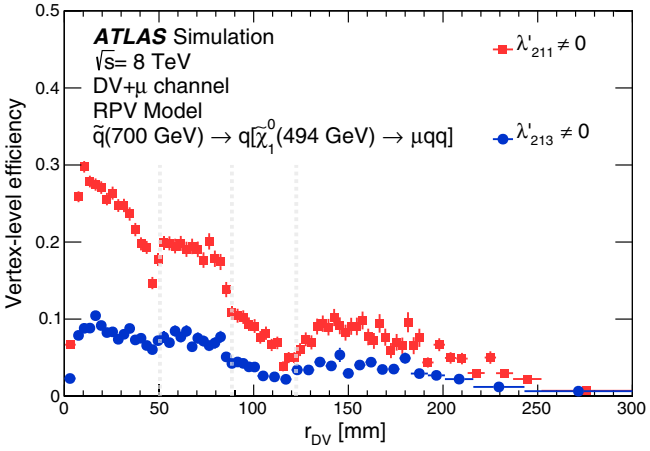
V. SIGNAL EFFICIENCY

In the dilepton and DV + lepton searches, where the selection criteria rely only on the particles produced in the DV, the vertex-level efficiency ϵ_{DV} is defined to be the product of acceptance and efficiency for reconstructing one signal DV, produced in the given search model, with all the trigger, filter, and final selection criteria. The event-level efficiency ϵ_{ev}, defined as the probability for an event containing two DVs to be identified with at least one DV satisfying all the selection criteria, is then obtained from the relation



$$\epsilon_{\text{ev}} = 2\mathcal{B}\epsilon_{\text{DV}} - \mathcal{B}^2\epsilon_{\text{DV}}^2, \tag{1}$$

where $\mathcal{B}$ is the LLP branching fraction into the specific search channel. In the DV + jets and DV + $E_{\text{T}}^{\text{miss}}$ searches, only the event-level efficiency is defined, since the selection criteria involve the entire event.



The efficiency for reconstructing a multitrack or dilepton DV with the above selection criteria depends strongly on the efficiencies for track reconstruction and track selection, which are affected by several factors: (1) The number of tracks originating from the DV and their total invariant mass increase with the LLP mass. (2) More tracks fail the minimal-d_0 requirement for small r_{DV}, or when the LLP is highly boosted. (3) The efficiency for reconstructing tracks decreases with increasing values of d_0. (4) When an LLP decays at a radius somewhat smaller than that of a pixel layer, many tracks share hits on that pixel layer, failing to meet the track-selection criteria. The resulting impact on efficiency can be seen in Fig. 3 at radii around 45 mm, 80 mm, and 115 mm.

The efficiency for reconstructing a multitrack DV is reduced when the LLP decays to charm or bottom hadrons, resulting in two or more nearby DVs. Each of these DVs has a high probability of failing to meet the N_{tr} and m_{DV} criteria, resulting in low efficiency if these DVs are not merged. This happens less at large values of r_{DV}, where DVs are more readily merged due to the worse position resolution.

The vertex-level efficiency does not depend appreciably on whether the primary particle is a squark or a gluino.

(b)

FIG. 3 (color online). Comparisons of the vertex-level efficiency as a function of the vertex radial position r_{DV} for different RPV samples. The vertical gray lines show the position of the first, second, and third pixel layers. (a) For the $\tilde{q} \to q[\tilde{\chi}_1^0 \to \mu qq]$ (λ'_{211}) samples with $m_{\tilde{q}} = 700$ GeV, comparing two cases of different LLP masses: $m_{\tilde{\chi}_1^0} = 494$ GeV, and $m_{\tilde{\chi}_1^0} = 108$ GeV. (b) For the $\tilde{q} \to q[\tilde{\chi}_1^0 \to \mu qq]$ (λ'_{211}) and $\tilde{q} \to q[\tilde{\chi}_1^0 \to \mu qb]$ (λ'_{213}) samples, indicated by the relevant nonzero RPV couplings.

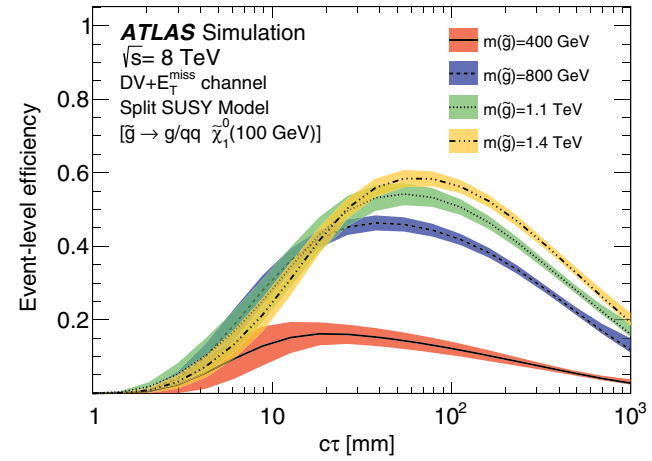

FIG. 4 (color online). (a) The event-level efficiency as a function of $c\tau$ for split-supersymmetry $[\tilde{g} \to g/qq\tilde{\chi}_1^0(100\ \mathrm{GeV})]$ samples with various gluino masses, reconstructed in the DV + $E_{\mathrm{T}}^{\mathrm{miss}}$ channel. (b) The vertex-level efficiency for the RPV $\tilde{g} \to qq[\tilde{\chi}_1^0 \to e\mu\nu]$ samples with combinations of gluino and neutralino masses, reconstructed in the $e\mu$ dilepton channel. The total uncertainties on the efficiencies are shown as bands (see Sec. VII).

However, the nature of the primary particle determines the number of jets, and hence impacts the event-level efficiency in the DV + jets and DV + $E_{\mathrm{T}}^{\mathrm{miss}}$ channels.

Examples of the impact of LLP boost, mass, and heavy-flavor decays on the vertex-level efficiency are shown in Fig. 3 for $\tilde{q} > q[\tilde{\chi}_1^0 \to \mu qq]$ samples. As an example of the benefits of retracking, it is worthwhile to note that without retracking, the vertex-level efficiency for the $m(\tilde{\chi}_1^0) = 494$ GeV, $\lambda'_{211} \neq 0$ sample shown in this figure is about 1% at $r_{\mathrm{DV}} = 80$ mm and is negligible for larger radii.

Events in each MC sample are generated with a fixed value of the LLP lifetime τ_{MC}. To obtain the vertex-level efficiency for a different lifetime τ, each LLP is given a weight

$$W_{\mathrm{DV}}(t,\tau) = \frac{\tau_{\mathrm{MC}}}{\tau}\exp\left(\frac{t}{\tau_{\mathrm{MC}}} - \frac{t}{\tau}\right), \tag{2}$$

where t is the true proper decay time of the generated LLP. The vertex-level efficiency is then the sum of weights for LLPs that satisfy all the criteria in the sample. The same procedure is applied when calculating the event-level efficiency, except that the entire event is weighted by

$$W_{\mathrm{evt}}(t_1,t_2,\tau) = W_{\mathrm{DV}}(t_1,\tau)W_{\mathrm{DV}}(t_2,\tau), \tag{3}$$

where t_1 and t_2 are the true proper decay times of the two LLPs in the event. Examples of the resulting dependence of ϵ_{DV} and ϵ_{ev} on the average proper decay distance $c\tau$ are shown in Fig. 4. For most models considered in this analysis, the peak efficiency is typically greater than 5%, and it occurs in the range $10 \lesssim c\tau \lesssim 100$ mm.

VI. BACKGROUND ESTIMATION

The expected number of background vertices is estimated from the collision data for each channel. Since the number of events satisfying the final selection criteria is very small, the general approach is to first obtain a high-statistical-precision assessment of the probability for background-vertex formation using a large data control sample. That probability is then scaled by the size of the signal-candidate sample relative to that of the control sample.

A. Multitrack-vertex background estimation

Background vertices that are due to accidental spatial crossing of tracks in a jet, particle interactions with material, or heavy-flavor decays have low values of m_{DV} and/or N_{tr} and thus fail the selection requirements. Such vertices may contribute to high-m_{DV}, high-N_{tr} background vertices via two mechanisms.

(i) The dominant source of backgrounds are low-m_{DV} vertices that are accidentally crossed by an unrelated, high-p_{T} track at large angle [$\mathcal{O}$(1 radian)] to the other tracks in the vertex. This is referred to as the accidental-crossing background.

(ii) A much smaller background contribution is due to merged vertices. In this case, two low-m_{DV} vertices are less than 1 mm apart, and thus may be combined by the vertex-reconstruction algorithm into a single vertex that satisfies the N_{tr} and m_{DV} criteria.

The expected background levels from the two sources are estimated from the data. In order for the background estimate to have high statistical precision, it is performed with a large sample containing all events that have undergone retracking. This includes the events selected for this search, as described in Sec. IV C, as well as events used for other ATLAS analyses. The sample is divided into three subsamples, referred to as the muon stream, the electron stream, and the jets + $E_{\mathrm{T}}^{\mathrm{miss}}$ stream, with the name

indicating the type of trigger used to select the events. The background level is estimated separately in each of these streams with the methods described below, and the results are used for the DV + muon, DV + electron, and DV + jets and DV + $E_{\mathrm{T}}^{\mathrm{miss}}$ signal regions, respectively.

To obtain the final background estimate in the signal region, the background estimate in each stream is multiplied by a final-selection scale factor F^{stream}, which is the fraction of events in the given stream that satisfy the final event-selection criteria, other than the DV selection criteria. The values of these fractions are 0.08%, 5.0%, 1.45%, and 0.04%, for the DV + muon, DV + electron, DV + jet, and DV + $E_{\mathrm{T}}^{\mathrm{miss}}$ searches, respectively. This use of F^{stream} assumes that the average number of vertices per event, $N_{\mathrm{ev}}^{\mathrm{DV}}$, is independent of the selection criteria. Based on the change in $N_{\mathrm{ev}}^{\mathrm{DV}}$ when the final selection criteria are applied, an upward bias correction of 60% is applied to the estimated background level in the DV + electron channel (the correction is included in the $F^{\mathrm{stream}} = 5.0\%$ value quoted above). The other channels have negligible bias. A 10% systematic uncertainty is estimated for all channels from the statistical uncertainty of the bias estimate.

1. Background from accidental vertex-track crossings

The accidental-crossing background is estimated separately in six radial regions, ordered from the inside out. Region 1 is inside the beam pipe. Regions 2, 3, and 4 correspond to the volumes just before each of the three pixel layers. Regions 5 and 6 are outside the pixel layers. Region 5 extends outwards to $r_{\mathrm{DV}} = 180$ mm, where there is essentially no detector material, while Region 6 covers the volume from $180 < r_{\mathrm{DV}} < 300$ mm. In each region, a study of the m_{DV} distribution of N_{tr}-track vertices, where $N_{\mathrm{tr}} = 3$ through 6, leads to identification of two types of background vertices, as follows.

The first type, which dominates the low-m_{DV} range, is due to accidental track crossings in Region 1, and particle-material interactions in the other regions. This contribution to the m_{DV} spectrum is referred to as collimated-tracks background, reflecting the typically small angle between the tracks. The m_{DV} distribution $P_{N_{\mathrm{tr}}}^{\mathrm{coll}}(m_{\mathrm{DV}})$ for this contribution is modeled from the N_{tr}-track vertices for which the average three-dimensional angle between every pair of tracks is less than 0.5. In Fig. 5, $P_3^{\mathrm{coll}}(m_{\mathrm{DV}})$ is seen to fully account for 3-track vertices with m_{DV} less than about 3 GeV. However, it does not account for vertices with higher masses, particularly the signal region, $m_{\mathrm{DV}} > 10$ GeV.

The high-m_{DV} part of the m_{DV} distribution is dominated by the second contribution, referred to as "DV + track." In this case, a $(N_{\mathrm{tr}} - 1)$-track vertex is crossed by an unrelated track at a large angle with respect to the momentum vector of the vertex tracks. To construct a model of the DV + track m_{DV} distribution of N_{tr}-track vertices, every $(N_{\mathrm{tr}} - 1)$-track

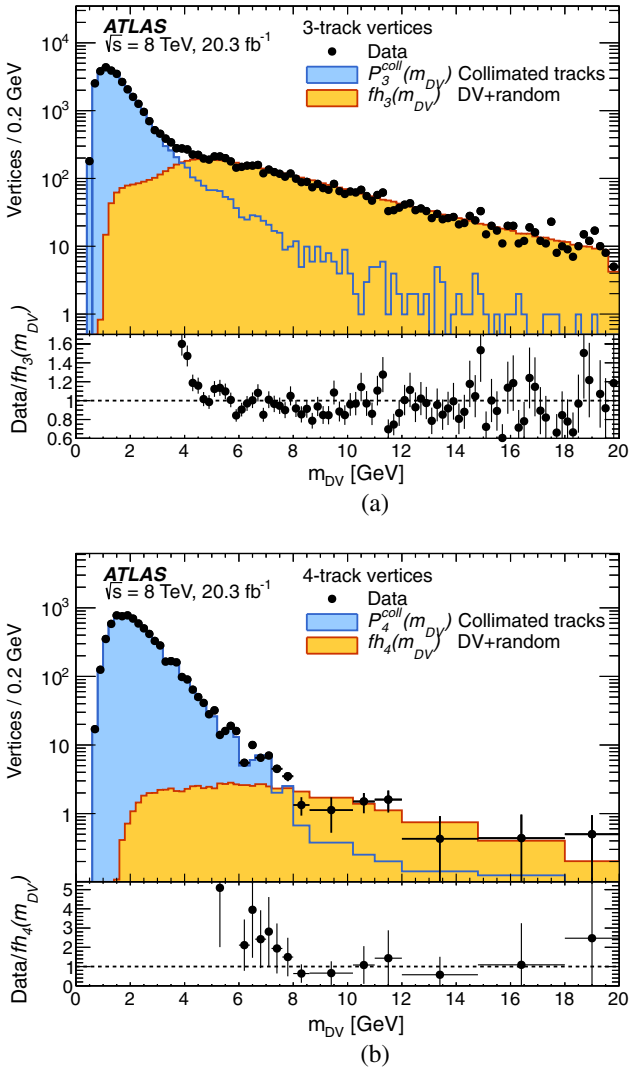

FIG. 5 (color online). The mass distribution for (a) 3-track and (b) 4-track vertices (data points) from the jets + $E_{\mathrm{T}}^{\mathrm{miss}}$ stream in Region 6, overlaid with the model $fh_3(m_{\mathrm{DV}})$ of Eq. (5) (yellow-shaded histogram) at high mass. The lower panel of each plot shows the ratio of the data to this model. The model for the collimated-track contribution $P_3^{\mathrm{coll}}(m_{\mathrm{DV}})$ (blue-shaded histogram), which is correlated with the low-mass data but not used for estimating the signal-region background, is also shown.

vertex, referred to as an "acceptor" vertex, is paired with a "donated" track that is taken from a "donor" vertex in another event. This is done for $N_{\mathrm{tr}} - 1$ in the range 2–5, where acceptor vertices with five tracks are required to have mass below 10 GeV, to avoid the signal region.

The pairing of a vertex and a track is performed with the following procedure. The donor vertex must satisfy all the DV selection criteria, except that the requirement on its mass is not applied, and it may have as few as two tracks. To ensure that the donated track is able to accurately model the effects of a large-angle crossing, it is required that the donor vertex be from the same radial region as the acceptor vertex, and that there is a large angle between the direction

of the donated track and the distance vector of the donor vertex.

In all regions apart from Region 1, the momentum vector of the donated track is then rotated, so that its azimuthal and polar angles ($\Delta\phi_{\text{donor}}$ and $\Delta\theta_{\text{donor}}$) with respect to the distance vector of the acceptor vertex match those that it originally had with respect to the donor vertex. This ensures that the contribution of the donated track to the acceptor vertex mass correctly reflects the accidental-crossing probability as a function of $\Delta\eta_{\text{donor}}$ and $\Delta\phi_{\text{donor}}$.

Then, the four-momentum of the acceptor vertex and the rotated four-momentum of the track are added, obtaining the m_{DV} value of the N_{tr}-track vertex that would have been formed from an accidental crossing of the acceptor vertex and the rotated donated track. The resulting m_{DV} distribution for the N_{pairs} DV + track pairs found in each region is denoted $h_{N_{\text{tr}}}(m_{\text{DV}})$, such that

$$\int_0^\infty h_{N_{\text{tr}}}(m_{\text{DV}})dm_{\text{DV}} = N_{\text{pairs}}. \tag{4}$$

Tracks from donor vertices in Region 1 are treated differently, since they tend to have high pseudorapidity, which impacts their DV-crossing probability more than their $\Delta\phi_{\text{donor}}$ and $\Delta\theta_{\text{donor}}$ values. Therefore, a Region-1 track is not rotated before its four-momentum is added to that of the acceptor vertex.

The high-m_{DV} distribution for N_{tr}-track vertices is then modeled by

$$P_{N_{\text{tr}}}(m_{\text{DV}}) = f h_{N_{\text{tr}}}(m_{\text{DV}}), \tag{5}$$

where

$$f = \frac{N_3^{10\text{ GeV}}}{\int_{10\text{ GeV}}^\infty h_3(m_{\text{DV}})dm_{\text{DV}}} \tag{6}$$

is the scale factor that normalizes the model to the data, and $N_3^{10\text{ GeV}}$ is the number of 3-track vertices with $m_{\text{DV}} > 10$ GeV. The model-predicted number of N_{tr}-track background vertices with $m_{\text{DV}} > 10$ GeV for a given stream and region is given by

$$N_{N_{\text{tr}}}^{\text{stream}} = \int_{10\text{ GeV}}^\infty P_{N_{\text{tr}}}(m_{\text{DV}})dm_{\text{DV}}. \tag{7}$$

The model describes the high-m_{DV} background distribution in data well, as seen in Fig. 5 for jets + $E_{\text{T}}^{\text{miss}}$-stream 3-track and 4-track vertices in Region 6. Also shown is the collimated-track contribution, which accounts for the low-m_{DV} part of the distribution. Using 4-track vertices to validate Eq. (7), the prediction for each of the three streams and six regions is compared with the observed number of vertices. The comparison, summarized in Fig. 6, shows good agreement within the statistical precision.

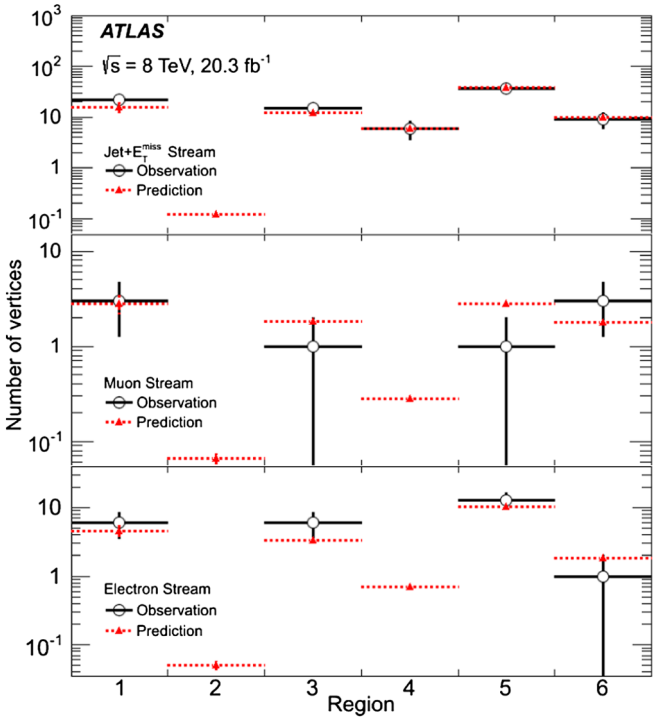

FIG. 6 (color online). Summary of the number of observed (black open circles) 4-track, high-m_{DV} vertices in each of the radial regions and filter-selection streams and the predicted number (red triangles), from Eq. (7). In Region 1, the prediction includes the contribution from merging of two 2-track vertices (see Sec. VI A 2). The error bars on the prediction are too small to be visible, and in some bins no events are observed.

The final numbers of expected background vertices, after multiplying $N_{N_{\text{tr}}}^{\text{stream}}$ by the scale factor F^{stream}, are shown in Table I.

2. Background due to merged vertices

In the last step of DV reconstruction (see Sec. IV E 1), vertices are combined if they are separated by less than 1 mm. To estimate the background arising from this procedure, the distribution of the distance $d_{2\text{DV}}$ between two 2-track or 3-track vertices is studied. Each of the selected vertices is required to satisfy the DV selection criteria of Sec. IV E 2 except the m_{DV} and N_{tr} requirements,

TABLE I. Estimated numbers of background vertices satisfying all of the multitrack signal selection criteria, which arise from a low-mass DV accidentally crossed by an unrelated track. In each entry, the first uncertainty is statistical, and the second is systematic (see Sec. VII).

Channel	No. of background vertices ($\times 10^{-3}$)
DV + jet	$410 \pm 7 \pm 60$
DV + $E_{\text{T}}^{\text{miss}}$	$10.9 \pm 0.2 \pm 1.5$
DV + muon	$1.5 \pm 0.1 \pm 0.2$
DV + electron	$207 \pm 9 \pm 29$

and their combined mass is required to be greater than 10 GeV. To obtain a sufficient number of vertices for studying the d_{2DV} distribution, the distribution is reconstructed from a much larger sample of vertex pairs, where each vertex in the pair is found in a different event. This is referred to as the "model" sample.

To validate the d_{2DV} distribution of the model sample, it is compared to that of vertices that occur in the same event, referred to as the "same-event" sample. It is found that the z positions of vertices in the same event are correlated, since more vertices are formed in high-track-multiplicity regions corresponding to jets. This effect is absent in the model sample. As a result, the distributions of the longitudinal distance between the vertices in the model and the same-event samples differ by up to 30% at low values of d_{2DV}. To correct for this difference, each vertex pair in the model sample is weighted so as to match the z component distribution of the same-event sample. After weighting, the model distribution of the three-dimensional distance d_{2DV} agrees well with that of the same-event sample in the entire study range of $d_{2DV} < 120$ mm. This is demonstrated in Fig. 7 for pairs of 2-track vertices and for the case of a 2-track vertex paired with a 3-track vertex.

The background level for the analysis requirement of $N_{tr} \geq 5$ tracks is estimated from vertex pairs where one vertex has two tracks and the other has three tracks. The area under the model distribution in the range $d_{2DV} < 1$ mm yields a background prediction of 0.02 ± 0.02 events in each of the DV + lepton channels, and 0.03 ± 0.03 events in the DV + jets and DV + E_T^{miss} channels. After multiplication by F^{stream}, this background is negligible relative to the accidental-crossing background, described in Sec. VI A 1. Background from the merging of two 3-track vertices or a 2-track and a 4-track vertex is deemed much smaller still.
